NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Preface xxxiii

Introduction xxxv

PART I SPECIAL POPULATIONS 1

1. Geriatrics: Safe Medication Use in Older Adults 3
Jeannie K. Lee, Damian M. Mendoza, and Shaun M. Chatelain

2. Pediatrics Pharmacotherapy 15
Hanna Phan, Vinita B. Pai, and Milap C. Nahata

3. Palliative Care Management 27
Kelly R. Kroustos and Marc A. Sweeney

4. Critical Care Pharmacotherapy 39
Brittany D. Bissell and Brian W. Gilbert

5. Global Health and Travel Medicine 49
Sonak D. Pastakia, Alyssa P. Gould, Benson N. Njuguna, and Jeffrey W. Hall

PART II DISORDERS OF ORGAN SYSTEMS 83

SECTION 1 Cardiovascular Disorders 85

6. Hypertension 85
Augustus Hough, Ya-Feng Wen, Jonathan Taylor Huff, Jeffery L. Kibert II, and Shannon W. Finks

7. Heart Failure 107
Tien M. H. Ng and Samantha L. Yeung

8. Stable Ischemic Heart Disease 135
Dejan Landup and Dawn Havrda

9. Acute Coronary Syndromes 157
Kelly C. Rogers and Sarah A. Spinler

10. Arrhythmias 185
Robert B. Parker and James C. Coons

11. Venous Thromboembolism 213
James C. Lee, Bryan Zobeck, and Edith A. Nutescu

12. Stroke 243
Susan R. Winkler

13. Dyslipidemia 257
Joel C. Marrs and Matthew D. Kostoff

14. Circulatory Shock Syndromes 279
Bradley A. Boucher and G. Christopher Wood

SECTION 2 Respiratory Disorders 293

15. Asthma 293
Lori Wilken and Amanda Eades

16. Chronic Obstructive Pulmonary Disease 311
Jon P. Wietholter and Tara R. Whetsel

17. Cystic Fibrosis 325
Kimberly J. Novak

SECTION 3 Gastrointestinal Disorders 337

18. Gastroesophageal Reflux Disease 337
Jeremy J. Prunty and Leesa M. Prunty

19. Peptic Ulcer Disease 347
Ashley H. Meredith

20. Inflammatory Bowel Disease 357
Brian A. Hemstreet

21. Nausea and Vomiting 373
Sheila Wilhelm and Melissa Lipari

22. Constipation, Diarrhea, and Irritable Bowel Syndrome 383
Beverly C. Mims

23. Portal Hypertension and Cirrhosis 401
Laurajo Ryan

24. Pancreatitis 413
Lara M. Groetzinger

25. Viral Hepatitis 423
Juliana Chan

SECTION 4 Renal Disorders 439

26. Acute Kidney Injury 439
Mary K. Stamatakis

27. Chronic and End-Stage Kidney Disease 453
Kristine S. Schonder and Alicia Lichvar

ALGRAWANY

28. Fluids and Electrolytes 479
Mark A. Malesker and Lee E. Morrow

29. Acid–Base Disturbances 493
Lee E. Morrow and Mark A Malesker

SECTION 5 Neurologic Disorders 503

30. Alzheimer Disease 503
Megan J. Ehret and Kevin W. Chamberlin

31. Multiple Sclerosis 513
Sarah Rajkovic and Jacquelyn L. Bainbridge

32. Epilepsy 529
Timothy E. Welty and Edward Faught

33. Status Epilepticus 547
Eljim P. Tesoro and Gretchen M. Brophy

34. Parkinson Disease 557
Thomas R. Smith

35. Pain Management 571
Christine Karabin O'Neil

36. Headache 585
Laurie W. Fleming, Leigh Ann Ross, and Brendan S. Ross

SECTION 6 Psychiatric Disorders 595

37. Substance-Related Disorders 595
Chris Paxos and Christian J. Teter

38. Schizophrenia 611
Deanna L. Kelly, Mary Borovicka, and Heidi J. Wehring

39. Major Depressive Disorder 633
J. Michael McGuire and Cherry W. Jackson

40. Bipolar Disorder 651
Sarah E. Goldsborough, Opal M. Bacon, and Lydia E. Weisser

41. Anxiety and Trauma-Related Disorders 665
Bridget Bradley

42. Sleep Disorders 681
Jessa Marie Koch and Azita Alipour

43. Attention-Deficit/Hyperactivity Disorder 693
Kevin W. Cleveland, Julia Boyle, and Renee F. Robinson

SECTION 7 Endocrinologic Disorders 701

44. Diabetes Mellitus 701
Julie M. Sease and Elizabeth W. Blake

45. Thyroid Disorders 731
Michael D. Katz

46. Adrenal Gland Disorders 749
Christina M. Polomoff, Devra K. Dang, and Judy T. Chen

47. Pituitary Gland Disorders 765
Christina M. Polomoff, Devra K. Dang, and Judy T. Chen

SECTION 8 Gynecologic and Obstetric Disorders 785

48. Pregnancy and Lactation: Therapeutic Considerations 785
Rebecca H. Stone

49. Contraception 803
Julia M. Koehler and Kathleen B. Haynes

50. Menopause and Menstruation-Related Disorders 817
Nicole E. Cieri-Hutcherson and Kylie N. Barnes

SECTION 9 Urologic Disorders 837

51. Erectile Dysfunction 837
Cara Liday

52. Benign Prostatic Hyperplasia 847
Mary Lee and Roohollah Sharifi

53. Urinary Incontinence and Pediatric Enuresis 863
Sum Lam and Gladys El-Chaar

SECTION 10 Immunologic Disorders 881

54. Drug Hypersensitivity Reactions 881
J. Russell May, Dixie D. Griffin, and Kathleen May

55. Solid Organ Transplantation 891
Steven Gabardi, Miae Kim, and Ali J. Olyaei

56. Systemic Lupus Erythematosus 915
Cassandra Dolecki, Marisha Okpala, and Jessica Farrell

SECTION 11 Bone and Joint Disorders 937

57. Osteoporosis 937
Beth Bryles Phillips and Morgan K. Moulton

58. Rheumatoid Arthritis 951
Susan P. Bruce

59. Osteoarthritis 967
Christopher R. Piszczatoski, Steven M. Smith, and John Gums

60. Gout and Hyperuricemia 979
Maria Miller Thurston and Jenny Lin

61. Musculoskeletal Injuries 991
Jill S. Borchert and Lisa M. Palmisano

SECTION 12 Disorders of the Eyes, Ears, Nose, and Throat 1003

62. Glaucoma 1003
Daniel O. Clegg, Jr.

63. Minor Ophthalmic and Otic Disorders 1017
Lauren R. Biehle and Michelle L. Hilaire

64. Nose, Mouth, and Throat Disorders 1029
Alexandra Hintz, Phu Trinh, and Luke Dearden

65. Allergic Rhinitis 1049
Hanna Phan and Michael Daines

SECTION 13 Dermatologic Disorders 1065

66. Acne Vulgaris 1065
Laura A. Perry and Jenna M. Mills

67. Dermatitis 1075
Lori Ernsthausen and Jenna M. Mills

68. Psoriasis 1087
Amy K. Kennedy

SECTION 14 Hematologic Disorders 1103

69. Anemia 1103
Maribel A. Pereiras

70. Coagulation and Platelet Disorders 1117
Anna Dushenkov and Paiboon Jungsuwadee

71. Sickle Cell Disease 1137
Tracy M. Hagemann and Teresa V. Lewis

SECTION 15 Diseases of Infectious Origin 1151

72. Patient Assessment, Antimicrobial Selection, and Stewardship 1151
Angharad Ratliff and Catherine Oliphant

73. Central Nervous System Infections 1167
April Miller Quidley and P. Brandon Bookstaver

74. Lower Respiratory Tract Infections 1185
Diane M. Cappelletty

75. Upper Respiratory Tract Infections 1199
Heather L. Girand

76. Skin and Skin Structure Infections 1217
Jaime R. Hornecker and Lauren R. Biehle

77. Osteomyelitis 1229
Jessica E. Burchette and David B. Cluck

78. Infective Endocarditis 1237
Ronda L. Akins

79. Tuberculosis 1255
Rocsanna Namdar and Charles Peloquin

80. Gastrointestinal Infections 1267
Megan M. Seddon and Jamie J. Kisgen

81. Intra-Abdominal Infections 1279
Joseph E. Mazur and Melanie Smith Condeni

82. Urinary Tract Infections and Prostatitis 1289
Spencer H. Durham

83. Sexually Transmitted Infections 1299
Marlon S. Honeywell and Evans Branch, III

84. Sepsis and Septic Shock 1321
Trisha N. Branan, Susan E. Smith, and Christopher M. Bland

85. Superficial Fungal Infections 1333
Kathryn A. Fuller and Lauren S. Schlesselman

86. Invasive Fungal Disease 1345
Jeffrey M. Rybak

87. Human Immunodeficiency Virus Infection 1363
Mary F. Banoub, Jennifer L. Bailey, and Fidelia Bernice

ALGRAWANY

SECTION 16 Oncologic Disorders 1389

88. Cancer Principles and Therapeutics 1389
Lisa M. Holle

89. Breast Cancer 1421
Gerald M. Higa

90. Lung Cancer 1435
Ninh M. La-Beck and Christopher Selby

91. Colorectal Cancer 1455
Emily B. Borders and Allison Baxley

92. Prostate Cancer 1471
Amber B. Cipriani and Daniel J. Crona

93. Melanoma 1487
Chung-Shien Lee

94. Ovarian Cancer 1503
Judith A. Smith

95. Lymphomas 1517
Keith A. Hecht and Susanne Liewer

96. Acute Leukemias 1529
Nancy H. Heideman and Dulcinea Quintana

97. Chronic Leukemias and Multiple Myeloma 1545
Amy M. Pick and Jared E. Matya

98. Hematopoietic Stem-Cell Transplantation 1561
Gianni Scappaticci and David G. Frame

99. Supportive Care in Oncology 1581
Alexandre Chan and Lee Nguyen

SECTION 17 Nutrition and Nutritional Disorders 1611

100. Parenteral Nutrition 1611
Melissa R. Pleva and Michael D. Kraft

101. Enteral Nutrition 1631
Sarah J. Miller

102. Overweight and Obesity 1645
April Smith

ABOUT THE EDITORS

Marie A. Chisholm-Burns, PharmD, PhD MPH, MBA, FCCP, FASHP, FAST, is Dean of the College of Pharmacy and UTHSC Distinguished Professor in the Colleges of Pharmacy and Medicine at the University of Tennessee Health Science Center. She received her BS and PharmD degrees from the University of Georgia, her PhD from the University of South Dakota, and completed a residency at Mercer University Southern School of Pharmacy and at Piedmont Hospital in Atlanta, Georgia. Dr. Chisholm-Burns is Founder and Director of the Medication Access Program which increases medication access to transplant recipients. She is a Commissioner on the State of Tennessee Education Recovery and Innovation Commission. She has also served as a member of the Accreditation Council for Pharmacy Education and in elected positions in numerous professional organizations, including a member of the American Society of Transplantation Board of Directors. Dr. Chisholm-Burns has more than 355 publications and approximately $17 million in external funding. Textbooks co-edited by Dr. Chisholm-Burns, *Pharmacotherapy Principles & Practice* and *Pharmacy Management, Leadership, Marketing, and Finance*, respectively, previously received the Medical Book Award from the American Medical Writers Association. She has also received numerous honors including the Distinguished Teaching Scholar Award and Robert K. Chalmers Distinguished Pharmacy Educator Award from the American Association of Colleges of Pharmacy, Russell R. Miller Award and Education Award from the American College of Clinical Pharmacy, Daniel B. Smith Practice Excellence Award and Research Achievement Award from the American Pharmacists Association, Nicholas Andrew Cummings Award from the National Academies of Practice, Award of Excellence from the American Society of Health-System Pharmacists (ASHP), Pharmacy Practice Research Award (2011 and 2014) and Award for Sustained Contributions to the Literature from the ASHP Foundation, Inspiring Women in STEM Award from INSIGHT Into Diversity, and Rufus A. Lyman Award for most outstanding publication in the *American Journal of Pharmaceutical Education* (1996 and 2007). She lives in Memphis with her husband and son, John Fitzgerald Burns Jr. She enjoys writing, painting (the cover of this textbook is an original piece by Dr. Chisholm-Burns), and playing chess.

Terry L. Schwinghammer, PharmD, is Professor Emeritus at the West Virginia University (WVU) School of Pharmacy. From 2005 to 2018, he was Professor and Chair of the Department of Clinical Pharmacy, and from 2015 to 2018 he held the Arthur I. Jacknowitz Distinguished Chair in Clinical Pharmacy at WVU. He was previously Professor of Pharmaceutical Sciences at the University of Pittsburgh School of Pharmacy. Dr. Schwinghammer received his BS and PharmD degrees from Purdue University and completed a pharmacy residency at Indiana University Hospitals. He has maintained clinical pharmacy practices in adult inpatient and ambulatory care. Dr. Schwinghammer is a recipient of the American Pharmacists Association-APPM Distinguished Achievement Award in Clinical/Pharmacotherapeutic Practice and is a Distinguished Practitioner in the National Academies of Practice. He is a member of the Academy of Excellence in Teaching and Learning of the WVU Health Sciences Center. In addition to authoring over 100 research and other publications, he is the founding editor of *The Pharmacotherapy Casebook* and co-editor of *The Pharmacotherapy Handbook* and the textbook *Pharmacotherapy Principles & Practice*. Dr. Schwinghammer has served the American Association of Colleges of Pharmacy (AACP) as Chair of the Pharmacy Practice Section, Chair of the Council of Faculties, and member of the Board of Directors. He is a past president of the Pennsylvania Society of Health-System Pharmacists and received the Pharmacist of the Year, Community Service, and Sister M. Gonzales Duffy Awards from the organization. He has served as Chair of the Board of Pharmacy Specialties and elected member of the Board of Regents of the American College of Clinical Pharmacy (ACCP). He is a Fellow of ACCP, the American Society of Health-System Pharmacists, and the American Pharmacists Association and has been elected to membership in the Rho Chi Pharmacy Honor Society and the Phi Lambda Sigma Pharmacy Leadership Society. He was named a Distinguished Alumnus of Purdue University in 2004. In 2016, he was named the recipient of the AACP Robert K. Chalmers Distinguished Pharmacy Educator Award.

ALGRAWANY

Patrick M. Malone, PharmD, FASHP, recently retired from being Professor and Associate Dean of Internal Affairs at the University of Findlay College of Pharmacy and now does drug information consulting. Dr. Malone received his BS in Pharmacy from Albany College of Pharmacy and PharmD from the University of Michigan. He completed a clinical pharmacy residency at the Buffalo General Hospital, Drug Information Fellowship at the University of Nebraska Medical Center, and US West Fellowship in Academic Development and Technology at Creighton University. His practice and teaching have centered on drug information, and he is the first author for all seven editions of *Drug Information—A Guide for Pharmacists* and has overseen the Innovations in Drug Information Practice and Research sessions at the ASHP Midyear Clinical Meetings for over 20 years. Dr. Malone was also the drug information pharmacist at the XIII Winter Olympics. He has approximately 120 publications and numerous presentations, and has held various offices in national organizations. He was the Director of the Web-Based Pharmacy Pathway at Creighton University Medical Center, from its initial establishment until after graduation of the first class. His hobby is building and flying radio-controlled aircraft.

Jill M. Kolesar, PharmD, MS, FCCP, BCPS, is a University Research Professor of Pharmacy and Medicine at the University of Kentucky and holds administrative positions at the Markey Cancer Center including the Co-Leader of the Translational Oncology Research Program. Dr. Kolesar received her Doctor of Pharmacy degree at the University of Texas Health Science Center in San Antonio, where she also completed a specialty practice residency in oncology/hematology and a fellowship in molecular oncology pharmacotherapy. She received an MS in Epidemiology from the University of Wisconsin-Madison in 2016. Dr. Kolesar contributes professional service to both the National Cancer Institute (NCI) and several pharmacy organizations. She is serving on the Cancer Prevention Central IRB (CIRB), multiple NCI study sections, and the Cancer Therapy and Evaluation Program (CTEP) Investigational Drug Steering Committee. She is also a past President of ACCP. Dr. Kolesar's research focuses on the drug development of anticancer agents with an emphasis on targeted therapies and biomarkers. She has authored more than 400 abstracts, research articles, and book chapters, and as a principal investigator she has received more than $15.0 million in research funding from the NCI, American Cancer Society, and other sources. She has received teaching and research awards from local, national, and international organizations including the Innovations in Teaching Award from the American Association of Colleges of Pharmacy. Other books she co-edits are the *Top 300 Pharmacy Drug Cards,* the *Top 200 Injectable Drug Cards*, *Top 125 Drug Card Case Quiz,* and the *Top 100 Nonprescription Drug Cards*. Dr. Kolesar loves to read, run, ski, scuba dive, and travel with her husband and five children. She has completed two marathons and 17 half-marathons.

Kelly C. Lee, PharmD, MAS, FCCP, BCPP, is Professor of Clinical Pharmacy and Associate Dean for Assessment and Accreditation at the University of California, San Diego (UCSD) Skaggs School of Pharmacy and Pharmaceutical Sciences. She is also the Director of the PGY2 Psychiatric Pharmacy Residency at UCSD. Dr. Lee received her BS in Biology from UCLA, her PharmD from UCSF, and Master of Advanced Studies in Clinical Research at UCSD. She completed a PGY1 Residency in Pharmacy Practice and a 2-year fellowship in Behavioral Health Sciences at UCSF. She is a Fellow of American College of Clinical Pharmacy and has been elected to membership in the Rho Chi Pharmacy Honor Society and the Phi Lambda Sigma Pharmacy Leadership Society. She has published over 90 peer-reviewed journal articles and book chapters and consults for large health systems to optimize psychotropic drug utilization and establish innovative psychiatric pharmacy care models. She has received the Dorfman Journal Paper Award from the Academy of Psychosomatic Medicine and Collaborative Research Awards from the American Association of Colleges of Pharmacy Assessment SIG. Dr. Lee loves to play tennis, travel, and spend time with her husband Douglas and son, Travis.

P. Brandon Bookstaver, PharmD, FCCP, FIDSA, is Associate Professor and Director of Residency and Fellowship Training in the Department of Clinical Pharmacy and Outcomes Sciences at the University of South (UofSC) Carolina College of Pharmacy (COP) in Columbia, South Carolina. He also serves as Infectious Diseases Pharmacist at Prisma Health Richland. Following graduation from the UofSC COP in 2004, he completed a Pharmacy Practice residency and Infectious Diseases specialty residency at Wake Forest University Baptist Medical Center. Brandon is heavily involved in pharmacy residency training, serving as the Infectious Diseases PGY2 Residency Director and Clinical Fellowship Director at Prisma Health/UofSC COP and the PGY1 Residency Director at Tandem Health/UofSC COP. He has over 125 peer-reviewed publications in the areas of infectious diseases and teaching and learning, and serves as co-director of the research network, SERGE-45. Outside of work, he enjoys spending time with his wife Nicole, son Aaron, and daughter Maddie; traveling; and Gamecock athletics.

CONTRIBUTORS

Ronda L. Akins, PharmD
Infectious Diseases Clinical Specialist, Methodist Charlton Medical Center, Dallas, Texas
Chapter 78

Azita Alipour, PharmD, BCGP, BCPP, APh
Associate Professor – Psychiatric Pharmacy, Department of Pharmacy Practice, College of Pharmacy, Marshall B. Ketchum University, Fullerton, California
Chapter 42

Opal Bacon, PharmD, BCPS, BCPP
Clinical Pharmacy Specialist, Outpatient Mental Health, U.S. Department of Veterans Affairs, Nebraska-Western Iowa Health Care System, Grand Island, Nebraska; Adjunct Clinical Assistant Professor, Eugene Applebaum College of Pharmacy and Health Sciences, Wayne State University, Detroit, Michigan
Chapter 40

Jennifer Bailey, PharmD, BCPS, AAHIVP
Associate Professor and Chair, Department of Clinical and Administrative Sciences, Notre Dame of Maryland University School of Pharmacy, Baltimore, Maryland
Chapter 87

Jacquelyn L. Bainbridge, BSPharm, PharmD, FCCP, FAES, MSCS
Professor, Department of Clinical Pharmacy Skaggs School of Pharmacy and Pharmaceutical Sciences and Department of Neurology School of Medicine, University of Colorado, Anschutz Medical Campus, Aurora, Colorado
Chapter 31

Mary F. Banoub, PharmD, BCIDP
Clinical Pharmacy Specialist, Infectious Diseases, University of Maryland Medical Center; Clinical Assistant Professor, School of Pharmacy, University of Maryland, Baltimore, Maryland
Chapter 87

Kylie N. Barnes, PharmD, BCPS
Clinical Associate Professor, Division of Pharmacy Practice and Administration, Kansas City School of Pharmacy, University of Missouri; Clinical Pharmacist in Maternal Fetal Medicine, Truman Medical Center, Kansas City, Missouri
Chapter 50

Allison Baxley, PharmD, BCOP
Director of Pharmacy, Stephenson Cancer Center, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma
Chapter 91

Fidelia Bernice, PharmD, BCIDP
Clinical Pharmacy Specialist, Infectious Diseases, University of Maryland Medical Center, Baltimore, Maryland
Chapter 87

Lauren R. Biehle, PharmD, BCPS, BCIDP
Clinical Associate Professor, Department of Pharmacy Practice, School of Pharmacy, University of Wyoming, Laramie, Wyoming
Chapters 63 and 76

Brittany D. Bissell, PharmD, PhD, BCCCP
Assistant Professor, Department of Pulmonary, Critical Care, and Sleep Medicine, College of Medicine, University of Kentucky; Clinical Pharmacist, Medical Intensive Care Unit, UK Healthcare, Lexington, Kentucky
Chapter 4

Elizabeth W. Blake, PharmD, BCPS, FNAP
Clinical Associate Professor and Director of Interprofessional Education, College of Pharmacy, Clinical Pharmacy and Outcomes Sciences, University of South Carolina, Columbia, South Carolina
Chapter 44

Christopher M. Bland, PharmD, FCCP, FIDSA, BCPS
Clinical Professor, Department of Clinical and Administrative Pharmacy, College of Pharmacy, University of Georgia, Savannah, Georgia
Chapter 84

P. Brandon Bookstaver, PharmD, FCCP, FIDSA
Associate Professor and Director of Residency and Fellowship Training, Department of Clinical Pharmacy and Outcomes Sciences, University of South Carolina College of Pharmacy, Columbia, South Carolina
Chapter 73

Jill S. Borchert, PharmD, BCACP, BCPS, FCCP
Professor and Vice Chair, College of Pharmacy, Midwestern University, Downers Grove, Illinois
Chapter 61

Emily Borders, PharmD, MS, BCOP
Assistant Professor, Department of Pharmacy Practice, College of Pharmacy, Southwestern Oklahoma State University Weatherford, Oklahoma; Clinical Pharmacist in Oncology, Mercy Health Care, Oklahoma City, Oklahoma
Chapter 91

Mary C. Borovicka, PharmD, BCPP
Clinical Pharmacist – Psychiatry, MetroHealth Medical Center, Cleveland, Ohio
Chapter 37

Bradley A. Boucher, PharmD, FCCP, MCCM
Professor, Department of Clinical Pharmacy and Translational Science, College of Pharmacy, University of Tennessee Health Science Center; Clinical Pharmacist in Critical Care, Regional One Health, Memphis, Tennessee

Professor, Department of Pharmacy Practice, College of Pharmacy and Pharmaceutical Sciences, University of Toledo, Toledo, Ohio
Chapter 74

Kevin W. Chamberlin, PharmD, FASCP
University Director of Pharmacy Residency Programs, UConn Health; Adjunct Clinical Associate Professor of Pharmacy Practice, School of Pharmacy, University of Connecticut, Farmington, Connecticut
Chapter 30

Alexandre Chan, PharmD, MPH, FCCP, FISOPP, BCPS, BCOP, APh
Professor of Clinical Pharmacy and Chair, Department of Clinical Pharmacy Practice, School of Pharmacy and Pharmaceutical Sciences, University of California, Irvine, California
Chapter 99

Juliana Chan, PharmD, FCCP, BCPS
Clinical Associate Professor, Colleges of Pharmacy and Medicine, University of Illinois, Chicago, Illinois
Chapter 25

Shaun Chatelain, DO
Department of Medicine and Banner University Medical Center, College of Medicine, University of Arizona, Tucson, Arizona
Chapter 1

Judy T. Chen, PharmD, BCPS, BCACP, CDCES, FNAP
Clinical Associate Professor, College of Pharmacy, Purdue University, Indianapolis, Indiana
Chapters 46 and 47

Nicole E. Cieri-Hutcherson, PharmD, BCPS, NCMP
Clinical Assistant Professor, Department of Pharmacy Practice, University at Buffalo School of Pharmacy and Pharmaceutical Sciences; Clinical Pharmacist in Internal Medicine, Buffalo General Medical Center, Buffalo, New York
Chapter 50

Amber B. Cipriani, PharmD, BCOP
Clinical Assistant Professor, Division of Pharmacotherapy and Experimental Therapeutics, Eshelman School of Pharmacy, University of North Carolina; Precision Medicine Pharmacy Coordinator, UNC Health, Chapel Hill, North Carolina
Chapter 92

Daniel O. Clegg, Jr., PharmD
Supervising Pharmacist, Moran Eye Center Pharmacy, University of Utah; Adjunct Instructor, L.S. Skaggs Pharmacy Institute, College of Pharmacy, University of Utah, Salt Lake City, Utah
Chapter 62

Kevin W. Cleveland, PharmD, ANP
Assistant Dean and Director of Experiential Education, Associate Professor, Department of Pharmacy Practice, Idaho State University College of Pharmacy, Meridian, Idaho
Chapter 43

David B. Cluck, PharmD, BCPS, BCIDP, AAHIVP
Associate Professor of Pharmacy Practice, Gatton College of Pharmacy, East Tennessee State University, Johnson City, Tennessee
Chapter 77

Melanie Smith Condeni, PharmD, BCPS, BCCCP
Affiliate Assistant Professor, College of Pharmacy, Medical University of South Carolina; Surgery, Trauma, and Burn ICU Clinical Pharmacy Specialist, College of Pharmacy, Medical University of South Carolina, Charleston, South Carolina
Chapter 81

James C. Coons, PharmD, FCCP, BCCP
Associate Professor, School of Pharmacy, University of Pittsburgh; Clinical Pharmacist, Cardiology, UPMC Presbyterian Hospital, Pittsburgh, Pennsylvania
Chapter 10

Daniel J. Crona, PharmD, PhD, CPP
Assistant Professor, Division of Pharmacotherapy and Experimental Therapeutics, Eshelman School of Pharmacy, University of North Carolina; Clinical Pharmacist Practitioner, Genitourinary Malignancies, UNC Health, Chapel Hill, North Carolina
Chapter 92

Devra K. Dang, PharmD, BCPS, CDCES, FNAP
Associate Clinical Professor, School of Pharmacy, University of Connecticut, Storrs, Connecticut
Chapters 46 and 47

Michael Daines, MD
Associate Professor, Division Chief, Pediatric Allergy, Immunology, and Rheumatology; Associate Director, Pediatric Pulmonary Fellowship; Department of Pediatrics; College of Medicine, University of Arizona, Tucson, Arizona
Chapter 65

Luke Dearden, PharmD, BCPS
Clinical Pharmacist, Washington State Health Care Authority, Tacoma, Washington
Chapter 64

Cassandra Dolecki, PharmD, MBA, BCACP, TTS
Clinical Pharmacy Specialist, Autoimmunity Institute, Allegheny Health Network, Pittsburgh, Pennsylvania
Chapter 56

Spencer H. Durham, PharmD, BCPS, BCIDP
Associate Clinical Professor, Department of Pharmacy Practice; Director, Alumni and Professional Affairs, Harrison School of Pharmacy, Auburn University, Auburn; Clinical Pharmacist Specialist – Infectious Diseases; Central Alabama Veterans Health Care System, Montgomery, Alabama
Chapter 82

Anna Dushenkov, BS Pharm, PharmD, BCPS
Associate Professor, Department of Pharmacy Practice, School of Pharmacy and Health Sciences, Fairleigh Dickinson University, Florham Park, New Jersey
Chapter 70

Amanda Eades, PharmD, BCACP, AE-C
Clinical Assistant Professor, College of Pharmacy, University of Illinois, Chicago, Illinois
Chapter 15

Megan J. Ehret, PharmD, MS, BCPP
Professor, Department of Pharmacy Practice and Science, School of Pharmacy, University of Maryland, Baltimore, Maryland
Chapter 30

Gladys Jamil El-Chaar, PharmD
Clinical Pharmacy Professor, Department of Clinical Health Professions, St John's University College of Pharmacy and Health Sciences, Queens, New York; Clinical Pharmacist in Pediatric Intensive Care, Department of Pharmacy, NYU Lagone - Long Island, Mineola, New York
Chapter 53

Lori Ernsthausen, PharmD, BCPS
Associate Dean of Curricular Affairs, Chair and Associate Professor of Pharmacy Practice, College of Pharmacy, University of Findlay, Findlay, Ohio
Chapter 67

Jessica Farrell, PharmD
Associate Professor of Pharmacy Practice, Albany College of Pharmacy and Health Sciences, Clinical Pharmacist, Center for Rheumatology, Albany, New York
Chapter 56

Edward Faught, MD
Professor and Director of Emory University Epilepsy Program, Department of Neurology, School of Medicine, Emory University, Atlanta, Georgia
Chapter 32

Jack E. Fincham, PhD, RPh
Faculty, Osher Life Long Learning Institute, University of Arizona, Tucson, Arizona
Chapter Introduction

Shannon W. Finks, PharmD, FCCP, BCPS, BCCP, AHSCP-CHC
Professor, Department of Clinical Pharmacy and Translational Science, College of Pharmacy, University of Tennessee, Health Science Center, Memphis, Tennessee
Chapter 6

Laurie W. Fleming, PharmD, BCACP
Director of Professional Experience Programs and Experiential Affairs, Clinical Associate Professor, Department of Pharmacy Practice, School of Pharmacy, University of Mississippi Jackson, Mississippi
Chapter 36

David G. Frame, PharmD
Clinical Assistant Professor, Department of Clinical Pharmacy, School of Pharmacy, University of Michigan; Clinical BMT/Cellular Therapies and Immunohematology Specialist, Michigan Medicine, Ann Arbor, Michigan
Chapter 98

Kathryn A. Fuller, PharmD, BCPS
Clinical Assistant Professor, Division of Practice Advancement and Clinical Eduction, Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, North Carolina
Chapter 85

Steven Gabardi, PharmD, BCPS, FAST, FCCP
Abdominal Organ Transplant Clinical Specialist – Brigham and Women's Hospital / Assistant Professor of Medicine – Harvard Medical School, Boston, Massachusetts
Chapter 55

Brian W. Gilbert, PharmD, BCPS, BCCCP
Clinical Pharmacist, Emergency Medicine/Critical Care, Wesley Medical Center, Wichita, Kansas
Chapter 4

Heather L. Girand, PharmD, BCPPS
Professor and Chair, Department of Pharmacy Practice, College of Pharmacy, Ferris State University, Big Rapids, Michigan
Chapter 75

Sarah Goldsborough, PharmD, BCPP
Psychiatry Clinical Pharmacist Specialist, Beaumont Health, Royal Oak; Adjunct Assistant Professor, Eugene Applebaum College of Pharmacy and Health Sciences, Wayne State University, Detroit, Michigan
Chapter 40

ALGRAWANY

Alyssa P. Gould, PharmD, BCIDP
Clinical Pharmacy Specialist – Infectious Diseases, Novant Health, Charlotte, North Carolina
Chapter 5

Dixie D. Griffin, MD
Fellow, Allergy-Immunology, Medical College of Georgia at Augusta University, Augusta, Georgia
Chapter 54

Lara M. Groetzinger, PharmD, BCCCP
Unit-Based Clinical Pharmacist, Medical Intensive Care Unit, University of Pittsburgh Medical Center, Presbyterian Hospital, Pittsburgh, Pennsylvania
Chapter 24

John Gums, PharmD, FCCP
Associate Dean for Clinical and Administrative Affairs; Professor, Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida; Professor, Department of Community Health and Family Medicine, College of Medicine, University of Florida, Gainesville, Florida
Chapter 59

Tracy M. Hagemann, PharmD, FCCP, FPPA
Associate Dean and Professor, Department of Clinical and Translation Science, College of Pharmacy, University of Tennessee Health Science Center, Nashville, Tennessee
Chapter 71

Jeffrey W. Hall, MD
Clinical Associate Professor, Department of Family and Preventive Medicine; Adjunct Associate Professor, Department of Clinical Pharmacy and Outcomes Sciences, College of Pharmacy, University of South Carolina, Columbia, South Carolina
Chapter 5

Dawn E. Havrda, PharmD, BCPS, FCCP
Associate Professor and Associate Dean for Academic Affairs and Assessment, College of Pharmacy, University of Tennessee Health Science Center, Memphis, Tennessee
Chapter 8

Kim Hawkins, PhD, APRN, FNP-C
Associate Professor, Donna and Allan Lansing School of Nursing and Clinical Sciences, Bellarmine University, Louisville, Kentucky
Appendix A

Kathleen B. Haynes, PharmD, CDCES
Manager – Clinical Pharmacy, Medicare Stars, Aetna, Carmel, Indiana
Chapter 49

Keith A. Hecht, PharmD, BCOP
Associate Professor, Pharmacy Practice, School of Pharmacy, Southern Illinois University Edwardsville, Edwardsville, Illinois
Chapter 95

Nancy H. Heideman, PharmD, BCOP, BCPS
Oncology Clinical Pharmacy Lead, PGY2 Oncology Residency Director, University of New Mexico Comprehensive Cancer Center, Albuquerque, New Mexico
Chapter 96

Brian A. Hemstreet, PharmD, FCCP, BCPS
Associate Dean for Student Affairs and Professor, Department of Clinical Pharmacy, Skaggs School of Pharmacy and Pharmaceutical Sciences, University of Colorado, Aurora, Colorado
Chapter 20

Gerald M. Higa, PharmD
Professor of Clinical Pharmacy, Department of Clinical Pharmacy, Clinical Professor of Medicine, Department of Medicine, Schools of Pharmacy and Medicine, West Virginia University, Morgantown, West Virginia
Chapter 89

Michelle L. Hilaire, PharmD, FCCP, CDE, BCPS, BCACP
Chair-Department of Pharmacy Practice, Clinical Professor of Pharmacy Practice, School of Pharmacy, University of Wyoming, Laramie, Wyoming
Chapter 63

Alexandra Hintz, PharmD
Assistant Professor of Pharmacy Practice, Cedarville University, Cedarville; Clinical Pharmacist, Riverside Family Practice, Columbus, Ohio
Chapter 64

Lisa M. Holle, PharmD, BCOP, FHOPA, FISOPP
Clinical Professor, Department of Pharmacy Practice, School of Pharmacy, University of Connecticut, Storrs, Connecticut; Clinical Oncology Pharmacist, UConn Health, Farmington, Connecticut
Chapter 88

Marlon S. Honeywell, PharmD
Professor and Executive Associate Dean, College of Pharmacy, Pharmaceutical Sciences and Institute of Public Health, Florida A&M University, Tallahassee, Florida
Chapter 83

Jaime R. Hornecker, PharmD, BCPS, BCACP, CDCES, DPLA
Clinical Professor, Department of Pharmacy Practice, School of Pharmacy, University of Wyoming, Laramie, Wyoming
Chapter 76

Augustus Hough, PharmD, BCPS, BCCP
Clinical Pharmacy Specialist – Cardiology, Director PGY2 Cardiology Pharmacy Residency Program, West Palm Beach VA Medical Center, West Palm Beach, Florida
Chapter 6

Jonathan Taylor Huff, PharmD
PGY2 Cardiology Pharmacy Practice Resident, West Palm Beach VA Medical Center, West Palm Beach, Florida
Chapter 6

Jill L. Isaacs, DNP, NP-C
Palliative Care Associates, P.C., Omaha, Nebraska
Appendix A

Cherry W. Jackson, PharmD, FASHP, FCCP, BCPP
Professor of Pharmacy, Department of Pharmacy Practice, Auburn University; Clinical Professor, Department of Psychiatry and Behavioral Neurobiology, University of Alabama, Birmingham, Alabama
Chapter 39

Paiboon Jungsuwadee, BPharm, MSc, PhD
Associate Professor, Department of Pharmaceutical Sciences, School of Pharmacy and Health Sciences, Fairleigh Dickinson University, Florham Park, New Jersey
Chapter 70

Michael D. Katz, PharmD
Professor, Department of Pharmacy Practice; Director of International Programs; Director of Residency Program, College of Pharmacy, University of Arizona, Tucson, Arizona
Chapter 45

Deanna L. Kelly, PharmD, BCPP
Professor of Psychiatry, Director, Treatment Research Program (TRP), Maryland Psychiatric Research Center (MPRC), School of Medicine, University of Maryland, Baltimore, Maryland
Chapter 38

Amy K. Kennedy, PharmD, BCACP, FAPhA
Associate Professor, Department of Pharmacy Practice and Science, College of Pharmacy, University of Arizona; Advance Practice Pharmacist, El Rio Health, Tucson, Arizona
Chapter 68

Jeffery L. Kibert II, PharmD, BCPS
Clinical Pharmacy Specialist in Cardiology, Columbia VA Healthcare System, Columbia, South Carolina
Chapter 6

Miae Kim, PharmD, MS, BCPS
Heart Transplant Clinical Specialist – Brigham and Women's Hospital, Boston, Massachusetts
Chapter 55

Jamie J. Kisgen, PharmD, BCPS, BCIDP
Pharmacy Manager, Infectious Diseases Services and PGY1 Residency Program Director, Sarasota Memorial Health Care System, Sarasota, Florida
Chapter 80

Emily Knezevich, PharmD, BCPS, CDCES, FCCP
Associate Professor, School of Pharmacy and Health Professions, Creighton University, Omaha, Nebraska
Appendix A

Jon Knezevich, PharmD, BCPS
Pharmacy Coordinator – Diabetes Stewardship, Nebraska Medicine, Omaha, Nebraska
Appendix A

Jessa Marie Koch, PharmD, BCPP, APh
Associate Professor, Department of Pharmacy Practice, School of Pharmacy; Assistant Professor, Department of Neurology, School of Medicine, Loma Linda University, Loma Linda, California
Chapter 42

Julia M. Koehler, PharmD, FCCP
Professor and Associate Dean for External Affiliations, College of Pharmacy and Health Sciences, Butler University; Ambulatory Care Clinical Pharmacist, Pulmonary Rehabilitation, Indiana University Health Methodist Hospital, Indianapolis, Indiana
Chapter 49

Matthew D. Kostoff, PharmD, BCPS, BCACP, CLS, FNLA
Assistant Professor, Pharmacy Practice, Northeast Ohio Medical University, Rootstown, Ohio
Chapter 13

Michael D. Kraft, PharmD, BCNSP, FASPEN
Clinical Professor, Department of Clinical Pharmacy, College of Pharmacy, University of Michigan; Assistant Director-Education and Professional Development, Department of Pharmacy Services, University of Michigan Health, Ann Arbor, Michigan
Chapter 100

Kelly Kroustos, PharmD, CDP
Professor of Pharmacy Practice, Raabe College of Pharmacy, Ohio Northern University; Clinical Consultant Pharmacist, Vancrest Healthcare Centers, Ada, Ohio
Chapter 3

Ninh (Irene) M. La-Beck, PharmD
Associate Professor, Department of Immunotherapeutics and Biotechnology, and Department of Pharmacy Practice, Jerry H. Hodge School of Pharmacy, Texas Tech University Health Sciences Center, Abilene, Texas
Chapter 90

Sum Lam, PharmD, BCPS, BCGP
Clinical Professor, Department of Clinical Health Professions, College of Pharmacy and Health Sciences, St John's University, Queens, New York; Clinical Specialist in Geriatric Pharmacotherapy, Division of Geriatric Medicine and Department of Pharmacy, NYU Langone Hospital_Long Island, Mineola, New York
Chapter 53

Dejan Landup, PharmD, BCPS
Cardiovascular Clinical Pharmacist, Advocate Aurora Health, Advocate Medical Group – Evergreen Center Heart Failure and Anticoagulation Clinic, Chicago, Illinois
Chapter 8

Chung-Shien Lee, PharmD, BCPS, BCOP
Associate Professor, Department of Clinical Health Professions, College of Pharmacy and Health Sciences, St. John's University, Queens, New York; Clinical Coordinator, Monter Cancer Center, Northwell Cancer Institute, Lake Success, New York
Chapter 93

James C. Lee, PharmD, FCCP, BCACP
Clinical Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Illinois at Chicago; Co-Director, Precision Medicine Program, University of Illinois Hospital and Clinics, Chicago, Illinois
Chapter 11

Jeannie K. Lee, PharmD, BCPS, BCGP, FASHP
Associate Professor of Pharmacy Practice and Science and Assistant Dean, College of Pharmacy; Clinical Associate Professor, College of Medicine, Section of Geriatrics, General Internal Medicine and Palliative Medicine, University of Arizona, Tucson, Arizona
Chapter 1

ALGRAWANY

Mary Lee, PharmD, BCPS, FCCP
Professor of Pharmacy Practice, Chicago College of Pharmacy, Midwestern University; Vice President and Special Assistant to the President, Midwestern University, Downers Grove, Illinois
Chapter 52

Teresa V. Lewis, PharmD, BCPS
Assistant Professor, Department of Pharmacy: Clinical and Administrative Sciences, College of Pharmacy, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma
Chapter 71

Alicia Lichvar, PharmD, MS, BCPS
Pharmacist Specialist, Solid Organ Transplantation, UC San Diego Health, Center for Transplantation, La Jolla, California
Chapter 27

Cara Liday, PharmD, CDCES
Associate Professor and Co-Chair, Department of Pharmacy Practice, College of Pharmacy, Idaho State University; Clinical Pharmacist in Ambulatory Care, InterMountain Medical Clinic, Pocatello, Idaho
Chapter 51

Susanne Liewer, PharmD, BCOP, FHOPA
Clinical Associate Professor, Pharmacy Practice, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 95

Jenny Lin, PharmD
PGY2 Ambulatory Care Resident, University of Washington – Harborview Medical Center, Seattle, Washington
Chapter 60

Melissa Lipari, PharmD, BCACP
Associate Professor (Clinical), Department of Pharmacy Practice, Eugene Applebaum College of Pharmacy and Health Sciences, Wayne State University; Clinical Pharmacy Specialist, Ambulatory Care, Ascension St. John, Detroit, Michigan
Chapter 21

Mark A. Malesker, PharmD, FCCP, FCCP, FCCM, FASHP, BCPS
Professor of Pharmacy Practice, Professor of Medicine, Creighton University, Omaha, Nebraska
Chapters 28 and 29

Joel C. Marrs, PharmD, MPH, BCACP, BCCP, BCPS-AQ Cardiology, CHC, CLS, FAHA, FASHP, FCCP, FNLA
Visiting Associate Professor, Department of Pediatrics, School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, Colorado
Chapter 13

Jared E. Matya, PharmD, BCOP
Focused Population Pharmacist, Blood and Marrow Transplant Nebraska Medicine, Omaha, Nebraska
Chapter 97

J. Russell May, PharmD, FASHP
Assistant Dean for Extended Campuses and Clinical Professor, Department of Clinical and Administrative Pharmacy, College of Pharmacy, University of Georgia, Augusta, Georgia
Chapter 54

Kathleen R. May, MD
Division Chief, Allergy-Immunology and Pediatric Rheumatology, Associate Program Director, AI Fellowship, Associate Professor of Pediatrics and Internal Medicine, Medical College of Georgia at Augusta University, Augusta, Georgia
Chapter 54

Joseph E. Mazur, PharmD, BCPS, BCCCP
Affiliate Associate Professor, College of Pharmacy, Medical University of South Carolina; Medical ICU Clinical Pharmacy Specialist, Department of Pharmacy, Medical University of South Carolina, Charleston, South Carolina
Chapter 81

J. Michael McGuire, PharmD, BCPP
Associate Professor of Pharmacy Practice, College of Pharmacy Belmont University, Nashville, Tennessee
Chapter 39

Damian M. Mendoza, PharmD, BCGP
Clinical Pharmacist, Geriatrics, CareMore Health, Tucson, Arizona
Chapter 1

Ashley H. Meredith, PharmD, MPH, FCCP, BCPS, BCACP, CDCES
Clinical Associate Professor, Department of Pharmacy Practice, College of Pharmacy, Purdue University, West Lafayette, Indiana; Clinical Pharmacist in Ambulatory Care, Eskenazi Health, Indianapolis, Indiana
Chapter 19

Sarah J. Miller, PharmD, MS, BCNSP
Professor, Department of Pharmacy Practice, Skaggs School of Pharmacy, University of Montana; Clinical Pharmacy Consultant, Providence Saint Patrick Hospital, Missoula, Montana
Chapter 101

Jenna M. Mills, PharmD
Assistant Professor of Pharmacy Practice, College of Pharmacy, University of Findlay, Findlay, Ohio
Chapter 66 and *67*

Beverly C. Mims, PharmD
Associate Professor, Department of Clinical and Administrative Pharmacy Sciences, Howard University; Clinical Pharmacist, Howard University Hospital, Washington, DC
Chapter 22

Lee E. Morrow, MD, MSc, FCP, FCCP, FCCM, ATSF
Professor of Medicine, Professor of Pharmacy Practice, Creighton University, Omaha, Nebraska
Chapters 28 and 29

Morgan K. Moulton, PharmD
PGY2 Ambulatory Care Pharmacy Resident, Charlie Norwood VA Medical Center, College of Pharmacy, University of Georgia, Athens, Georgia
Chapter 57

Milap C. Nahata, MS, PharmD, FAPhA, FASHP, FCCP, FPPA
Founding Director, Institute of Therapeutic Innovations and Outcomes, Professor Emeritus of Pharmacy, Pediatrics and Internal Medicine Divisions of Pharmacy Practice & Science and Outcomes & Translational Sciences, Colleges of Pharmacy and Medicine, Ohio State University, Columbus, Ohio
Chapter 2

Rocsanna Namdar, PharmD, BCPS, FCCP
Associate Professor of Pharmacy Practice, Philadelphia College of Osteopathic Medicine, Georgia Campus, Suwanee, Georgia
Chapter 79

Tien M.H. Ng, PharmD, BCPS AQ Cardiology, FCCP, FHFSA, FACC
Professor of Clinical Pharmacy and Medicine, Vice-chair, Department of Clinical Pharmacy, School of Pharmacy and Keck School of Medicine, University of Southern California, Los Angeles, California
Chapter 7

Lee Nguyen, PharmD, APh, BCPS-AQ ID, BCIDP
Health Sciences Associate Clinical Professor, Department of Clinical Pharmacy Practice, School of Pharmacy and Pharmaceutical Sciences, University of California, Irvine, California
Chapter 99

Benson N. Njuguna, BPharm, Post-graduate Diploma, Clinical Pharmacy
Clinical Pharmacist – Cardiology, Moi Teaching and Referral Hospital, Eldoret, Kenya
Chapter 5

Kimberly J. Novak, PharmD, BCPS, BCPPS, FPPA
Advanced Patient Care Pharmacist – Pediatric and Adult Cystic Fibrosis, Nationwide Children's Hospital; Clinical Assistant Professor, Ohio State University, Columbus, Ohio
Chapter 17

Edith A. Nutescu, PharmD, MS CTS, FCCP
Michael Reese Endowed Professor of Cardiovascular Pharmacotherapy, Professor and Head, Department of Pharmacy Practice, College of Pharmacy, University of Illinois at Chicago, Illinois
Chapter 11

Marisha Okpala, PharmD
Advanced Practice Pharmacist, Clinical Pharmacy Specialist, United Regional Health Care System, Wichita Falls, Texas
Chapter 56

Catherine M. Oliphant, PharmD
Professor and Co-Chair, Department of Pharmacy Practice and Administrative Sciences, College of Pharmacy, Idaho State University, Meridian, Idaho
Chapter 72

Ali J. Olyaei, PharmD
Professor, Department of Medicine and Pharmacy Practice, Oregon State University and Oregon Health Sciences University, Portland, Oregon
Chapter 55

Christine Karabin O'Neil, BS, PharmD, BCPS, BCGP, FCCP, FACSP, TTS
Professor of Pharmacy Practice, Assistant Dean, Curricular Development and Interprofessional Education, School of Pharmacy, Duquesne University, Pittsburgh, Pennsylvania
Chapter 35

Vinita B. Pai, PharmD, MS
Associate Professor of Clinical Pharmacy, Division of Pharmacy Practice and Science, College of Pharmacy, Ohio State University, Advanced Patient Care Pharmacist, Pediatric Blood and Marrow Transplantation Program, Nationwide Children's Hospital, Columbus, Ohio
Chapter 2

Lisa M. Palmisano, PharmD, BCACP
Associate Professor, Midwestern University College of Pharmacy, Downer's Grove Campus; Clinical Pharmacist, Midwestern Multispecialty Clinic, Downers Grove, Illinois
Chapter 61

Robert B. Parker, PharmD, FCCP
Professor, Department of Clinical Pharmacy and Translational Science, College of Pharmacy, University of Tennessee Health Science Center, Memphis, Tennessee
Chapter 10

Sonak D. Pastakia, PharmD, MPH, PhD, BCPS, FCCP
Professor, Department of Pharmacy Practice, Center for Health Equity and Innovation, College of Pharmacy, Purdue University; Adjunct Professor, Center for Global Health, School of Medicine, Indiana University; Visiting Lecturer, Department of Pharmacology, School of Medicine, Moi University, Eldoret, Kenya; Clinical Pharmacist, Academic Model Providing Access to Healthcare (AMPATH), Eldoret, Kenya
Chapter 5

Chris Paxos, PharmD, BCPP, BCPS, BCGP
Professor, Department of Pharmacy Practice; Associate Professor, Department of Psychiatry, Northeast Ohio Medical University, Rootstown, Ohio
Chapter 37

Charles Peloquin, PharmD, FCCP
Professor and Director, Infectious Disease Pharmacokinetics Laboratory, College of Pharmacy and Emerging Pathogens Institute, University of Florida, Gainesville, Florida
Chapter 79

Maribel A. Pereiras, PharmD, BCPS, BCOP
Clinical Oncology Specialist, Hematopoietic Stem Cell Transplant and Cellular Therapies, John Theurer Cancer Center at Hackensack University Medical Center, Hackensack, New Jersey
Chapter 69

Laura A. Perry, PharmD, BCPS
Professor of Pharmacy Practice, College of Pharmacy, University of Findlay, Findlay, Ohio
Chapter 66

ALGRAWANY

Hanna Phan, PharmD, FCCP, FPPA
Clinical Associate Professor, Department of Clinical Pharmacy, College of Pharmacy, University of Michigan; Clinical Pharmacist Specialist, Ambulatory Care, Pediatric Pulmonary, C.S. Mott Children's Hospital-Michigan Medicine, Ann Arbor, Michigan
Chapter 2 and 65

Beth Bryles Phillips, PharmD, FCCP, FASHP, BCPS, BCACP
Rite Aid Professor and Assistant Department Head for Residency Programs, College of Pharmacy, University of Georgia; Clinical Pharmacist Specialist, Ambulatory Care, Charlie Norwood VA Medical Center, Athens, Georgia
Chapter 57

Amy M. Pick, PharmD, MS, BCOP
Assistant Dean for Experiential Education, Associate Professor, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 97

Christopher R. Piszczatoski, PharmD
Post-Doctoral Pharmacy Fellow, Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida; Post-Doctoral Pharmacy Fellow, Department of Community Health and Family Medicine, College of Medicine, University of Florida, Gainesville, Florida
Chapter 59

Melissa R. Pleva, PharmD, BCNSP, BCCCP, BCPS
Manager – Surgery and Cardiovascular Services, Department of Pharmacy Services, Michigan Medicine; Adjunct Clinical Assistant Professor, Department of Clinical, Social, and Administrative Sciences, College of Pharmacy, University of Michigan, Ann Arbor, Michigan
Chapter 100

Christina M. Polomoff, PharmD, BCACP, BCGP
Assistant Clinical Professor, School of Pharmacy, University of Connecticut; Population Health Clinical Pharmacist, Hartford HealthCare Integrated Care Partners, Storrs, Connecticut
Chapters 46 and 47

Jeremy J. Prunty, PharmD, BCPS
Clinical Pharmacy Specialist – Internal Medicine, Department of Pharmacy, University Hospitals Cleveland Medical Center, Cleveland, Ohio
Chapter 18

Leesa M. Prunty, PharmD, BCPS, BCPPS
Clinical Pharmacy Specialist – Cystic Fibrosis, Department of Pharmacy, University Hospitals Home Care Services and Rainbow Babies & Children's Hospital, Cleveland, Ohio
Chapter 18

April Miller Quidley, PharmD, BCCCP, BCPS, FCCM, FCCP
Supervisor, Critical Care and Emergency Medicine; PGY1 Residency Program Director, Vidant Medical Center, Greenville, North Carolina
Chapter 73

Dulcinea Quintana, MD
Associate Professor, School of Medicine; University of New Mexico Cancer Center, University of New Mexico, Albuquerque, New Mexico
Chapter 96

Sarah Rajkovic, PharmD, MSCS
Clinical Senior Instructor, Department of Clinical Pharmacy, Skaggs School of Pharmacy and Pharmaceutical Sciences; Clinical Pharmacist, Marcus Institute for Brain Health, University of Colorado Anschutz Medical Campus, Aurora, Colorado
Chapter 31

Angharad Ratliff, PharmD, BCCCP, BCPS
Clinical Assistant Professor, Department of Pharmacy Practice and Administrative Sciences, College of Pharmacy, Idaho State University, Anchorage, Alaska
Chapter 72

Renee F. Robinson, PharmD, MPH, MSPharm
Associate Professor, Department of Pharmacy Practice and Administrative Sciences, College of Pharmacy, Idaho State University – Anchorage Campus, Anchorage, Alaska
Chapter 43

Kelly C. Rogers, PharmD, BCCP, FCCP, FACC
Professor, Department of Clinical Pharmacy and Translational Science, College of Pharmacy, University of Tennessee Health Science Center, Memphis, Tennessee
Chapter 9

Brendan S. Ross, MD
Clinical Associate Professor, Department of Pharmacy Practice, School of Pharmacy, University of Mississippi; Staff Physician, G. V. (Sonny) Montgomery Veterans Affairs Medical Center, Jackson, Mississippi
Chapter 36

Leigh Ann Ross, PharmD, BCPS, FCCP, FASHP
Professor, Department of Pharmacy Practice; Associate Dean for Clinical Affairs; Director, Center for Clinical and Translational Science, School of Pharmacy, University of Mississippi, Jackson, Mississippi
Chapter 36

Laurajo Ryan, PharmD, BCPS
Clinical Professor, College of Pharmacy, University of Texas, Austin, Texas; UT Health San Antonio, Department of Medicine, Pharmacotherapy Education Research Center, San Antonio, Texas
Chapter 23

Jeffrey M. Rybak, PharmD, PhD
Instructor, Department of Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, Tennessee
Chapter 86

Gianni B. Scappaticci, PharmD, BCOP
Clinical Pharmacist Specialist – BMT/Cellular Therapies, Michigan Medicine; Adjunct Clinical Instructor, College of Pharmacy, University of Michigan, Ann Arbor, Michigan
Chapter 98

Lauren S. Schlesselman, MA Ed Psych, PharmD
Executive Director, Learning Initiatives and Program Assessment, Center for Excellence in Teaching and Learning; University of Connecticut, Storrs, Connecticut
Chapter 85

Kristine S. Schonder, PharmD
Associate Professor, Department of Pharmacy and Therapeutics, School of Pharmacy, University of Pittsburgh; Clinical Specialist, Transplant, University of Pittsburgh Medical Center Health System, Pittsburgh, Pennsylvania
Chapter 27

Julie M. Sease, PharmD, FCCP, BCPS, CDCES, BCACP
Senior Associate Dean and Clinical Professor, College of Pharmacy, University of South Carolina, Columbia, South Carolina
Chapter 44

Megan M. Seddon, PharmD, BCIDP
Clinical Pharmacist in Infectious Diseases and Antimicrobial Stewardship, Sarasota Memorial Health Care System, Sarasota, Florida
Chapter 80

Christopher Selby, PharmD, BCOP
Assistant Professor, Department of Pharmacy Practice, Jerry H. Hodge School of Pharmacy, Texas Tech University Health Sciences Center, Dallas, Texas
Chapter 90

Roohollah Sharifi, MD, FACS
Professor of Surgery and Urology, College of Medicine, University of Illinois; Section Chief, Urology, Jesse Brown Veterans Administration Medical Center, Chicago, Illinois
Chapter 52

April Smith, PharmD, MA, BCPS
Associate Professor of Pharmacy Practice, School of Pharmacy and Health Professions, Creighton University; Acute Care and Bariatric Surgery Pharmacist, CHI Immanuel Medical Center, Omaha, Nebraska
Chapter 102

Judith A. Smith, BS, PharmD, BCOP, CPHQ, FCCP, FHOPA, FISOPP
Professor and Director of Women's Health Integrative Medicine Research Program, Division of Gynecologic Oncology, Department of Obstetrics, Gynecology and Reproductive Sciences, University of Texas Health Sciences Center McGovern Medical School; Oncology Clinical Pharmacy Specialist, Department of Pharmacy, UTHealth-Memorial Hermann Cancer Center-Texas Medical Center, Houston, Texas
Chapter 94

Steven M. Smith, PharmD, MPH, FCCP
Assistant Professor, Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida, Gainesville, Florida
Chapter 59

Susan E. Smith, PharmD, BCCCP, BCPS
Clinical Associate Professor, Department of Clinical and Administrative Pharmacy, College of Pharmacy, University of Georgia; Adjunct Assistant Professor, Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta University, Athens, Georgia
Chapter 84

Thomas R. Smith, PharmD, BCPP
Associate Professor of Pharmacy Practice and Pharmacogenomics, Department of Pharmacy Practice, College of Pharmacy, Natural and Health Sciences, Manchester University, Fort Wayne, Indiana
Chapter 34

Sarah A. Spinler, PharmD, BCPS-AQ Cardiology, FCCP, FASHP, FAHA, AACC
Professor and Chair, Department of Pharmacy Practice, Binghamton University, Johnson City, New York
Chapter 9

Mary K. Stamatakis, PharmD
Senior Associate Dean for Academic Affairs and Educational Innovation and Professor, Clinical Pharmacy, School of Pharmacy, West Virginia University, Morgantown, West Virginia
Chapter 26

Rebecca H. Stone, PharmD, BCPS, BCACP, FCCP
Clinical Associate Professor, Department of Clinical and Administrative Pharmacy, College of Pharmacy, University of Georgia; Clinical Pharmacist in Ambulatory Care, Mercy Health Center, Athens, Georgia
Chapter 48

Marc A. Sweeney, PharmD, BCMAS
Chief Executive Officer, Profero Team, Xenia, Ohio
Chapter 3

Christian J. Teter, PharmD, BCPP, RPh
Research Pharmacist, Department of Pharmacy, McLean Hospital, Belmont, Massachusetts; Academic Consultant, Marblehead NeuroPsychiatric Rx, LLC, Marblehead, Massachusetts
Chapter 37

Eljim P. Tesoro, PharmD, BCCCP, FNCS, FCCM
Clinical Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Illinois; Clinical Pharmacist in Neurocritical Care, University of Illinois Health, Chicago, Illinois
Chapter 33

Maria Miller Thurston, PharmD, BCPS, FGSHP, FCCP
Clinical Associate Professor, Department of Pharmacy Practice, College of Pharmacy, Mercer University; Clinical Pharmacist in Ambulatory Care, Wellstar Atlanta Medical Center, Atlanta, Georgia
Chapter 60

ALGRAWANY

Phu Trinh, PharmD, BCACP
Assistant Professor, HSC College of Pharmacy, University of Population Health Pharmacist, University of North Texas Health Science Center at Fort Worth; HSC Health, Fort Worth, Texas
Chapter 64

Heidi J. Wehring, PharmD, BCPP
Adjunct Associate Professor of Psychiatry, School of Medicine, University of Maryland Baltimore, Baltimore, Maryland
Chapter 38

Lydia E. Weisser, DO, MBA
Medical Director, Mississippi Department of Mental Health (Retired), Martinez, Georgia
Chapter 40

Timothy E. Welty, PharmD, FCCP, FAES
Professor and Director of Research, Innovation, and International Initiatives, Department of Clinical Sciences, College of Pharmacy and Health Sciences, Drake University, Des Moines, Iowa
Chapter 32

Ya-Feng Wen, PharmD
PhD student, Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota, Minneapolis, Minnesota
Chapter 6

Tara Whetsel, PharmD, BCACP, BC-ADM, CTTS
Clinical Associate Professor, Department of Clinical Pharmacy, School of Pharmacy, West Virginia University; Clinical Pharmacist in Ambulatory Care, WVU Medicine Cheat Lake Physicians, Morgantown, West Virginia
Chapter 16

Jon P. Wietholter, PharmD, BCPS, FCCP
Clinical Associate Professor, Department of Clinical Pharmacy, School of Pharmacy; Adjunct Associate Professor, Department of Medicine, School of Medicine, West Virginia University; Internal Medicine Clinical Specialist, WVU Medicine Ruby Memorial Hospital, Morgantown, West Virginia
Chapter 16

Sheila M. Wilhelm, PharmD, FCCP, BCPS
Professor (Clinical), Department of Pharmacy Practice, Eugene Applebaum College of Pharmacy and Health Sciences, Wayne State University, Detroit, Michigan
Chapter 21

Lori Wilken, PharmD, BCACP, AE-C, NCTTP
Clinical Assistant Professor, College of Pharmacy, University of Illinois, Chicago, Illinois
Chapter 15

Susan R. Winkler, PharmD, BCPS, FCCP
Professor and Chair, Department of Pharmacy Practice, College of Pharmacy, Midwestern University, Downers Grove, Illinois
Chapter 12

G. Christopher Wood, PharmD, FCCP, FCCM, BCCCP
Professor, Department of Clinical Pharmacy and Translational Science, College of Pharmacy, University of Tennessee Health Science Center; Clinical Pharmacist in Critical Care, Regional One Health, Memphis, Tennessee
Chapter 14

Samantha L. Yeung, PharmD, MS, BCCP
Clinical Translational Sciences Fellow in Cardiovascular Pharmacology, School of Pharmacy, University of Southern California, Los Angeles, California
Chapter 7

Bryan Zobeck, PharmD
Clinical Assistant Professor, Department of Pharmacy Practice, Rockford Regional Program, College of Pharmacy, University of Illinois at Chicago, Rockford, Illinois
Chapter 11

REVIEWERS

Kaitlin Alexander, PharmD
Associate Clinical Professor, Department of Pharmacy Practice, Harrison School of Pharmacy, Auburn University, Mobile, Alabama

Rita Alloway, PharmD, FCCP
Research Professor of Medicine, Director, Transplant Clinical Research, College of Medicine, University of Cincinnati, Cincinnati, Ohio

Justin Arnall, PharmD, BCOP
Clinical Coordinator, Bleeding Disorders, Malignant and Non-malignant Hematology, Atrium Health Specialty Pharmacy Service, Charlotte, NC

Carmela Avena-Woods, BS Pharm, PharmD, BCGP
Associate Clinical Professor, Department of Clinical Health Professions, College of Pharmacy and Health Sciences, St. John's University, Queens, New York

Deborah A. Yurovich-Berlekamp, PharmD, BCPS
Adjunct Professor of Pharmacy Practice, College of Pharmacy, University of Findlay, Findlay, Ohio

Martha Blackford, PharmD, BCPS
Clinical Pharmacologist and Toxicologist, Akron Childrens Hospital, Akron, Ohio

Elizabeth W. Blake, PharmD, BCPS
Director, Interprofessional Education / Clinical Associate Professor, College of Pharmacy, University of South Carolina, Columbia, South Carolina

Mary Barna Bridgeman, PharmD, BCPS, BCGP
Clinical Professor, Department of Pharmacy Practice and Administration, Ernest Mario School of Pharmacy, Rutgers, State University of New Jersey, Piscataway, New Jersey

Tina Brock, MS, EdD
Associate Dean for Education and Professor, Department of Clinical Pharmacy, Skaggs School of Pharmacy and Pharmaceutical Sciences, University of Colorado Anschutz Medical Campus, Aurora, Colorado

Britny R. Brown, PharmD, BCOP
Clinical Assistant Professor Department of Pharmacy Practice College of Pharmacy, Kingston, Rhode Island

Jamal A. Brown, PharmD, BCGP
Associate Professor of Pharmacy Practice, College of Pharmacy, Florida A&M University; Ambulatory Care Pharmacist, Tampa General Hospital, Tampa, Florida

Wiyanna Bruck, PharmD, BCPS, BCIDP
Assistant Professor of Pharmacy Practice, South College; Clinical Pharmacist, Parkwest Medical Center, Knoxville, Tennessee

Christine Cadiz, PharmD, MA, BCPS
Health Sciences Assistant Clinical Professor, UC Irvine School of Pharmacy and Pharmaceutical Sciences, Irvine, California

Katherine Carey, PharmD, BCACP
Associate Professor of Pharmacy Practice, School of Pharmacy-Worcester/Manchester, Massachusetts College of Pharmacy and Health Sciences, Worcester, Massachusetts

Chelsea N. Carr, PharmD, BCPP
Advanced Practice Pharmacist, Department of Pharmacy Practice and Science, School of Pharmacy, University of Maryland, Baltimore, Maryland

Manouchkathe Cassagnol, PharmD, BCPS, BCCP, CTTS, FACC, FAHA
Clinical Professor; Assistant Dean, Community Engagement, Equity, and Belonging; Executive Director, Academic Center for Equity and Inclusion; College of Pharmacy and Health Sciences, St. John's University, Queens, New York

Elisabeth L. Chandler, PharmD, BCIDP
Pharmacy Clinical Specialist – Infectious Diseases, Lee Health, Fort Myers, Florida

Daniel B. Chastain, PharmD, BCIDP, AAHIVP
Clinical Associate Professor, University of Georgia College of Pharmacy, SWGA Clinical Campus; Infectious Diseases Pharmacist, Phoebe Putney Memorial Hospital, Albany, Georgia

Jonathan Cho, PharmD, MBA, BCIDP, BCPS
Director of Pharmacy, MountainView Hospital, Residency Program Director, PGY2 Infectious Diseases Residency Program, Las Vegas, Nevada

Julie Cooper, PharmD, BCPS, AQ-Cardiology, BCCP
Associate Professor of Clinical Sciences, Fred Wilson School of Pharmacy, High Point University, High Point, North Carolina

Kelli L. Coover, PharmD, BCGP, FASCP
Associate Professor and Vice-Chair of Pharmacy Practice/ Assistant Director of Experiential Education, School of Pharmacy and Health Professions, Creighton University, Omaha, Nebraska

Elizabeth Covington, PharmD, BCIDP
Assistant Professor of Pharmacy Practice, Samford University McWhorter School of Pharmacy Birmingham, Alabama

Sandra Cuellar, PharmD, BCOP, FASHP, FHOPA
Associate Professor, College of Pharmacy, University of Illinois at Chicago; Clinical Oncology Pharmacist, UI Health Program Director, PGY2 Oncology Residency, Chicago, Illinois

David Dadiomov, PharmD, BCPP
Assistant Professor of Clinical Pharmacy, Titus Family Department of Clinical Pharmacy, University of Southern California, Los Angeles, California

Lawrence Davidow, PhD, RPh
Clinical Assistant Professor, School of Pharmacy, University of Kansas, Lawrence, Kansas

ALGRAWANY

Joseph M. Davis, PharmD, BCPS

PREFACE

Safe and effective use of pharmacotherapy is critical for preventing and treating acute and chronic medical conditions. Although biomedical research continues to lead to production of medications with great potential to improve health, medications are often overused, underused, or misused, leading to suboptimal or unsafe results. As healthcare practitioners, we are responsible for optimizing positive health outcomes and limiting adverse effects from pharmacotherapy.

Providing high quality, cost-effective pharmacotherapy requires integration of scientific knowledge and clinical practice skills combined with patient-centered care. The development of healthcare practitioners occurs through structured educational processes that include didactic and experiential learning, independent study, mentorship, interprofessional experiences, and direct involvement in patient care.

The sixth edition of *Pharmacotherapy Principles & Practice* is designed to provide student learners and healthcare practitioners with essential knowledge of the pathophysiology and pharmacotherapy of acute and chronic diseases likely to be encountered in routine practice. Chapters are written by content experts and peer reviewed by pharmacists, nurse practitioners, physician assistants, and physicians who are authorities in their professional disciplines.

Pharmacotherapy Principles & Practice, sixth edition, opens with a brief Introduction chapter followed by five chapters focused on special populations: pediatrics, geriatrics, palliative care, critical care, and global health and travel medicine. These chapters are followed by 97 disease-based chapters that review epidemiology, etiology, pathophysiology, clinical presentation and diagnosis, and nonpharmacologic therapy, followed by an emphasis on clear recommendations for medication selection, desired outcomes, dosing, and patient monitoring. New chapters in this edition include critical care pharmacotherapy; global health and travel medicine; systemic lupus erythematosus; and nose, mouth, and throat disorders. There is also important new chapter content on circulatory shock syndromes, trauma-related anxiety disorder, otic disorders, and antimicrobial stewardship.The following textbook features were designed in collaboration with educational design specialists to enhance learning and retention:

- *Structured learning objectives* at the beginning of each chapter.
- *Key concepts related to the disease, patient assessment,* and *treatment* highlighted with an easily identifiable icon throughout the chapter.
- *Patient encounters*, updated and revised from the previous edition, that facilitate development of critical thinking skills and lend clinical relevance to the scientific foundation provided.
- A *patient care process* section modeling the Joint Commission of Pharmacy Practitioners (JCPP) that provides specific recommendations about the process of care for an individual patient involving five steps: collect information, assess information, develop a care plan, implement the care plan, and follow-up: monitor and evaluate.
- *Up-to-date literature citations* for each chapter to support treatment recommendations.
- *Tables, figures, and algorithms* that enhance understanding of pathophysiology, clinical presentation, medication selection, pharmacokinetics, and patient monitoring.
- *Medical abbreviations and their meanings* at the end of each chapter to facilitate learning the accepted shorthand used in real-world healthcare settings.
- *Self-assessment questions and answers for each chapter* in the Online Learning Center to facilitate self-evaluation of learning.
- *Laboratory values* expressed as both conventional units and Système International (SI) units.
- *Appendices* that contain: (1) conversion factors and anthropometrics; (2) common medical abbreviations; (3) glossary of medical terms (the first use of each term in a chapter appears in bold, colored font); and (4) prescription writing principles.
- *A table of common laboratory tests and reference ranges* appears on the inside covers of the book.

A companion website, *Pharmacotherapy Principles and Practice Study Guide: A Case-Based Care Plan Approach*, is available to further enhance learning by guiding students through the process of applying knowledge of pharmacotherapy to specific patient cases. This study guide contains approximately 100 patient cases that correspond to chapters in the textbook.

The Online Learning Center at www.ChisholmPharmacotherapy.com provides self-assessment questions, grading and immediate feedback on the questions, and reporting capabilities.

We are extremely grateful for the commitment and dedication of more than 190 contributing authors and more than 100 peer reviewers of the chapters in this new edition. We also thank the many educators, schools/colleges, and healthcare institutions that have adopted this textbook in courses or use it as a reference in practice settings. We extend our sincere thanks to the McGraw Hill team for their hard work and commitment to bringing this new edition to our readership.

The Editors

INTRODUCTION

Jack E. Fincham

INTRODUCTION

Health professionals are given significant responsibilities in our healthcare system. These roles may be taken for granted by patients until a pharmacist, nurse practitioner, physician assistant, physician, or others perform assigned tasks that make major positive impacts upon patients and patients' families lives in countless ways. The exemplary manner in which health professionals provide necessary care to patients is a hallmark of health professional practice and delivery of US health care. Patients are thus well served, and fellow health professionals share knowledge and expertise specific to their profession.

However, there are significant problems remaining in the US healthcare system from a structural standpoint. In 2018, the United States spent twice as much as comparative countries on health care, yet the United States ranks 11th in the list that considers increased hospitalization from preventable causes and an increase in avoidable deaths.[1] Keehan and colleagues[2] from the US Centers for Medicare and Medicaid Services (CMS) projected the costs of health care through 2028 and estimate that by 2028, US healthcare expenditures will exceed $6.2 trillion with prescription drug spending estimated to be $560.3 billion. This prescription drug spending amounts to a projected increase in spending of 74% between 2016 and 2028.

A significant issue in the United States is that countless Americans in our midst are uninsured or underinsured. They may have partial coverage after a fashion, but, for these Americans, the high price of deductibles, co-pays, and monthly payments for insurance create an economic dilemma each time they seek care or pay premiums. The Coronavirus Disease (COVID-19) pandemic has amplified the lack of health insurance for many in this country.[3] The swelling of the ranks of the unemployed also means many with prior health insurance through an employer are now not only out of work but also without health insurance. In addition, many other social determinants of care impact who receives health care or not.

The use of medications in the healthcare system provides enormous benefit to many; lives are saved or enhanced, and lifespans are lengthened. Many other uses of medications lead to significant side effects, worsening states of health, and premature deaths. So, how to separate these disparate pictures of drug use outcomes? You, within your practices and within your networks in the healthcare workplace, can help to promote the former and diminish the latter. The authors of the chapters in this book have written informative, current, and superb chapters that can empower you to positively influence medication use.

The following are issues that will impact you as you develop as a healthcare professional or impact your patients as they use medications. These are important issues to consider as you enhance your knowledge concerning medications and how they can impact your patients.

CORONOVIRUS DISEASE 2019 (COVID-19)

The COVID-19 pandemic has wreaked havoc globally upon economic, social, and health structures. Healthcare practitioners have been stressed as never before. Driggin and colleagues[4] have written of the risks heathcare workers are exposed to when providing cardiovascular care and become hosts or vectors of COVID-19 transmission. Much has been written of the fear healthcare workers are experiencing since they fear for their coworkers, their family and friends, and their communities.[5,6] Rose[7] has noted the rapid change of teaching techniques from traditional pre-clerkship course delivery to online learning applications that are now required for health professional curricula during this pandemic.

The general public has experienced significant detrimental emotional impacts due to the COVID-19 pandemic. Pfefferbaum and North[8] have written of the trauma, including post-traumatic stress disorders (PTSD), patients are experiencing due to concerns related to their health, safety, well-being, economic status, and stress disorders. You will have an enormous opportunity to positively impact patients and families in your practices.

DRUG USE IN THE HEALTHCARE SYSTEM

Prescription medications are used daily and problems occurring with the use of drugs can include:

- Medication errors
- Suboptimal drug, dose, regimen, dosage form, and duration of use
- Unnecessary drug therapy
- Therapeutic duplication
- Drug–drug, drug–disease, drug–food, or drug–nutrient interactions
- Drug allergies
- Adverse drug effects, some of which are preventable

Clinicians are often called upon to resolve problems that occur due to undertreatment, overtreatment, or inappropriate treatment. Individuals can purchase medications through numerous outlets. Over-the-counter (OTC) medications can be purchased virtually anywhere. OTCs are widely used by all age groups. Prescription medications can be purchased through traditional channels (community chain and independent pharmacies), from mail-order pharmacies, through the Internet, from physicians, from healthcare institutions, and elsewhere. Herbal remedies and countless cannabidiol (CBD) products are marketed and sold in numerous outlets. The monitoring of the positive and negative outcomes of the use of these drugs, both prescription and OTC, can be disjointed and incomplete. Clinicians and health professionals need to take ownership of these problems and improve patient outcomes resulting from drug use.

Although clinicians are the gatekeepers for patients to obtain prescription drugs, patients obtain prescription medications from numerous sources. Patients may also borrow from friends, relatives, or even casual acquaintances. In addition, patients obtain OTC medications from physicians through prescriptions, on advice from pharmacists and other health professionals, through self-selection, or through the recommendations of friends or acquaintances. Through all of this, it must be recognized that there are both formal (structural) and informal (word-of-mouth) components at play. Health professionals may or may not be consulted regarding the use of medications, and in some cases are unaware of the drugs patients are taking.

External variables may greatly influence patients and their drug-taking behaviors. Coverage for prescribed drugs allows those with coverage to obtain medications with varying cost-sharing requirements. However, many do not have insurance coverage for drugs or other health-related needs.

Self-Medication

Self-medication can be broadly defined as a decision made by a patient to consume a drug with or without the approval or direction of a health professional. The self-medication activities of patients have increased dramatically in the late 20th and early 21st centuries. Many factors affecting patients have continued to fuel this increase in self-medication. There have been many prescription items switched to OTC classification in the last 50 years, which is dramatically and significantly fueling the rapid expansion of OTC drug usage. In addition, patients are increasingly comfortable with self-diagnosing and self-selection of OTC remedies.

Through the rational use of drugs, patients may avoid more costly therapies or expenditures for other professional services. Self-limiting conditions, and even some chronic health conditions (e.g., allergies and dermatologic conditions), if appropriately treated through patient self-medication, allow the patient to have a degree of autonomy in healthcare decisions.

Non-Adherence Issues

Non-adherence is not taking a prescribed medication or not taking it as prescribed and is one of the most understated problems in the healthcare system.[9] Reasons can include not being able to get the medication in a timely manner because of insurance requirements such as a prior approval from the insurance being denied or delayed, the prescribed drug may not be covered under the patient's insurance, the patient cannot afford to pay the drug cost or the copay, regimens are complicated or not understood by the patient, etc. The effects of non-adherence have enormous ramifications for patients, caregivers, and health professionals. Non-adherence is a multifaceted problem with a need for interprofessional, multidisciplinary solutions. Interventions that are organizational (how clinics are structured), educational (patient counseling, supportive approach), and behavioral (impacting health beliefs and expectations) are necessary. Compliant behavior can be enhanced through your actions with the patients for whom you provide care. Sometimes what is necessary is referral to specific clinicians for individualized treatment and monitoring to enhance compliance. The case histories provided in this textbook will allow you to follow what others have done in similar situations to optimally help patients succeed in improving adherence rates and subsequent positive health outcomes.

Drug Use by the Elderly

The major source of payment for prescription drugs for those age 65 years and older in the United States is the Medicare Part D Drug Benefit. Seniors have benefitted tremendously from this component. Estimates place the expenditure for Medicare Part D to be $88 billion in 2020.[10]

A joint effort by health professionals working together is the best approach to aiding seniors in achieving optimal drug therapy. Evaluation of all medications taken by seniors at each patient visit can help prevent polypharmacy from occurring.

IMPACTING THE PROBLEMS OF DRUG USE

Medication Errors

There is a tremendous opportunity in medication use and monitoring to reduce medication errors. Untold morbidity and mortality occur due to the many errors occurring in medication use. The increasing availability of artificial intelligence applications, and increased usage by healthcare professionals can enhance the proper provision of patient care for all patients.[11]

Avoiding Prescribing Cascades

Prescribing cascades occur in healthcare when the side effect from a medication is interpreted as a new condition—and a second drug is prescribed to "treat" the side effect. Prescribing cascades are important because they can be prevented.[12]

Impacting the Opioid Crisis

The use and misuse of prescription opioid analgesic medications are at an all-time high and are increasing, and the negative consequences of this epidemic are many.[13] Health professionals will play a key, vital role in reversing this epidemic and enhancing the health of many and society as well.

SUMMARY

Health professionals are at a crucial juncture facing an uncertain, yet promising future. The skills and knowledge that enable effective practice have never been more daunting among the numerous health professions. Technology can further empower health professionals to play an effective role in helping patients and fellow health professionals to practice safe and effective medicine. Continuing healthcare reforms will have the potential to dramatically impact your practices in the healthcare system for the length of your careers.

The use of this text, which incorporates materials written by the finest minds in pharmacy practice and education, can enable the reader to play a crucial role in improving the drug use process for patients, providers, payers, and society. The thorough analysis of common disease states, discussion of therapies to treat these conditions, and specific advice for patients will help you in your practices. The purpose of this book is to help you make a real improvement in the therapies you provide to your patients. Current and future clinicians can rely on the information laid out here to enhance your knowledge and allow you to assist your patients with the sound advice that they expect you to provide. Use the text, case histories, and numerous examples here to expand your therapeutic skills, and to help positively impact your patients in the years to come.

You can help to reverse medication-related problems, improve outcomes of care both clinically and economically, and enable drug use to meet stated goals and objectives. This text provides a thorough analysis and summary of treatment options for commonly occurring diseases and the medications or alternative therapies used to successfully treat these conditions.

Part I

Special Populations

1 Geriatrics: Safe Medication Use in Older Adults

Jeannie K. Lee, Damian M. Mendoza, and
Shaun M. Chatelain

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain changing aging population demographics.
2. Discuss age-related pharmacokinetic and pharmacodynamic changes.
3. Identify drug-related problems and associated morbidities commonly experienced by older adults.
4. Describe major components of geriatric assessment.
5. Recognize interprofessional patient care functions in various geriatric practice settings.

INTRODUCTION

The growth of the aging population and increasing lifespan require healthcare professionals to gain knowledge necessary to meet the needs of this patient group. Despite the availability and benefit of numerous pharmacotherapies, older patients commonly experience drug-related problems, resulting in additional morbidities. Therefore, it is essential for clinicians serving older adults across all healthcare settings to understand the epidemiology of aging, age-related physiological changes, drug-related problems prevalent in elders, comprehensive geriatric assessment, and interprofessional approaches to care.

EPIDEMIOLOGY AND ETIOLOGY

As humans age, they are at increasing risk of disease, disability, and death for three reasons: genetic predisposition; reduced immunological surveillance; and the accumulated effects of physical, social, environmental, and behavioral exposures over the life course. Elders experience variably increasing vulnerability (**homeostenosis**) as they age, resulting in heterogeneity in health states and care requirements. While resilient elders can maintain high levels of physical and cognitive functioning, others suffer functional decline, **frailty**, disability, or premature death. There is an urgent need for clinicians to better understand the epidemiology of aging to comprehensively provide high-value services to optimize the function and health-related quality of life of older adults.[1]

Sociodemographics

▶ *Population*

KEY CONCEPT The population is rapidly growing older. In 2020, 56.1 million US residents were 65 years and older, with projections to increase to 94.7 million by 2060.[2] Almost 6.7 million people were 85 years or older (the "oldest-old"), and 100 thousand persons were aged 100 or older.[2] Those 85+ years individuals are projected to grow from 6.4 million in 2016 to 14.4 million in 2040 and further increase to 19 million by 2060.[2] In 2020, older women aged 65 years and above (31 million) outnumbered older men (25 million), with a ratio of 100 to 81; this ratio widens as elders age.[2] Additionally, minority elders are projected to increase to 21.1 million in 2020.[3] With changing aging population demographics, surviving baby boomers will be disproportionally female, more ethnically/racially diverse, better educated, live alone, and have more financial resources than elders in previous generations.

▶ *Economics*

More elders have higher economic prosperity than ever before. In 2017 only 9.2% of Americans of 65 years and older and 11.6% of 80 years and older lived below the poverty line.[4] However, major inequalities persist, with older Blacks (poverty rates of 16.1% for men and 21.5% for women) and those without high school diplomas reporting fewer financial resources.[4,5] Considerable disparities exist and may prevent less advantaged elders from purchasing all prescribed medications.

▶ *Education and Health Literacy*

By 2007, more than 75% of US elders had graduated from high school, and nearly 20% had a bachelor's degree or higher. Still, substantial educational differences exist among racial and ethnic minorities. While more than 80% of non-Hispanic White elders had high school degrees in 2007, 72% of Asians, 58% of Blacks and 42% of Hispanic elders were graduates.[6] Nearly 40% of people 75+ years have low **health literacy**, more than any other age group.[5] Despite these limitations, the Pew Trust reports that 67% of adults aged 65 years and older say they use the Internet,[7] and healthcare systems are increasingly offering online health information to older consumers. These advances are important because communication between healthcare providers and elders is vital in providing quality care, supporting self-care, and navigating care transitions.

Health Status

▶ *Life Expectancy*

Americans are living longer than ever (average of 78.6 years in 2017), and life expectancy has increased (people who survive to age 65 can expect to live an average of 19.3 more years).[5] Yet, US life expectancy lags behind that of many other industrialized nations.[5,8] Disparities in mortality persist; in 2014 life expectancy at birth for the Whites was 3.4 years longer than for the Blacks.[5]

Nearly 35% of US deaths in 2000 were attributed to three risk behaviors: smoking, poor diet, and physical inactivity. Though only 8.4% of Americans 65+ years smoked in 2018, nearly 54% of men and 21% of women were former smokers.[5,9] Overweight elders aged 65 to 74 years increased from 57% to 73% in 2004, largely due to inactivity and a diet high in refined foods, saturated fats, and sugared beverages.[5] Despite proven health benefits of physical activity, 47% of elders 65 to 74 years and 61% of 75+ years reported no physical activity, and only 12% of older adults reported participating in aerobic and muscle-strengthening activities that meet US physical activity guidelines.[5,10]

The 2016 National Health Interview Survey indicated that in 2012 to 2014 older non-Hispanic Whites were more likely to report good to excellent health than non-Hispanic Blacks and Hispanic peers (80% vs 65% and 66%, respectively).[11] Approximately 85% of older adults have at least one chronic condition, and 60% have at least two. The prevalence of certain chronic conditions differs by sex, with women reporting higher levels of arthritis (54% vs 43%), and men reporting higher levels of heart disease (37% vs 26%) and cancer (24% vs 19%).[8] Figure 1–1 specifies the most common chronic conditions of older adults by sex. Frailty is a common biological syndrome in the elderly. Once frail, elders may rapidly progress toward failure to thrive and death. Among US adults 65 years and older, 15.3% were frail according to the National Health and Aging Trends Study.[12]

Healthcare Utilization and Cost

KEY CONCEPT Older Americans use more healthcare services than younger Americans do. Although older adults with one or more hospital stays decreased from 2000 to 2017 (18% vs 15.3%), they accounted for more than half of hospitalizations overall, with longer lengths of stay corresponding to increasing age.[8] Between 2015 and 2016, there were 1.2 million US nursing home residents aged 65+ years, and as the aged live longer, more will require assistance, which will be increasingly performed in the home.[8] Healthcare costs among older Americans are higher than costs for younger Americans. In 2015 older Americans spent 12.9% of their total expenditures on health compared with 7.8% among all consumers.[3] Medicare plays a major role in US healthcare costs, accounting for 20% of total health spending in 2012, 27% of spending on hospital care and 23% on physician services.[13]

Patient Encounter Part 1

CS is an 85-year-old widow who moved to California with her sister 10 years ago to be near their children at the end of life. Though CS has a college degree in art in Japan, she speaks very little English, has limited health literacy, and requires interpretation during health visits. CS comes to the Interprofessional Geriatrics Clinic to receive comprehensive care of her multimorbidity and polypharmacy management. Her past medical history includes depression, diabetes, dyslipidemia, hypertension, hypothyroidism, insomnia, myocardial infarction (14 years ago), and peripheral neuropathy. CS uses 19 medications that include prescription medications for her multiple chronic conditions, vitamins, and herbal supplements for "immune system and sleep." She is underweight, despite eating often to maintain her weight. She walks around her neighborhood with her sister for about 30 minutes every morning, then drinks three to four cups (about 0.75–1 L) of tea while listening to Japanese news.

What information is consistent with epidemiology of aging?

Which of CS's medical conditions are commonly found in older adults?

What additional information do you need before conducting a comprehensive medication review?

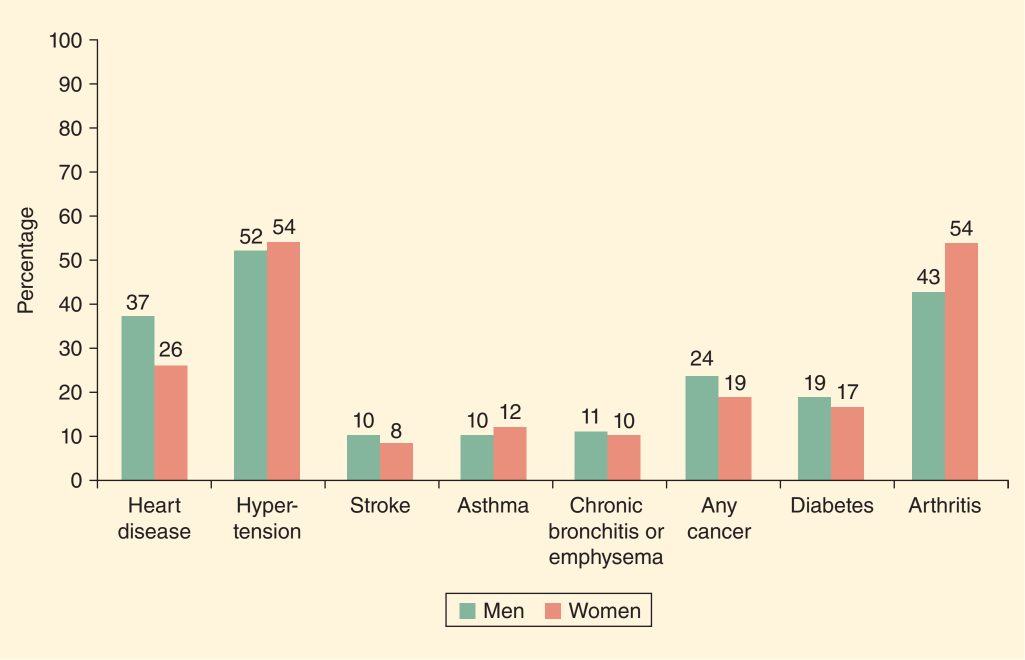

FIGURE 1–1. Percentage of people 65 years and older who reported having selected chronic conditions, by sex, 2005 to 2006. Note: Data are based on a 2-year average from 2005 to 2006. Reference population: These data refer to the noninstitutionalized population. (From Centers for Disease Control and Prevention, National Center for Health Statistics, National Health Interview Survey.)

AGE-RELATED CHANGES

In basic terms, pharmacokinetics is what the body does to the drug, and pharmacodynamics is what the drug does to the body. **KEY CONCEPT** All four components of pharmacokinetics—absorption, distribution, metabolism, and excretion—are affected by aging; the most clinically important and consistent is the reduction of renal elimination of drugs.[14] As people age, they can become frailer and are more likely to experience altered and variable drug pharmacokinetics and pharmacodynamics. Even though this change is influenced by a patient's clinical state more than their chronological age, the older patient is more likely to be malnourished or suffer from diseases that affect pharmacokinetics and pharmacodynamics.[14] Older adults can develop significant drug-related problems when alterations in pharmacokinetics and pharmacodynamics are not appropriately accounted for in prescribing and monitoring medications.[13] Clinicians have the responsibility to use pharmacokinetic and pharmacodynamic principles to improve elder care and avoid adverse effects of pharmacotherapy. Due to the many changes described below, certain chronic medications should be started at 50% of the recommended initial adult dose with doses titrated slowly in older adults. This is a general recommendation for initiating medications, such as antihypertensives and antidepressants, but does not apply to the treatment of acute illness (eg, antibiotics for pneumonia).

Pharmacokinetic Changes

▶ *Absorption*

Multiple changes occur throughout the gastrointestinal (GI) tract with aging, but little evidence indicates that drug absorption is significantly altered. The changes include decreases in overall surface of the intestinal epithelium, gastric acid secretion, and splanchnic blood flow.[14] Peristalsis becomes weaker, and gastric emptying is delayed. These changes slow absorption in the stomach, especially for enteric-coated and delayed-release preparations. Delays in absorption may lead to a longer time required to achieve peak drug effects, but it does not significantly alter the amount of drug absorbed, and drug movement from the GI tract into circulation is not meaningfully changed.[14,15] However, relative **achlorhydria** can decrease the absorption of nutrients, such as vitamin B_{12}, calcium, and iron.[15]

Aging facilitates atrophy of the epidermis and dermis along with a reduction in barrier function of the skin. Tissue blood perfusion is reduced, leading to decreased or variable rates of transdermal, subcutaneous, and intramuscular drug absorption. Therefore, intramuscular injections should generally be avoided in older adults due to unpredictable drug absorption.[14] Additionally, because saliva production decreases with age, medications that need to be absorbed rapidly by the buccal mucosa are absorbed at a slower rate. Yet, for most drugs, absorption is not significantly affected, and the changes described are clinically inconsequential.[15,16]

▶ *Distribution*

The main physiological changes that affect distribution of drugs in older adults are with body fat and water and protein binding. Lean body mass can decrease by 12% to 19% through loss of skeletal muscle in older adults. Thus, blood levels of drugs primarily distributed in muscle increase (eg, digoxin), presenting a risk for overdose.[15] While lean muscle mass decreases, adipose tissue can increase with aging by 18% to 36% in men and 33% to 45% in women. Therefore, fat-soluble drugs (eg, diazepam, amitriptyline, and amiodarone) have increased volume of distribution (V_d), leading to higher tissue concentrations and prolonged duration of action. Greater V_d leads to increased half-life and time required to reach steady-state serum concentration.[14,15]

Total body water decreases by 10% to 15% by age 80. This lowers V_d of water-soluble drugs (eg, aspirin, digoxin, and morphine) leading to higher plasma drug concentrations than in younger adults when equal doses are used.[14,15] Thus lower doses are needed to prevent toxicity. Toxic drug effects may be worsened when dehydration occurs, and when the extracellular space is reduced by diuretic use.

Likewise, plasma albumin concentration decreases by 10% to 20%, although disease and malnutrition contribute more to this decrease than age alone.[14] In patients with an acute illness, rapid decreases in serum albumin can increase drug effects. Examples of highly protein-bound medications include warfarin, phenytoin, and diazepam.[15] For most chronic medications, these changes are not clinically significant because although the changes affect peak level of a single dose, mean serum concentrations at steady state are not altered unless clearance is affected.[15] For highly protein-bound drugs with narrow therapeutic indices (eg, phenytoin), however, it is important to appropriately interpret serum drug levels in light of the older patient's albumin status. In a malnourished patient with hypoalbuminemia, a higher percentage of the total drug level consists of free drug than in a patient with normal serum albumin.[14] Hence, if a hypoalbuminemic patient has a low total phenytoin level, and phenytoin dose is increased, the free phenytoin concentration may reach toxicity.

▶ *Metabolism*

Drug metabolism is affected by age, acute and chronic diseases, and drug–drug interactions. The liver is the primary site of drug metabolism, which undergoes changes with age; though the decline is not consistent, older patients have decreased metabolism of many drugs.[14,16] Liver mass is reduced by 20% to 30% with aging, and hepatic blood flow is decreased by as much as 50%.[15] These changes can drastically reduce the amount of drug delivered to the liver per unit of time, reduce its metabolism, and increase the half-life.[15] Metabolic clearance of some drugs is decreased by 20% to 40% (eg, amiodarone, amitriptyline, and morphine), but it is unchanged for drugs with a low hepatic extraction.[15] Drugs that have high **extraction ratios** have significant first-pass metabolism, resulting in higher bioavailability for older adults. For example, the effect of morphine is increased due to a decrease in clearance by around 33%. Similar increases in bioavailability are seen with propranolol, levodopa, calcium channel blockers, tricyclic antidepressants, and statins. Thus, older patients may respond similarly to younger patients using lower doses of these medications.[14-16]

Aging affects liver enzymes (cytochrome P450 system [CYP450]) that may lead to a decreased elimination rate of drugs that undergo oxidative phase I metabolism, but this is controversial.[14] Originally, it was thought that the CYP450 system was impaired in older adults, leading to decreased drug clearance and increased serum half-life, but studies have not consistently confirmed this. The variations in the CYP450 activity may not be due to aging but lifestyle (eg, smoking), illness, or drug interactions.[14-16] Nutritional status also plays a role in drug metabolism. Frail elders have a more diminished drug metabolism than those with healthy body weight.[14,16] Aging does not affect drugs that undergo phase II hepatic metabolism (eg, lorazepam and temazepam), known as conjugation or glucuronidation, but conjugation is reduced with frailty.[15]

▶ *Elimination*

Clinically, the most important pharmacokinetic change in older adults is decreased renal drug elimination.[14] As people age, renal blood flow, renal mass, glomerular filtration rate, filtration fraction, and tubular secretion decrease. After age 40, the number of functional glomeruli declines, and renal blood flow decreases by approximately 1% yearly. From age 25 to 85 years, average renal clearance declines by as much as 50% and is independent of the effects of disease.[14,15] Still, the impact of age on renal function is variable and not always linear. Longitudinal studies have suggested that a percentage (up to 33%) of older adults do not experience this age-related decline in renal function.[15] Clinically significant effects of decreased renal clearance include prolonged drug half-life, increased serum drug level, and increased potential for adverse drug reactions (ADRs).[14] Special attention should be given to renally eliminated drugs with a narrow therapeutic index (eg, digoxin and aminoglycosides). Monitoring serum concentration and making appropriate dose adjustment for these agents can prevent serious ADRs resulting from drug accumulation.[17] Importantly, despite a dramatic decrease in renal function (creatinine clearance) with aging, serum creatinine may remain fairly unchanged and remain within normal limits. This is because frail older patients have decreased muscle mass resulting in less creatinine production for input into circulation.[14,15] Because chronic kidney disease can be overlooked if a clinician focuses only on the serum creatinine value, overdose and ADR can occur.

Creatinine clearance should be calculated when starting or adjusting pharmacotherapy in older adults. The Cockcroft-Gault equation is the most widely used formula for estimating creatinine clearance (mL/min; or multiply by 0.0167 to express in mL/s) for adjusting drug doses. See Chapter 26 (Table 26–3) for more details.

When serum creatinine is expressed in mg/dL,

$$\text{Creatinine Clearance} = \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{\text{Serum creatinine (mg/dL)} \times 72} \times (0.85 \text{ if female})$$

When serum creatinine is expressed in μmol/L,

$$\text{Creatinine Clearance} = 1.2 \times \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{\text{Serum creatinine } (\mu\text{mol/L})} \times (0.85 \text{ if female})$$

This equation is also used by most drug manufacturers to determine renal dosing guidelines. The Cockcroft-Gault equation provided the best balance between predictive ability and bias in a comparison study with the Modification of Diet in Renal Disease (MDRD) and Jelliffe "bedside" clearance equations.[15] The Cockcroft-Gault equation can overestimate renal function in obese individuals, so an adjusted body weight should be used in the calculation [AjBW = IBW + 0.4 (ABW − IBW)]. Understand that predictive formulas can also significantly overestimate actual renal function in chronically ill, debilitated older patients.

Pharmacodynamic Changes

Pharmacodynamics refers to the actions of a drug at its target site and the body's response to that drug. Compared to pharmacokinetics, there is less data on age-related pharmacodynamic changes. **KEY CONCEPT** In general, the pharmacodynamic changes that occur in older adults tend to increase their sensitivity to drug effects. Most pharmacodynamic changes in elders are associated with a progressive reduction in homeostatic mechanisms and changes in receptor properties. Although the result of these changes is an increased sensitivity to the effects of many drugs, a decrease in response can also occur. The changes in the receptor site include alterations in binding affinity of the drug, number/density of active receptors at the target organ, structural features, and postreceptor effects (biochemical processes/signal transmission). These include receptors in the adrenergic, cholinergic, and dopaminergic systems, as well as γ-*aminobutyric acid* (GABA) and opioid receptors.[14,15]

▶ *Cardiovascular System*

Decreased homeostatic mechanisms in older adults increase their susceptibility to orthostatic hypotension when taking drugs that affect the cardiovascular system and lower the arterial blood pressure. This is explained by decreased arterial compliance and baroreceptor reflex response, which limits the ability to compensate quickly for postural changes in blood pressure. It has been estimated that 5% to 33% of older adults experience drug-induced orthostasis. Examples, other than typical antihypertensives, that can cause orthostatic hypotension in older patients are antipsychotics, direct vasodilators, loop diuretics, and opioids.[14,15,17] Older people have a decreased β-adrenergic receptor function, and they are less sensitive to β-agonist and β-adrenergic antagonist effects in the cardiovascular system and possibly in the lungs, but their response to α-agonists and antagonists is unchanged.[14,15] Increased hypotensive and heart rate response (to a lesser degree) to calcium channel blockers (eg, verapamil) are reported. Increased risks of developing drug-induced QT prolongation and torsade de pointes are also present.[17] Therefore, clinicians must start medications at low doses and titrate slowly, closely monitoring the patient for any adverse effects.

▶ *Central Nervous System*

Overall, elders exhibit a greater sensitivity to the effects of drugs that gain access to the central nervous system (CNS), especially anticholinergic medications. In most cases, lower doses result in adequate response, and higher incidence of adverse effects may be seen with standard and high doses. For example, lower doses of opioids provide sufficient pain relief for older patients, whereas conventional doses can cause oversedation and respiratory depression.[14,15] The blood–brain barrier becomes more permeable as people age; more medications can cross the barrier and cause CNS effects. Examples include benzodiazepines, antidepressants, antipsychotics, neuroleptics, and antihistamines. There are decreased numbers of cholinergic neurons as well as nicotinic and muscarinic receptors, decreased choline uptake from the periphery, and increased acetylcholinesterase.[14,15] Older adults have a decreased ability to compensate for these imbalances of the neurotransmitters, leading to movement and memory disorders. Older adults have an increased number of dopamine type 2 receptors, making them more susceptible to delirium from anticholinergic and dopaminergic medications. At the same time, they have a reduced number of dopamine and dopaminergic neurons in the *substantia nigra* of the brain resulting in higher incidence of extrapyramidal symptoms from antidopaminergic medications (eg, antipsychotics).[14,15]

▶ *Fluids and Electrolytes*

Fluid and electrolyte homeostatic mechanism is decreased in elders. Older adults experience more severe dehydration with equal amounts of fluid loss compared with younger adults. The multitude of factors involved include decreased thirst and cardiovascular reflexes, decreased fluid intake, decreased ability of the kidneys to concentrate urine, increased atrial natriuretic peptide, decreased aldosterone response to hyperkalemia, and decreased response to antidiuretic hormone.[17] The result is increased incidences of hyponatremia, hyperkalemia, and prerenal azotemia, especially when the older patient is taking a diuretic (eg, hydrochlorothiazide, furosemide). Angiotensin-converting enzyme inhibitors have an increased potential to cause hyperkalemia and acute renal failure in older adults.[14] Thus, these agents need to be started with low doses, titrated slowly with frequent renal function monitoring.

▶ *Glucose Metabolism*

An inverse relationship between glucose tolerance and age has been reported, likely due to reduced insulin secretion and sensitivity (greater insulin resistance). Consequently, hypoglycemia incidences are increased when using sulfonylureas (eg, glyburide, glipizide) from age-related impairment to counter-regulate hypoglycemic responses.[14] Due to an impaired autonomic nervous system, older patients may not distinguish symptoms of hypoglycemia such as sweating, palpitations, or tremors. They still experience neurological symptoms of syncope, ataxia, confusion, or seizures.

DRUG-RELATED PROBLEMS

KEY CONCEPT Comorbidities and polypharmacy complicate health status of older adults, particularly inappropriate medications that lead to drug-related problems. It is estimated that 43.6% of emergency department visits leading to hospitalizations in older adults are due to adverse drug events.[18] Studies indicated that 59% of the older Medicare beneficiaries' sample had at least one medication-related problem, and drug-related morbidity and mortality costed US healthcare system $528.4 billion in 2016.[19,20] Drug-related problems result in poor health outcomes for older adults such as withdrawal effects, therapeutic failure, and adverse drug events.[21] Collaboration among interprofessional providers and older patients can ensure appropriate therapy, minimize adverse drug events, and maximize medication adherence and health outcomes.

Polypharmacy

Polypharmacy is defined as taking multiple medications concurrently (≥ 4–10 medications have been used as criteria in studies). Polypharmacy is prevalent among elders with 39% reporting the use of five or more medications in 2012 compared with polypharmacy use by 24% in 1999, signifying a dramatic increase.[22] In 2011, 67% of older adults used polypharmacy including nonprescription products, an increase from 53% in 2006.[18] The common use of dietary supplements and herbal products in this population adds to polypharmacy. In nursing home settings 50.7% of patients with severe cognitive impairment received polypharmacy (5–9 medications), and 16.9% received excessive polypharmacy (≥ 10 medications).[23] Among various reasons for polypharmacy, an apparent one is an older patient receiving multiple medications from different providers who treat the patient's comorbidities without coordinated care. Hence, medication reconciliation becomes increasingly important as the aging population continues to grow.

A complete evaluation of all medications should be conducted by healthcare providers at each elder's visit to prevent inappropriate polypharmacy. Efforts should be made to reduce polypharmacy by discontinuing any medication without indication. However, clinicians should also understand that appropriate polypharmacy is indicated for older adults who have multimorbidity, and support should be provided for optimal adherence. Drug-related problems associated with polypharmacy can be identified by performing a comprehensive medication review (see Patient Care Process).

Inappropriate Prescribing

Inappropriate prescribing is defined as prescribing medications that cause a significant risk of an adverse event when there is an effective and safer alternative. Potentially inappropriate medications in older adults have been associated with negative outcomes such as confusion, falls, and mortality.[24] At times, medications are continued long after the initial indication has resolved. The clinician prescribing for older adults must understand the rate of adverse reactions and drug–drug interactions, the evidence available for using a specific medication, and patient's use of over-the-counter (OTC) agents and herbal supplements.[21]

Screening tools have been developed to help the clinician identify potentially inappropriate medications in older adults. The most utilized tool in the US is the Beers criteria.[24] The 2019 Beers criteria includes 30 medications and medication classes that are potentially inappropriate in older patients, listed in five categories: medications potentially inappropriate in most older adults, medications that should typically be avoided in older adults with certain conditions, medications to use with caution, drug–drug interactions, and drug dose adjustment based on kidney function.[24]

Examples of medications included in the Beers criteria are as follows[24]:

- Benzodiazepines such as diazepam and alprazolam (risk of cognitive impairment, delirium, falls, fractures, and motor vehicle accidents)
- First-generation antihistamines such as diphenhydramine and hydroxyzine (risk of confusion, dry mouth, constipation, and other anticholinergic symptoms)
- Tricyclic antidepressants (TCAs) such as amitriptyline and nortriptyline (risk of sedation, orthostatic hypotension, and anticholinergic symptoms)
- Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and naproxen (risk of GI bleeding and ulcers)

Practical strategies for appropriate medication prescribing include establishing a partnership with patients and their care partners to enable them to understand and monitor medication effects. Clinicians should perform a comprehensive medication assessment to obtain accurate history of medication use, determine appropriateness of the regimen, conduct drug–drug and drug–disease interaction screenings, use time-limited trials to evaluate the benefits and risks of new medications, and trial off medications to assess continued need.[21]

Undertreatment

Much has been written about the consequences of overmedication and polypharmacy in older adults. However, underutilization of medications is just as harmful, resulting in reduced functioning, and increased morbidity and mortality. There are instances when a drug is truly contraindicated, when a lower dose is indicated, or when prognoses dictate withholding therapy. Outside of these scenarios, many elders do not receive therapeutic interventions that would provide benefit.[21,25] Undertreatment is prevalent across diverse settings in the community, hospitals, and long-term care facilities.[21] Many reasons include multimorbidity, polypharmacy, cost, concerns of nonadherence, fear of adverse effects and associated liability, limited evidence in the age group, starting low and failing to increase to an appropriate dose, skepticism regarding secondary prevention benefits, or ageism.[21,26] Common categories of geriatric undertreatment are listed in Table 1–1.

Table 1–1

Common Categories of Geriatric Undertreatment

Therapy	Concern
Anticoagulation in patients with atrial fibrillation	Overly concerned with risk of bleeding or the risk of falls if anticoagulated
Malignant and nonmalignant pain	Hesitant to prescribe opioids due to possible cognitive and bowel side effects, concerns about addiction; patients may often be hesitant to use opioids
Antihypertensive therapy	Underestimate the benefit on stroke and cardiovascular event prevention and/or fail to add the second or third medication needed to attain control
β-Blocker treatment in heart failure	Concerned about complications in high-risk patients despite the substantial evidence of mortality benefit
Statin treatment for ASCVD	Underestimate benefit or have concerns about adverse events

ASCVD, atherosclerotic cardiovascular disease.

A clinical assessment to weigh the potential benefit versus harm of the older patient's complete medication regimen is required. Once obvious contraindications have been dismissed, the patient's goals and preferences, prognosis or life expectancy, and time to therapeutic benefit should be taken into consideration to determine whether pharmacotherapy meets treatment goals. Underprescribing can best be avoided by using clinical assessment strategies, improving adherence support, and assisting financial coverage of drugs.

Adverse Drug Reaction

ADR is defined by the World Health Organization as a reaction that is noxious and unintended, which occurs at dosages normally used in humans for prophylaxis, diagnosis, or therapy. ADRs increase with polypharmacy use and are the most frequently occurring drug-related problem among older nursing home residents. A brown bag medication review study found that 25% of community-dwelling older adults using at least five medications experienced ADRs.[27] Approximately 9% of hospitalizations among older adults are caused by ADRs.[28] Medication classes causing serious ADRs in older adults include anticoagulants, antidiabetics, and opioids.[29]

Seven predictors of ADRs in elders are[30] taking more than four medications; more than 14-day hospital stay; having more than four active medical problems; general medical unit admission versus geriatric ward; alcohol use history; lower Mini-Mental State Examination score (confusion, dementia); and two to four new medications added during a hospitalization. Similarly, four predictors of severe ADRs in older adults are[31] use of certain medications including diuretics, NSAIDs, antiplatelets, and digoxin; number of drugs taken; age; and comorbidities. Suggested strategies to prevent ADRs in older adults are described in Table 1–2.[31] Particular caution must be taken when prescribing drugs that alter cognition in older adults, including antidepressants, antihistamines, antipsychotics, benzodiazepines, opioids, and muscle relaxants.[31]

One of the most damaging ADRs that frequently occurs in elders is medication-related falls. Falls are associated with a poor prognosis ranging from premature institutionalization to early death, and polypharmacy is a risk factor. Multiple medications included in the Beers criteria are related to falls.[24] For example, benzodiazepine studies found significant association with falls including an increased risk after a new prescription for benzodiazepines and twofold risk with combined use of two or more benzodiazepines.[32] Other agents having strong association with increased fall risk include sedative hypnotics, neuroleptics, antidepressants, and antipsychotics.[32] A comprehensive fall prevention intervention should include deprescribing by slow taper with close monitoring.

Table 1–2

Strategies to Prevent Adverse Drug Reactions in Older Adults

- Evaluating comorbidities, frailty, and cognitive function
- Identifying caregivers to take responsibility for medication management
- Evaluating renal function and adjusting doses appropriately
- Monitoring drug effects
- Recognizing that clinical signs or symptoms can be an ADR
- Minimizing number of medications prescribed
- Adapting treatment to patient's life expectancy
- Realizing that self-medication and nonadherence are common and can induce ADRs

ADR, adverse drug reaction.

Adapted, with permission, from Merle L, Laroche ML, Dantoine T, Charmes JP. Predicting and preventing adverse drug reactions in the very old. Drugs Aging. 2005;22(5):375–392.

Nonadherence

America's other drug problem is the term given to medication nonadherence by the National Council on Patient Information and Education. Nonadherence to chronic medications is prevalent and escalates healthcare costs associated with worsening disease and increased hospitalization. *Medication adherence* describes a patient's medication-taking behavior, generally defined as the extent to which one adheres to an agreed regimen derived from collaboration with their healthcare provider.[33]

KEY CONCEPT Older adults are at greater risk for medication nonadherence due to the high prevalence of multimorbidities, cognitive deficit, polypharmacy use, and financial barriers. Numerous barriers to optimal adherence exist and include patient's lack of understanding, provider's failure to educate, polypharmacy leading to complex regimen and inconvenience, treatment of asymptomatic conditions (such as hypertension and dyslipidemia), and cost of medications.[33] Factors influencing nonadherence are listed in Table 1–3.

Following is a list of six "how" questions to ask when assessing medication adherence[34]:

1. How do you take your medicines?
2. How do you organize your medicines to help you remember to take them?
3. How do you schedule your meal and medicine times?
4. How do you pay for your medicines?
5. How do you think the medicines are working for your conditions?
6. How many times in the last week/month have you missed your medicines?

Table 1–3

Factors Influencing Medication Nonadherence

Three or more chronic medical conditions
Five or more chronic medications
Three times or more per day dosing or 12 or more medication doses per day
Four or more medication changes in past 12 months
Three or more prescribers
Significant cognitive or physical impairments
Recent hospital discharge
Caregiver reliance
Low health literacy
Medication cost
History of medication nonadherence
Living alone in the community

Although no single intervention has found to improve adherence consistently, older person-centered multicomponent interventions, such as combining education, adherence aid, and regular follow-up, have resulted in a positive impact on medication adherence and associated health outcomes.[35] Future research needs include adherence studies evaluating belief-related variables, such as personal and cultural beliefs, in larger and more ethnically/racially diverse samples of older populations.

Patient Encounter Part 2

CS was recently hospitalized after an episode of dizziness and near-fall. Her daughter (interpreter) states that there were several medication changes while CS was in the hospital with some confusion as to what to do at home. CS brought in all medication bottles used at home: (1) amlodipine 10 mg by mouth every morning, (2) aspirin 81 mg by mouth every morning, (3) calcium-vitamin D 600 mg-500 units by mouth every morning and evening, (4) eszopiclone 2 mg by mouth at bedtime, (5) gabapentin 900 mg by mouth three times a day, (6) hydrochlorothiazide 50 mg by mouth every morning, (7) levothyroxine 50 mcg by mouth in the morning, (8) melatonin 3 mg by mouth at bedtime, (9) metformin 500 mg morning and evening, (10) omeprazole 40 mg by mouth every morning, (11) rosuvastatin 5 mg by mouth every evening, (12) valsartan 40 mg by mouth every morning and evening, (13) vitamin B$_6$ 200 mg by mouth every morning and evening, (14) vitamin C 5000 mg by mouth every morning and evening, (15) vitamin E 400 units by mouth every morning and evening, (16) acetaminophen 500 mg two tablets by mouth every 4 hours as needed for pain, (17) ibuprofen 200 mg by mouth three times a day as needed for headaches, (18) pantoprazole 20 mg by mouth in the morning as needed for stomach upset, (19) valerian root 1200 mg by mouth at night as needed for sleep.

She is allergic to sulfa drugs (rash) and intolerant to ramipril (cough).

She does not smoke, has one or two drinks a night, does not use any illicit drug.

VS: BP 122/64 mm Hg, P: 70 beats/min, RR: 12, T: 37.2°C (99°F) Ht: 5 ft (152 cm), Wt: 42 kg, Pain 1/10

Labs: Na 139 mEq/L (mmol/L), K 4.1 mEq/L (mmol/L), Cl 98 mEq/L (mmol/L), CO$_2$ 25 mEq/L (mmol/L), BUN 22 mg/dL (7.9 mmol/L), creatinine 1.5 mg/dL (133 μmol/L), glucose 97 mg/dL (5.4 mmol/L), HgbA$_{1c}$ 6.5% (0.065; 48 mmol/mol Hgb), eGFR 35.1 mL/min/1.73 m^2

What is CS's estimated creatinine clearance?

What drug-related problems are included in CS's medication list?

What steps should be taken to simplify CS's medication regimen?

Patient Encounter Part 3

CS is now 91 years old and has been living at a long-term care facility for a year. She still struggles to maintain her weight, is in pain daily, and has developed a new coccyx ulcer. She is currently on multiple medications including (1) amitriptyline 10 mg by mouth at bedtime, (2) aspirin 81 mg by mouth daily, (3) docusate sodium 100 mg by mouth twice daily, (4) hydrochlorothiazide 25 mg by mouth daily, (5) ibuprofen 600 mg by mouth daily, (6) levothyroxine 25 mcg by mouth daily, (7) lorazepam 1 mg by mouth twice daily, (8) metformin 500 mg by mouth daily, (9) rosuvastatin 5 mg by mouth every evening, (10) vitamin C 500 mg by mouth twice daily, (11) valsartan 40 mg by mouth twice daily.

Today her pain score is 8/10.

Which quality indicators should be of concern in CS?

What recommendations can be made about CS's medication regimen at this time?

GERIATRIC ASSESSMENT

The term *geriatric assessment* is used to describe the comprehensive interprofessional team evaluation of the frail or complex older adult's health including multimorbidity with functional and cognitive status. Such a team may include, but is not limited to, a geriatrician, nurse, pharmacist, case manager/social worker, physical therapist, occupational therapist, speech therapist, psychologist, dietician, dentist, optometrist, and audiologist. Assessment may be performed in various care settings and by a series of evaluations after which the team will conduct an interprofessional case conference to discuss the patient's care plan.

Patient Interview

KEY CONCEPT The clinical approach to assessing older adults frequently goes beyond a traditional "history and physical" used in general internal medicine practice.[36] Functional status must be determined, including the activities of daily living (ADLs) and instrumental activities of daily living (IADLs), see Table 1–4. Cognitive assessment, which may require collateral history from family or care partners, is important in determining the patient's capacity to manage their medications and consent to medical treatment.[37] The mini-cog mental status examination[38] shown in Figure 1–2, is a quick tool to assess patient's cognition. Elders commonly have decreased visual acuity, hearing loss, dysphagia, and impaired dexterity. Decreased skin integrity greatly increases risk for pressure ulcers. Sexual function is a sensitive but important topic and should be specifically addressed. Cardiac, renal, hepatic, and digestive insufficiencies can have significant implications for pharmacotherapy. Inadequate nutrition may lead to weight loss and impaired functioning at the cellular or organ level. See Table 1–5 for common problems experienced by older adults.

It is important to recognize geriatric syndromes such as cognitive decline, functional impairment, polypharmacy, delirium, frailty, falls, osteoporosis, insomnia, and incontinence. In elders, common diseases may present with atypical symptoms, such as thyroid dysfunction or infection presenting as delirium. It is also important to assess for caregiver stress and be aware of older

Table 1–4

Activities of Daily Living and Instrumental Activities of Daily Living

ADLs			
Transfers	Dressing	Mobility	Eating
Bathing	Toileting	Grooming	

IADLs	
Using transportation	If still driving, assess driving ability (including cognitive function, medications that can impair driving ability, vision, neuromuscular conditions that may interfere with reaction time, ability to turn head) at the time of license renewal
Using the telephone	Check for emergency phone numbers located near the telephone
Management of finances	Assess the ability to balance checkbook and pay bills on time
Cooking	Check for safe operation of appliances and cooking tools as well as ability to prepare balanced meals
Housekeeping	Check for decline in cleanliness or neatness
Medication administration	Assess organization skills and adherence

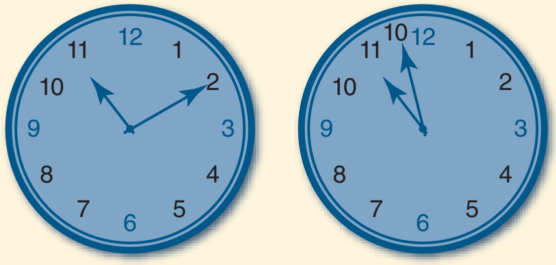
ADL, activity of daily living; IADL, instrumental activity of daily living.

Three item recall

1. Ask the patient if you may test his or her memory.
2. Give the patient 3 words (eg. apple, table, penny) to repeat and remember.
3. Have the patient repeat the 3 words from memory later (eg. after the clock drawing test).

Clock drawing test

1. Have the patient draw the face of a clock, including numbers.
2. Instruct the patient to place the hands at a specific time, such as 11:10.



Correct

Incorrect hands and inserted number

A positive dementia screen

1. Failure to remember all 3 words.
2. Failure to remember 1–2 words plus an abnormal clock drawing.

From Hajjar ER, Hersh LR, Gray SL. Prescribing in the older adult. In: DiPiro JT, Yee GC, Posey L, Haines ST, Nolin TD, Ellingrod V, eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020. Available from: https://accesspharmacy.mhmedical.com/content.aspx?bookid=2577&sectionid=233054609. Accessed September 1, 2020.

patients' support systems that may include family, friends, social or religious networks, home health agencies, and hired caregivers. Such networks may facilitate older individuals to continue living independently. Safety should be assessed and includes a home safety assessment and a driving assessment for patients with cognitive or functional limitations. In addition, look for signs and symptoms of elder abuse, neglect, or exploitation. Health professionals are mandatory reporters of elder mistreatment to Adult Protective Services.[39]

Drug Therapy Monitoring

Geriatric patients often have multiple medications, comorbidities, and prescribers. It is essential that there be a single provider who oversees the patient's pharmacotherapy. Particularly challenging in elders is identifying the cause(s) of medication nonadherence. Providers assessing older patients' medication regimens should keep the following questions in mind:

- Are medications skipped or reduced due to cost?
- Can the patient benefit from sample drugs? Starting a patient on a free drug sample may increase patient costs in the long term because samples typically are newer, expensive medications.[40]
- Is there an educational barrier such as low health literacy?
- Does the patient speak English but only read in another language?
- Can the patient see labels and written instructions?
- Does the patient have hearing problems? Patients might not admit they cannot hear instructions.
- Can the patient manipulate pill bottles, syringes, inhalers, eye/ear drops?
- Has the patient's cognitive functioning worsened over time such that they can no longer follow the medication regimen?

Regarding cost, the providers need to be aware of the patient's Medicare Part C or D plan, and what type of coverage these plans afford. What is the copayment for generic, formulary, and nonformulary drugs? Is the patient responsible for all drug costs during the Medicare "donut hole" period? (In basic part D plans, patients pay increasing percentages of drug costs up to $7425 per year.[40]) Many Medicare patients, especially the socioeconomically challenged, have limited understanding of the complex Medicare drug benefit. This problem is compounded when the prescriber also does not understand the patient's insurance program.[41] Providers can assist patients by prescribing generic medications that are offered through community pharmacy discount plans ($4 retail pharmacy programs do not bill insurance, thus are not counted toward their Medicare part D deductible) and help patients apply for the medication assistance programs offered by drug manufacturers.

Documentation

A clear, current, and accurate medication list must be available to the patient and all individuals involved in their care. It is particularly important for older adults to bring medication containers for reconciliation by a clinician. Medication adherence may require verification with the pharmacist, caregivers, or family. Transitions in care, such as hospital to subacute nursing facility or home, lead to medication errors because medications may have been deleted or added.[42] It is standard of care to conduct medication reconciliation upon hospital admission and discharge to ensure that the medication list is up to date.

Patient Education

Geriatric patients often have difficulty understanding and retaining provider instructions. "Ask me 3" cues the patient to ask three important questions of their providers to improve health literacy[43]:

1. What is my main problem?
2. What do I need to do?
3. Why is it important for me to do this?

The provider can assess patient grasp of medication instructions by asking the patient to repeat instructions initially and again in 3 minutes (teach-back method).

KEY CONCEPT Addressing deficits in vision, hearing, swallowing, cognition, motor impairment, and health literacy can lead to enhanced medication adherence. Specific drug formulations, such as inhalers, ophthalmic/otic drops, nasal sprays, and subcutaneous injections, will require detailed education and practice. Patients who cannot swallow tablets/capsules need instructions on which tablets are safe to crush and which capsules safe to open and sprinkle on food. Patients and/or caregivers need to be advised of potential ADRs and when to notify the provider.

GERIATRIC PRACTICE SITES

Some say geriatrics has become a nonspecialty due to the aging population. Clinicians with geriatric certification or training practice in nearly all settings of healthcare, primary care to wide spectrums of specialty care and long-term care. A few interprofessional practice sites are highlighted here. See Chapter e3 for information on palliative care practices.

Ambulatory Care Clinic and Home-Based Primary Care

Geriatric clinics are established to provide a multitude of primary care needs specifically tailored to older adults. Home-based primary care is delivered in the home or independent living facility of homebound patients to facilitate independent living. Patients are usually referred by their primary care providers to increase access to services, meet complex care needs due to multimorbidity and polypharmacy, and offer a comprehensive geriatric assessment. It is common for the onset of cognitive impairment to be the catalyst for a referral to geriatric services. Interprofessional team care is the norm in these settings, which benefits patients with multifaceted needs. The interprofessional teams hold regular meetings to discuss care plans of involved patients. Geriatricians, who specialize in elder care, assess and treat physical, medical, emotional, and social needs. Nurses provide medical triage and day-to-day patient care activities such as obtaining vitals, providing wound care, educating and ensuring adherence. Clinical pharmacists focus on medication regimen optimization, evidence-based disease state management, drug-related problem resolution, and patient, caregiver, and healthcare team education about pharmacotherapy and monitoring parameters. Social workers address social and structural needs, in addition to assessing mood and cognitive status, facilitating completion of advance directives and obtaining placement in higher levels of care. Physical/occupational therapists work to improve the patient's functional status, provide fall prevention interventions, and maintain a safe home environment. They provide adaptive equipment such as grab bars, raised toilet seats and shower benches for the bathroom, and cane/walker for ambulation. Dieticians evaluate the patient's nutritional status and educate on proper diet and weight management. Using these team collaborations, specialty settings have been developed including a multidisciplinary geriatric oncology clinic[44] and PACE centers (Programs of All-inclusive Care for the Elderly) that incorporate the interdisciplinary team and adult day healthcare in one center.[45]

Long-Term Care

Long-term care provides support for people who are dependent to varying degrees in ADLs and IADLs, numbering about 9 million people 65+ years in 2008.[46] Care is provided in the patient's home, in community settings such as adult care homes or assisted living facilities, and in nursing homes. Long-term care is expensive, typically several thousand dollars per month. Most care is provided at home by unpaid family members or friends. Medicare covers all or part of the cost of skilled nursing care for a limited-period posthospitalization.[46] Medicare does not cover long-term care. Financing of long-term care comes from patients' and family savings and/or private long-term care insurance. When a patient's assets have been depleted, Medicaid provides basic nursing home care under long-term care insurance coverage.[46] However, this care is heavily discounted, often resulting in economizing such as lower caregiver-to-patient ratios and higher number of patients per room. Nursing homes are highly regulated by state and federal government through the Center for Medicare and Medicaid Services.[47] Initial and continuing certification of the facility depends on periodic state and federal review of the facility. Auditors' ratings are available to consumers in an online Nursing Home Report Card.[47] **Quality indicators** are used by facility administrators and government overseers to identify the following problem areas[48]:

- Use of more than nine medications in a single patient
- Prevalence of indwelling catheters
- Prevalence of antipsychotic, anxiolytic, and hypnotic use
- Use of physical restraints
- Prevalence of depression in patients without antidepressant therapy
- Clinical quality measures such as pressure ulcers
- Moderate daily pain or excruciating pain

Long-term care practices emphasize the interprofessional team approach. The medical director leads regular meetings with care providers. The pharmacist conducts a monthly drug review of

Patient Care Process

1. Collect Information:

- Perform a comprehensive medication reconciliation and review.
- Have the patient bring all medication bottles, including prescriptions, OTC agents, vitamins, supplements, and herbal products.
- Review medical history and physical assessment.
- Ask about allergies/intolerance.
- Inquire about ADRs (Table 1–2).
- Collect adherence information using combination of methods (eg, self-report, refill history, dosage form count, demonstration of nonoral agent use).
- Ask about prevention including vaccinations.
- Collect vital signs and laboratory results.
- Inquire about functional status (Table 1–4).
- Measure cognitive status (Figure 1–2).

2. Assess the Information:

- Identify indication(s) for all medications.
- Assess for potential inappropriate medications using Beers criteria.[24]
- Assess medication doses to determine underdose/overdose.
- Screen for drug–drug/disease/supplement/herbal/food interactions.
- Check against allergies/intolerance.
- Identify ADRs.
- Assess medication adherence (Table 1–3).
- Identify untreated indication/undertreatment (Table 1–1).
- Evaluate vital signs, including pain, and laboratory.
- Assess medication needs based on cognitive and functional status.
- Recognize common problems in older adults (Table 1–5).

3. Develop a Care Plan:

- Discontinue unnecessary medications.
- Tailor regimen: simplify dosing frequency, modify time of dosing based on ADRs and drug interactions, and tie medication taking to individuals' daily routine to improve adherence.
- Develop educational materials, keeping in mind health literacy and cognitive status.
- Create solutions to any functional barriers (eg, non–child-resistant caps, tablet cutters).
- Draft referral plan to target nonpharmacological strategies (eg, diet, physical therapy, behavioral health, integrative health approaches).

4. Implement the Care Plan:

- Educate about medications and disease states in health literacy-sensitive manner.
- Highlight any medication changes and tailored regimen.
- Educate on the use of nonoral agents (eg, inhalers, insulin, ophthalmic/otic drops).
- Provide a medication chart/list to include generic/brand names, indication, dose, directions for use, timing of dose, etc.
- Teach about medication storage, expiration date, and refill status.
- Emphasize adherence and what to do when a dose is missed/forgotten.
- Use medication organizers (eg, pillbox, blister pack) or other adherence aids (eg, alarm, phone reminder) when indicated.
- Implement solutions to any physical/functional barriers (eg, non-childproof caps).
- Refer for nonpharmacological interventions.

5. Follow-up: Monitor and Evaluate:

- Provide a list of future appointments and follow-up.
- Promote self-monitoring (eg, recognize and report ADRs, use blood pressure monitor or glucometer).
- Encourage therapeutic lifestyle modifications including diet, exercise, and smoking cessation.
- Endorse prevention including immunizations, wellness visits, eye examinations, and dental care.
- Formulate a patient-centered and interprofessional team-based follow-up plan to track patient response, adverse events, adherence, and health outcomes.

each patient's medication list.[46] The physician is alerted to medication concerns and approves the patient's orders every 60 days. Such a team approach is vital to coordinate care for the typical frail, complex long-term care patient.

CONCLUSION

By applying the principles of geriatrics, clinicians can better intervene with pharmacotherapy to postpone disease, disability, and mortality, and promote health, functioning, and health-related quality of life. In addition, interprofessional geriatric care improves health outcomes.

List of Abbreviations

ADL	Activities of daily living
ADR	Adverse drug reaction
GABA	γ-Aminobutyric acid
$HgbA_{1c}$	Hemoglobin A_{1c}
IADL	Instrumental activities of daily living
LDL-C	Low-density lipoprotein-cholesterol
MDRD	Modification of diet in renal disease
NSAID	Nonsteroidal anti-inflammatory drug
OTC	Over-the-counter
V_d	Volume of distribution

2 Pediatrics Pharmacotherapy

Hanna Phan, Vinita B. Pai, and Milap C. Nahata

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Define different age groups within the pediatric population.
2. Identify factors that affect selection of safe and effective drug therapy in pediatric patients.
3. Explain general pharmacokinetic and pharmacodynamic differences in pediatric versus adult patients.
4. Develop strategies for appropriate and effective medication administration to infants and young children.
5. Determine approaches to effectively communicate with patients and caregivers about appropriate medication use including expected outcomes, possible adverse effects, and appropriate administration.

INTRODUCTION

Pediatric clinical practice involves care of infants, children, and adolescents with the goal of optimizing health, growth, and development toward adulthood. Clinicians serve as advocates for this unique and vulnerable patient population to optimize their well-being. Care for pediatric patients is relevant in both inpatient and outpatient settings and requires additional considerations with regard to selection and monitoring of drug therapy.

KEY CONCEPT Despite the common misconception of pediatric patients as "smaller adults" where doses are scaled only for their smaller size, there are multiple factors to consider when selecting and providing drug therapy for patients in this specific population. Pediatric patients significantly differ within their age groups and from adults regarding drug administration, psychosocial development, and organ function development, which affect the efficacy and safety of pharmacotherapy.

FUNDAMENTALS OF PEDIATRIC PATIENTS

Classification of Pediatric Patients

Pediatric patients are those younger than 18 years, although some pediatric clinicians may care for patients up to age 21. Unlike an adult patient, whose age is commonly measured in years, a pediatric patient's age can be expressed in days, weeks, months, and years. Patients are classified based on age and may be further described based on other factors, including birth weight and prematurity status (Table 2–1).[1–3]

Growth and Development

Children are monitored for physical, motor, cognitive, and psychosocial development through clinical recognition of timely milestones during routine well-child visits. As a newborn continues to progress to infant, child, and adolescent stages, different variables are monitored to assess growth compared with the general population of similar age and size. Growth charts are used to plot head circumference, weight, length or stature, weight-for-length, and body mass index for a graphical representation of a child's growth compared with the general pediatric population. These markers of growth and development are both age- and gender-dependent; thus, the use of the correct tool for measurement is important. For children younger than 2 years, one should use the World Health Organization's (WHO) growth standards (Figure 2–1).[4] For children 2 years and older, the Centers for Disease Control and Prevention (CDC) Growth Charts (Figure 2–2) are used.[5,6] These tools assess whether a child is meeting the appropriate physical growth milestones, thereby allowing identification of nutritional issues such as poor weight and height gain (eg, failure to thrive). Failure to thrive is defined as inadequate physical growth with weight that falls below the fifth percentile or decreases over time, crossing two or more major percentile lines. **Body habitus** is often evaluated at routine checkups or well-check visits, with definitions of underweight as body mass index (BMI) less than the 5th percentile for age, overweight as BMI between 85th to 94th percentile for age, and obese as BMI greater than 95th percentile.[7] Since these charts were developed based on a general, healthy population, growth charts may not be accurate evaluation of physical development in children with congenital diseases. Growth charts specific to disease states (eg, Turner syndrome or cystic fibrosis) with regard to expected growth trajectory and/or nutritional goals may be utilized by clinicians as part of care.

Differences in Vital Signs

Normal values for heart rate and respiratory rate vary based on age. Normal values for blood pressure vary based on gender and age for all pediatric patients and height percentile for patients older than 1 year. Respiratory rates are also higher in neonates and infants (30–60 breaths/min), decreasing with age to adult rates around 15 years of age (12–20 breaths/min).[8–10] (Table 2–2).

Normal values for blood pressure in pediatric patients are found in various national guidelines and other pediatric diagnostic references. In general, blood pressure increases with age, with average blood pressures of approximately 70/50 in neonates, increasing throughout childhood to approximately

Table 2–1

Pediatric Age Groups, Age Terminology, and Weight Classification[1-3]

Age Group	Age
Neonate	≤ 28 days (4 weeks) of life
Infant	29 days to < 12 months
Child	1–12 years
Adolescent	13–17 years (most common definition)
Age Terminology	**Definition**
GA	Age from date of mother's first day of last menstrual period to date of birth
Full term	Describes infants born at 37-weeks' gestation or greater
Premature	Describes infants born before 37-weeks' gestation
Small for GA	Neonates with birth weight below the 10th percentile among neonates of the same GA
Large for GA	Neonates with birth weight above the 90th percentile among neonates of the same GA
Chronological or postnatal age	Age from birth to present, measured in days, weeks, months, or years
Corrected or adjusted age	May be used to describe the age of a premature child up to 3 years of age: Corrected age = Chronological age in months – [(40 – GA at birth in weeks) × 1 month ÷ 4 weeks]. For example, if a former 29-week GA child is now 10 months old chronologically, his corrected age is approximately 7 months: 10 months – [(40–29 weeks) × 1 month ÷ 4 weeks] = 7.25 months
Weight Classification	**Definition**
LBW infant	Premature infant with birth weight between 1500 and 2500 g
VLBW infant	Premature infant with birth weight 1000 g to < 1500 g
ELBW infant	Premature infant with birth weight < 1000 g

ELBW, extremely low birth weight; GA, gestational age; LBW, low birth weight; VLBW, very low birth weight.

110/65 in adolescents.[8,9] Heart rates are highest in neonates and infants, ranging from 90 to 205 beats/min and decrease with age, reaching adult rates (60–100 beats/min) around 10 years of age.[8-10]

Another vital sign commonly monitored in children by their caregivers is body temperature, especially when they seem "warm to the touch." The American Academy of Pediatrics (AAP) supports the use of rectal measurement of body temperature as it is most accurate when appropriate technique is used; however, for other routes, the AAP offers an age-specific guideline on routes of measurement.[11,12] For patients younger than 3 months, rectal measurement using a digital thermometer is recommended. For those 3 months and older, use of temporal artery is an available option. The use of tympanic measurement is appropriate for patients who are 6 months and older. Axillary measurement is not considered first-line in all these age groups, as proper technique is important for accurate measurement, and other accurate options are available. For patients age 4 or 5 years and older, oral measurement is reliable. Generally, fever is defined as temperature 100.4°F (38°C) and greater measured via rectal, otic, or temporal artery technique. For oral and axillary measurement, fever is defined as temperature 100°F (37.8°C) and 99°F (37.2°C) and greater, respectively.[12] Low-grade fevers range from 100° to 102°F (37.8°–38.9°C), with antipyretic treatment (eg, acetaminophen) considered by most pediatricians in cases of temperature greater than 38.3°C (101°F, any measurement route) accompanied by patient discomfort. Formal definition of fever, like other vital signs, is also age dependent, with a lower temperature threshold for neonates (38°C or 100.4°F) and infants (38.2°C or 100.7°F).[11,12]

Pain assessment is more challenging in neonate, infants, and young children due to their inability to communicate symptoms. Indicators of possible pain include physiological changes, such as increased heart rate, respiratory rate, and blood pressure, decreased oxygen saturation, as well as behavior changes such as prolonged, high-pitched crying, and facial expressions.[13] Such indicators are used in validated assessment scales, such as the FACES scale and FLACC behavioral tools.[14,15] The FACES scale is a visual analog scale, where patients age 3 years and older can select a face that best associates with their current pain level.[14] The FLACC scale, intended for patients of age 2 months to 7 years or those patients unable to communicate pain, is a scale in which a clinician scores a patient based on series of criteria (facial expression, leg movement, activity, crying, and consolability).[15]

Fluid Requirements

Fluid requirement and balance are important to monitor in pediatric patients, especially in premature neonates and infants. Maintenance fluid requirement can be calculated based on body surface area for patients greater than 10 kg, with a range of 1500 to 2000 mL/m^2 per day. However, a weight-based method of determining normal maintenance fluid requirement for children is often used (Table 2–3).[16]

Patient Encounter Part 1

HM is a 33-week GA premature newborn boy weighing 1.6 kg (3.5 lb), length 39 cm (15.4 in), born to a 25-year-old woman today. HM is currently admitted to the neonatal intensive care unit.

What is HM's weight classification as a neonate?

Calculate HM's corrected age for 6 months from today.

How much maintenance fluid per day (mL) and overall rate (mL/hour), is appropriate at this time for HM?

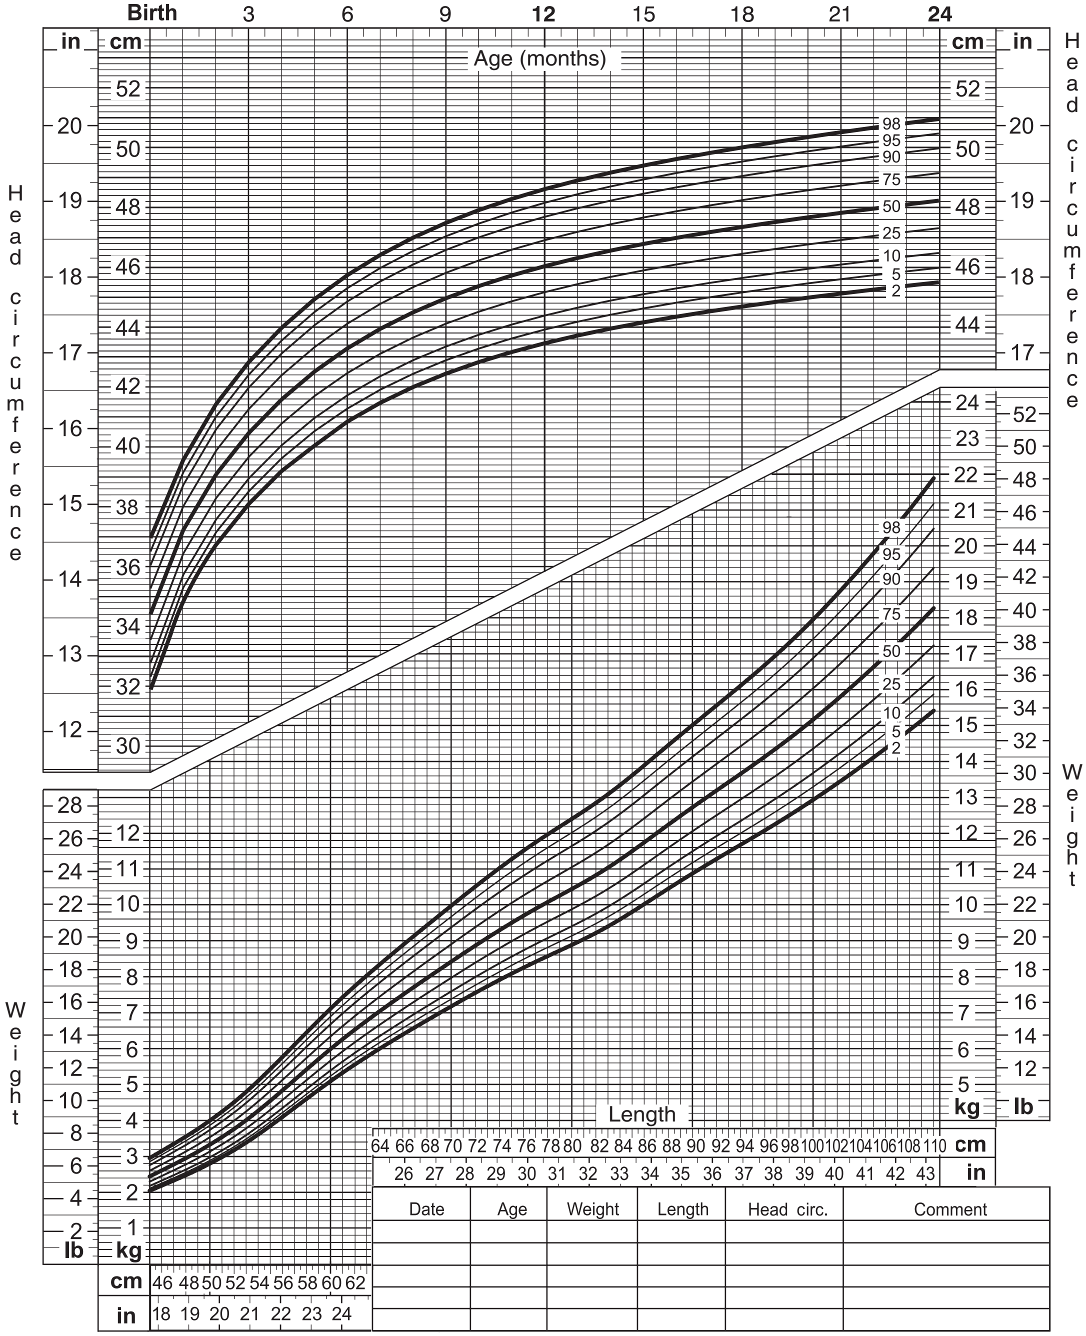

FIGURE 2–1. Example of WHO growth chart of girls, birth to 24 months: Head circumference-for-age and weight-for-length percentile, 2000. (From Centers for Disease Control and Prevention from the WHO Growth Standards. World Health Organization [WHO] Growth Standards are recommended for use in the U.S. for infants and children 0 to 2 years of age. [updated 2010 Sept 9; cited 2020 Nov 16]. Available from: http://www.cdc.gov/growthcharts/who_charts.htm.)

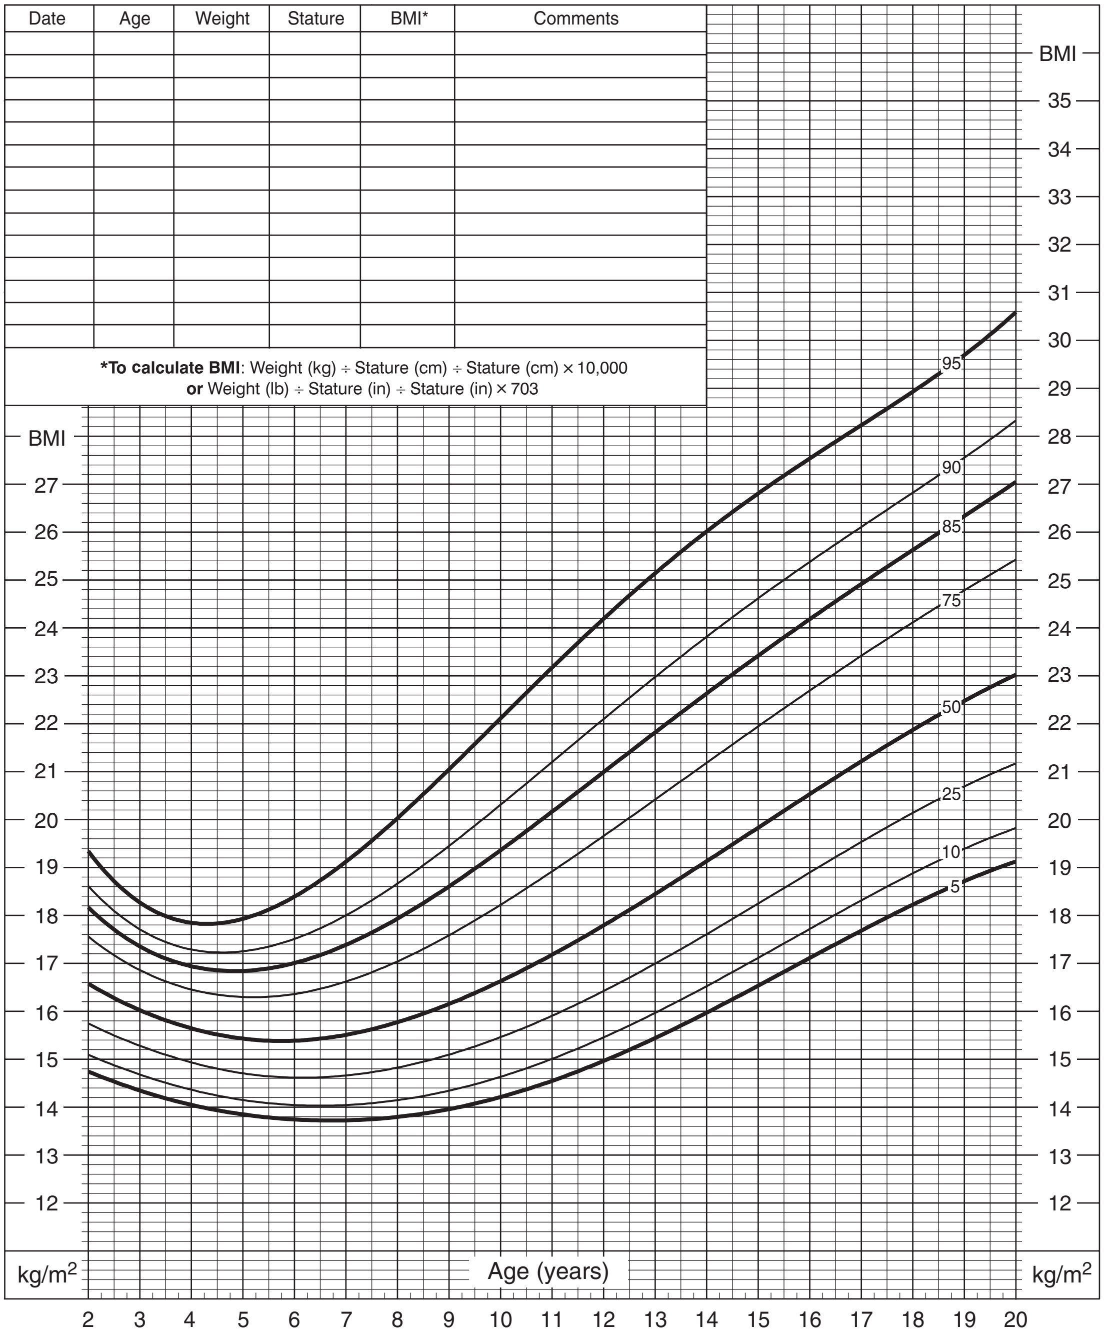
EFFECTS OF PHARMACOKINETIC AND PHARMACODYNAMIC DIFFERENCES ON DRUG THERAPY

Drug selection strategy may be similar or different depending on age and disease state, as a result of differences in pathophysiology of certain diseases and pharmacokinetic and pharmacodynamic parameters among pediatric and adult patients. It is noteworthy that pediatric patients may require different medications from those used in adults affected by certain diseases. For example, phenobarbital is commonly used for treatment of neonatal seizures, but seldom used for seizure treatment in adults, due to differences in seizure etiology and availability of extensive data regarding its use in neonates compared with newer antiepileptic medications. There also exist commonalties between pediatric and adult patients, such as therapeutic serum drug concentrations required to treat certain diseases. For example, target vancomycin serum concentrations needed for treatment of a given infection are often similar between children and adults. Appropriate selection and dosing of drug therapy for a pediatric patient depends on a number of specific factors, such as



***To calculate BMI**: Weight (kg) ÷ Stature (cm) ÷ Stature (cm) × 10,000
or Weight (lb) ÷ Stature (in) ÷ Stature (in) × 703

FIGURE 2–2. Example of CDC growth chart of boys, 2 to 20 years: Body mass index for age percentile, 2000. (From Centers for Disease Control and Prevention. CDC Growth Charts. [updated 2016 Dec 7; cited 2020 Nov 16]. Available from: https://www.cdc.gov/growthcharts/cdc_charts.htm.)

age, weight, height, disease, comorbidities, developmental pharmacokinetics, and available drug dosage forms. Pediatric drug doses are often calculated based on body weight (eg, mg/kg/dose) compared with uniform dosing (eg, mg/day or mg/dose) for adult patients. Thus, accurate weight should be available while prescribing or dispensing medications for this patient population. Pediatric doses may exceed adult doses by body weight for certain medications due to differences in pharmacokinetics and pharmacodynamics; hence, the use of pediatric drug dosing guides is recommended.

KEY CONCEPT Due to multiple differences, including age-dependent development of organ function in pediatric patients, the pharmacokinetics, efficacy, and safety of drugs often differ between pediatric and adult patients; thus, pediatric dosing should not be calculated based on a single factor of difference. Equations proposed to estimate pediatric doses based on adjusted age or weight, such as the Clark's, Fried's, or Young's rule, should not be routinely used to calculate pediatric doses because they account for only one factor of difference (eg, age or weight) and lack integration of the effect of growth and development on drug pharmacokinetics and pharmacodynamics in this population. For **off-label** medication dosing, when no alternative treatment is available and limited dosage guidelines have been published, clinicians

Table 2–2

Normal Ranges of Vital Signs (Heart Rate, Respiratory Rate, Blood Pressure) by Age Group[8-10]

Age Group	Heart Rate (Sleep)[a]	Heart Rate (Awake)[a]	Respiratory Rate[b]	Systolic Blood Pressure[c,d]	Diastolic Blood Pressure[c,d]
Neonate (< 28 days)	90–160	100–205	30–60	67–84	31–45
Infant (1–12 months)	90–160	100–190	30–53	72–104	37–56
Toddler (1–2 years)	80–120	98–140	22–37	86–106	42–63
Preschool (3–5 years)	65–100	80–120	20–28	89–112	46–72
School–Age (6–11 years)	58–90	75–118	18–25	97–115	57–76
Adolescent (12–15 years)	50–90	60–100	12–20	102–131	61–83

Note: prematurity can affect values. Values listed are average ranges.

[a] Beats per minute

[b] Breaths per minute

[c] mm Hg

[d] Exact normal values will vary based on age, height, and sex.

may estimate a pediatric dose based on body surface area ratio.

$$\textbf{Approximate pediatric dose} = \textbf{Adult dose} \times [\textbf{BSA (in m}^2\textbf{)} \div \textbf{1.73 m}^2]$$

Limitations for this dose-estimating approach include the need for the patient to be of normal height and weight for age and lack of incorporation of exact pharmacokinetic differences regarding each medication.[17]

Absorption

Oral absorption may be different in premature infants and neonates due to differences in gastric acid secretion and pancreatic and biliary function. Neonates and infants have increased gastric pH (eg, pH 6–8) due to lower gastric acid output by body weight, reaching adult values by approximately 2 years of age.[18] Low gastric acid secretion can result in increased serum concentrations of weak bases and acid-labile medications, such as penicillin, and decreased serum concentrations of weak acid medications, such as phenobarbital, due to increased ionization. Additionally, gastric emptying time and intestinal transit time are delayed in premature infants, increasing drug contact time with the gastrointestinal (GI) mucosa and drug absorption.[18,19] Diseases, such as gastroesophageal reflux, respiratory distress syndrome, and congenital heart disease may further delay gastric emptying time. Pancreatic exocrine and biliary function are also reduced in newborns, with about 50% less secretion of amylase and lipase than adults, reaching adult values as early as the end of the first year and as late as 5 years of age. Deficiency in pancreatic secretions and bile salts in newborns can decrease bioavailability of prodrug esters, such as erythromycin, which requires solubilization or intraluminal hydrolysis.[18] Due to limited data on oral bioavailability of medications in infants and children for newer agents, some drug dosing recommendations may be extrapolated from adult safety and efficacy studies and case reports.

Table 2–3

Maintenance Fluid Calculations by Body Weight[16]

Patient Body Weight	Maintenance Fluid Requirement
< 10 kg	100 mL/kg/day
11–20 kg	1000 mL + 50 mL/kg over 10 kg
> 20 kg	1500 mL + 20 mL/kg over 20 kg

Reproduced with permission from Holiday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. Pediatric. 1957;19(5):823–832, by the AAP.

Topical or percutaneous absorption in neonates and infants is increased due to a thinner stratum corneum, increased cutaneous perfusion, and greater body surface-to-weight ratio. Hence, application of topical medications, such as corticosteroids, should be limited to the smallest amount possible. Limiting exposure can help minimize serum concentrations of active as well as inactive drugs, yet potentially harmful additives such as propylene glycol.

Intramuscular absorption in premature and full-term infants can be erratic due to variable perfusion, poor muscle contraction, and decreased muscle mass compared with older patients.[18] Intramuscular administration may be appropriate for some medications; however, use of this route of administration can be painful and is usually reserved when other routes are not accessible, for example, initial intravenous (IV) doses of ampicillin and gentamicin for neonatal sepsis.

Intrapulmonary absorption and distribution are largely due to anatomical size of the lungs and drug delivery. The smaller airways of neonates and lower inspiratory volume can result in greater drug concentrations in the upper and central airways. Particle size, breathing pattern, and route (eg, oral vs nasal) can impact the amount of drug absorbed and should be considered when utilizing pulmonary drug delivery devices such as nebulizers or inhalers.[20]

Rectal absorption can also be erratic due to increased peristalsis causing early expulsion of the dosage form in younger patients (ie, infants and young children).[21] Thus it is not commonly recommended if other routes are available. This route is useful in cases of severe nausea and vomiting or seizure activity. For medications that undergo extensive first-pass metabolism, bioavailability increases as the blood supply bypasses the liver from the lower rectum directly to the inferior vena cava. Availability of rectal dosage forms varies and use of oral medications or other dosage forms rectally is based on limited studies and case reports. High osmolality and large volume of a liquid dosage form may present as a limitation to using an oral liquid formulation for rectal use.

Volume of Distribution

In pediatric patients, apparent volume of distribution (V_d) is normalized based on body weight and expressed as L/kg. Extracellular fluid and total body water per kilogram of body weight are increased in neonates and infants, resulting in higher V_d for water-soluble drugs, such as aminoglycosides, and decrease with age. Therefore, neonates and infants often require higher individual doses by weight (mg/kg) than older children and adolescents to achieve the same therapeutic serum concentrations.[18] Fluid overload and diuresis can affect V_d and should be assessed for when evaluating drug dosing and pharmacokinetics. The use of extracorporeal membrane oxygenation (ECMO) can further affect V_d of medications in patients due to the added volume from the circuit and potential fluid changes (eg, edema) while on the circuit. Thus, the use of additional clinical and, when available, therapeutic drug monitoring is recommended for those patients requiring ECMO.[22] Neonates and infants have a lower normal range for serum albumin (2–4 g/dL, 20–40 g/L), reaching adult levels after 1 year of age. Highly protein-bound drugs, such as sulfamethoxazole-trimethoprim and ceftriaxone, are not typically used in neonates due to theoretical concern for bilirubin displacement. This displacement may result in a complication known as **kernicterus**, from bilirubin encephalopathy.[23]

Although neonates have lower body adipose composition compared with older children and adults, their overall V_d for many lipid-soluble drugs (eg, lorazepam) is similar to infants and adults. Some medications (eg, vancomycin, phenobarbital) may also reach higher concentrations in the central nervous system (CNS) of neonates due to an immature blood–brain barrier.[24]

Metabolism

Hepatic drug metabolism is slower at birth in full-term infants compared with adolescents and adults, with further delay in premature neonates. Phase 1 reactions and enzymes, such as oxidation and alcohol dehydrogenase, are impaired in premature neonates and infants and do not fully develop until later childhood or adolescence. Accordingly, the use of products containing ethanol (eg, elixirs) can cause toxicities such as respiratory depression and thus should be avoided, whenever possible, in neonates and infants. Age at which cytochrome P450 isoenzymes (eg, CYP3A4, CYP2C19) activity reaches adult values varies, depending on the isoenzyme, with delayed development in premature infants. Increased dose requirements by body weight (eg, mg/kg) for some hepatically metabolized medications (eg, phenytoin, valproic acid) in young children (ie, ages 2–4 years) is theorized due to an increased liver mass to body mass ratio.[23] This increase in metabolism slows to adult levels as the child goes through puberty into adulthood.[18]

Among phase 2 reactions, sulfate conjugation by sulfotransferases is well developed at birth in term infants. Glucuronidation by the uridine diphosphate glucuronosyltransferases, in contrast, is immature in neonates and infants, reaching adult values at 2 to 4 years of age. In neonates, this deficiency results in adverse effects including cyanosis, ash gray color of the skin, limp body tone, and hypotension, also known as "gray baby syndrome" with use of chloramphenicol.[18] Products containing benzyl alcohol or benzoic acid should be avoided in neonates due to immature glycine conjugation, resulting in accumulation of benzoic acid. This accumulation can lead to "gasping syndrome," which includes respiratory depression, metabolic acidosis, hypotension, seizures or convulsions, and gasping respirations. Similarly, due to limited metabolic capacity, propylene glycol, a solvent found in some dosage forms, should be avoided, as toxicity results in serum hyperosmolality, seizures, and respiratory distress.[25] Acetylation via *N*-acetyltransferase reaches adult maturation at around 1 year of life; however, overall activity is dependent on genotypic variability.[18]

Elimination

Nephrogenesis completes at approximately 36 weeks gestation; thus, premature neonates and infants have compromised glomerular and tubular function that may correlate with a glomerular filtration rate (GFR). This reduction in GFR affects renal drug clearance, thereby necessitating longer dosing intervals for renally cleared medications, such as vancomycin, to prevent accumulation. GFR increases with age and exceeds adult values in early childhood, after which there is a gradual decline to approximate adult value during adolescence. For example, vancomycin is often given every 18 to 24 hours in a low-birth-weight (LBW) premature neonate, every 6 hours in children with normal renal function, and every 8 to 12 hours in adult patients with normal renal function. Children with cystic fibrosis also present with greater renal clearance of drugs such as aminoglycosides, compared with children without the disease, requiring higher doses by weight and more frequent dosing intervals.[26]

Creatinine clearance is used as a surrogate marker for GFR; however, there are equations available to estimate GFR in the pediatric population. Pediatric GFR is often calculated to mL/min/1.73 m^2. The Cockroft-Gault, Jelliffe, Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, or Modification of Diet in Renal Disease (MDRD) equations for estimating creatinine clearance or GFR in adults should not be used for evaluating patients younger than 18 years. This is due to potential for significant overestimation of GFR and/or lack of validation of these equations in pediatric age ranges, even adolescents. For example, past attempts for proposed application of equations, such as Cockroft-Gault, demonstrated that lack of agreement with measured GFR (via renal scan) in adolescents as young as 13 years of age.[27] The Schwartz's equation was previously used method of estimating pediatric GFR from infancy up to 21 years of age (**Figure 2–3**). This equation uses patient length (cm), serum creatinine (mg/dL) (or µmol/L × 0.0113), and a constant, *k*, which depends on age (including low-birth-weight status for infants).[28] This "original" Schwartz equation is no longer used by many clinicians, due to a change in measurement of serum creatinine methods with calibration traceable to isotope dilution mass spectrometry (IDMS), invalidating the original

"Original Schwartz" Equation

$$GFR = kL/SCr$$

Age	K
Low birth weight < 1 year	0.33
Full term < 1 year	0.45
1–12 years	0.55
13–21 years (female)	0.55
13–21 years (male)	0.70

K = proportionality constant
L = length in cm
SCr = serum creatinine in mg/dL
GFR = estimated glomerular filtration rate in mL/min/1.73 m^2

FIGURE 2–3. "Original" Schwartz equation for estimation of glomerular filtration rate (GFR)in pediatric patients up to 21 years of age. (From Schwartz GJ, Brion LP, Spitzer A. The use of plasma creatinine concentration for estimating glomerular filtration rate in infants, children, and adolescents. Pediatr Clin North Am. 1987;34(3):571–590.)

“Bedside Schwartz” Equation

$$GFR = [0.413 \times h]/SCr$$

H = height in cm
SCr = serum creatinine (in mg/dL)
GFR = estimated glomerular filtration rate in mL/min/1.73 m^2

FIGURE 2–4. Bedside Schwartz equation for estimation of glomerular filtration rate (GFR)in pediatric patients ages 1 to 18 years old. (From Staples A, LeBlong R, Watkins CW, Brandt J. Validation of the revised Schwartz estimating equation in a predominantly non-CKD population. Pediatr Nephrol. 2010;25:2321–2326.)

equation’s clinical application and can overestimate GFR by up to 40%.[27–31] The preferred method to estimate GFR in children (ages 1–18 years) is the “bedside” Schwartz as it was devised for use with creatinine methods traceable to IDMS (Figure 2–4).[29–31]

Urine output is also a parameter used to assess renal function in pediatric patients. Infants and children with acute kidney injury are likely to present with oliguria or anuria with urine output less than 1 mL/kg/hour.

SPECIFIC CONSIDERATIONS IN DRUG THERAPY

In addition to differences in pharmacokinetics and pharmacodynamic parameters, other factors, including dosage formulations, medication administration techniques, and parent/caregiver education, should be considered when selecting drug therapy.

Off-Label Medication Use

Currently, there is a lack of pediatric dosing, safety, and efficacy information; thus, many drugs remain off-label for children.[32] Off-label use of medications occur in both outpatient and inpatient settings. Off-label use of medication is the use of a drug outside of its approved labeled indication. This includes the use of a medication in the treatment of illnesses not listed on the manufacturer’s package insert, use outside the licensed age range, dosing outside those recommended, or use of a different route of administration.[32] **KEY CONCEPT** It is appropriate to use a drug off-label when no alternatives are available; however, clinicians should refer to published studies and case reports for available safety, efficacy, and dosing information. Food and Drug Administration (FDA) regulatory changes provide incentives for a pharmaceutical manufacturer to study and market new drugs for pediatric patients. However, such incentives are not available for generic drugs.

Patient Encounter Part 2

RG is a 1-week-old (weight 3.5 kg [7.7 lb], length 50 cm (19.7 in), no known drug or food allergies), full-term newborn male child admitted to the NICU now presenting lethargy, poor oral intake, and temperature instability. A neonatal sepsis and meningitis rule-out is started. Blood samples, cerebral spinal fluid, and urine were collected for Gram stain and culture, still pending results. Other laboratory results (complete blood count, complete metabolic panel) are still pending. The team requests the consultation regarding empiric antibiotic selection.

The medical resident asks you whether ceftriaxone (highly protein binding) or cefotaxime (low protein binding) should be used as part of the antibiotic regimen to treat RG. Which is the most appropriate and why?

Routes of Administration and Drug Formulations

Depending on age, disease, and disease severity, different routes of administration may be considered. The rectal route of administration is reserved for cases where oral administration is not possible and IV route is not necessary. Topical administration is often used for treatment of dermatologic ailments. Transdermal routes are not often used due to limited product availability. The injectable route of administration is used in patients with severe illnesses or when other routes of administration are not possible. As done with adult patients, IV compatibility and access should be evaluated when giving parenteral medications. Dilution of parenteral medications may be necessary to measure smaller doses for neonates. However, a higher concentration of parenteral medications may be necessary for patients with fluid restrictions, such as premature infants and patients with cardiac anomalies and/or renal disease. Appropriate stability and diluent selection data should be obtained from the literature.

When oral drug therapy is needed, one must also consider the dosage form availability and child’s ability to swallow a solid dosage form. Children younger than 6 years are often not able to swallow oral tablets or capsules and may require oral liquid formulations. Not all oral medications, especially those unapproved for use in infants and children, have a commercially available liquid dosage form. Use of a liquid formulation compounded from a solid oral dosage form is an option when compounding and stability data are available. Factors such as drug stability, suspendability, dose uniformity, and palatability should be considered when compounding a liquid formulation.[33] Commonly used suspending agents include methylcellulose and carboxymethylcellulose (eg, Ora-Plus). Palatability of a liquid formulation can be enhanced by using simple syrup or OraSweet. If no dietary contraindications or interactions exist, doses can be mixed with food items such as pudding, fruit-flavored gelatin, chocolate syrup, applesauce, or other fruit puree immediately before administration of individual doses. There may be instances when clinicians may elect to prescribe tablets or capsules that are to be crushed or opened, respectively, and mixed in soft foods. This should be limited to instances when a commercial or compounded liquid dosage form is not appropriate. Additionally, it is important in this scenario, to avoid use of sustained or extended formulations of tablets or capsules. Use should also be limited to wide therapeutic index medications (eg, β-lactam antibiotics) as they have a wide margin of safety, and dose rounding to a certain extent (eg, 10%) is likely feasible to fit an available tablet or capsule strength. To help with palatability of oral medication, some clinicians pair bitter tasting medications (eg, clindamycin) with chocolate flavoring and metallic tasting medications (eg, ferrous sulfate drops) with fruit (eg, citrus) flavoring. Honey, although capable of masking unpleasant taste of medication, may contain spores of *Clostridium botulinum* and should not be given to infants younger than 1 year due to increased risk for developing botulism. Most hospitals caring for pediatric patients compound formulations in their inpatient pharmacy. Limited accessibility to compounded oral liquids in community pharmacies poses a greater challenge. A list of community pharmacies with compounding capabilities should be maintained and provided to the parents and caregivers before discharge from the hospital.

Common Errors in Pediatric Drug Therapy

Prevention of errors in pediatric drug therapy begins with identification of possible sources. Unfortunately, medication errors are common in pediatrics with up to 27% of all pediatric medication orders resulting in an error.[34] Off-label use of medications increases risk of medication error and has been attributed to difference in frequency of errors compared with adults. One of the most common reasons for medication errors in this specialized population is incorrect dosing such as calculation error.[35] **KEY CONCEPT** Medication errors among pediatric patients are possible due to differences in dose calculation and preparation; it is important to identify potential errors through careful review of orders, calculations, dispensing, and administration of drug therapy to infants and children. It is crucial to verify accurate weight, height, and age for dosing calculations and dispensing of prescriptions because pediatric patients are a vulnerable population for medication error. Consistent units of measurements in reporting patient variables, such as weight (kg) and height (cm), should be used. Dosing units such as mg/kg, mcg/kg, mEq/kg, mmol/kg, or units/kg should also be used accurately. Given the age-related differences in metabolism of additives, such as propylene glycol and benzyl alcohol, careful consideration should be given to the active and inactive ingredients when selecting a formulation.

Decimal errors, including trailing zeroes (eg, 1.0 mg misread as 10 mg) and missing leading zeroes (eg, .5 mg misread as 5 mg) in drug dosing or body weight documentation, are possible, resulting in several-fold overdosing. Strength or concentration of drug should also be clearly communicated by the clinician in prescription orders. Similarly, labels that look alike may lead to drug therapy errors (eg, mistaking a vial of heparin for insulin). Dosing errors of combination drug products can be prevented by using the right component for dose calculation (eg, dose of sulfamethoxazole-trimethoprim is calculated based on the trimethoprim component).

Use of standardized concentrations and programmable infusion pumps, such as smart pumps with built-in libraries, is encouraged to minimize errors with parenteral medications, especially those for continuous infusions such as inotropes. Electronic health records (EMR) with clinical decision support systems and barcoding technology, with ability for dose range checks by weight for pediatric medication orders and accurate matching of correct ordered medication to patient, respectively, have decreased medication errors.[34]

Prevention of medication errors is a joint effort between healthcare professionals, patients, and parents/caregivers. Obtaining a complete medication history, including over-the-counter (OTC) and complementary and alternative medicines (CAMs), simplification of medication regimen, clinician awareness for potential errors, and appropriate patient/parent/caregiver education on measurement and administration of medications, are essential in preventing medication errors.

Complementary/Alternative and Over-the-Counter Medication Use

Between 30% and 70% of children with a chronic illness (eg, asthma, attention deficit hyperactivity disorder, autism, cancer) or disability use CAMs. CAMs can include mind-body therapy (eg, imagery, hypnosis), energy field therapies (eg, acupuncture, acupressure), massage, antioxidants (eg, vitamins C and E), herbs (eg, St. John's wort, kava, ginger, valerian), prayer, immune modulators (eg, echinacea), or other folk/home remedies. It is important to encourage communication about CAM use, including interdisciplinary discussion between CAM providers and pediatric healthcare providers.[36] It is critical to appreciate that there are limited data establishing efficacy of various CAM therapies in children. For example, colic is a condition of unclear etiology in which an infant cries inconsolably for over a few hours in a 24-hour period, usually during the same time of day. Symptoms of excessive crying usually improve by the third month of life and often resolve by 9 months of age. No medication has been approved by the FDA for colic; however, parents may be advised by family and friends to use products that may have harmful additive ingredients. Gripe water is an oral solution containing a combination of ingredients, such as chamomile and sodium bicarbonate, and is not regulated by the FDA. Some gripe water products may contain alcohol, which is not recommended for infants due to their limited metabolism ability (ie, alcohol dehydrogenase). Further, some CAM products (eg, St. John's wort) can interact with prescription drugs and produce undesired outcomes. It is important to assess OTC product use in pediatric patients. For example, treatment of the common cold in children is similar to adults, including symptom control with adequate fluid intake, rest, use of saline nasal spray, and acetaminophen (10–15 mg/kg/dose every 6–8 hours) or ibuprofen (4–10 mg/kg/dose every 8 hours) for relief of discomfort and fever. Other products, such as a topical vapor rub or oral honey, have demonstrated some potential for alleviation of symptoms, such as cough, based on survey studies of parents for children of 2 years and older.[37,38] Unlike adults, symptomatic relief through the use of pharmacologic agents, such as OTC combination cold remedies, is not recommended for pediatric patients younger than 4 years. Currently, the FDA does not recommend the use of OTC cough and cold medications (eg, diphenhydramine and dextromethorphan) in children younger than 2 years; however, the Consumer Healthcare Products Association, with the support of the FDA, has voluntarily changed product labeling of OTC cough and cold medications to state "do not use in children under 4 years of age." This is due to increased risk for adverse effects (eg, excessive sedation, respiratory depression) and no documented benefit in relieving symptoms. It has also been noted that these medications may be less effective in children younger than 6 years compared with older children and adults.[39,40] Also noteworthy is the potential for medication error with use of OTC products in older children, such as cold medications containing diphenhydramine and acetaminophen. A parent/caregiver may inadvertently overdose a child on one active ingredient, such as acetaminophen, by administering acetaminophen suspension for fever and an acetaminophen-containing combination product for cold symptoms. The use of aspirin in patients younger than 18 years with viral infections is not recommended due to the risk of Reye syndrome. Signs or symptoms of Reye syndrome, usually appearing several days after start of a viral infection, are relatively nonspecific, including diarrhea, persistent vomiting, increased respiratory rate, increasing lethargy, and seizure. While making an appropriate recommendation for an OTC product for a pediatric patient, the parent/caregiver should always be referred to their pediatrician for further advice and evaluation when severity of illness is a concern.

Clinicians should respect parents'/caregivers' beliefs in the use of CAM and OTC products and encourage open discussion with the intention of providing information regarding their risks and benefits to achieve desired health outcomes as well as optimize medication safety.

Medication Administration to Pediatric Patients and Caregiver Education

Considering the challenges in cooperation from infants and younger children, medication administration can become a difficult task for any parent or caregiver. One should also consider factors that may affect adherence to prescribed therapy including caregiver's and/or patient's personal beliefs, socioeconomic limitation(s), and fear of adverse drug effects. One common factor to consider is ease of measurement and administration when selecting and dosing pediatric drug therapy. Clinicians should check concentrations of available products and round doses to a measurable amount. For example, if a patient were to receive an oral formulation, such as amoxicillin 400 mg/5 mL suspension, and the dose was calculated to be 4.9 mL, the dose should be rounded to 5 mL for ease of administration. Rounding the dose by 10% to the closest easily measurable liquid amount or available tablet/capsule strength is commonly practiced for most medications (eg, antibiotics); however, drugs with narrow therapeutic indices (eg, anticoagulants) are exceptions to this guideline.

The means or devices for measuring and administering medications should also be closely considered. Special measuring devices as well as clear and complete education about their use are essential. Oral syringes are accurate and offered at most community pharmacies for the measurement of oral liquid medications. Studies have demonstrated less error in dose measurement using an oral syringe compared to other devices (eg, dosing cup, dropper, dosing spoon) and that in addition to appropriate device caregiver health literacy contributes to potential for medication dose measurement error.[41] Due to inconsistencies and risk for possible inaccuracy of measuring smaller doses, dosing or measuring spoons, oral droppers, and medicine cups are not recommended for measuring doses for infants and young children. Household dining or measuring spoons are not accurate or consistent and should not be used for the administration of oral liquids. Additionally, consistency in dosing units used for liquid formulation (eg, milliliters instead of teaspoons or ounces) is necessary to minimize further medication dosing errors.[42] Individuals in supervision of infants and children attending daycare and schools should also be educated about medication administration. Guidelines with regard to medication use in school settings are available.[43–45]

KEY CONCEPT Comprehensive and clear parent/caregiver education improves medication adherence, safety, and therapeutic outcomes and is essential in care of infants and young children. Information about the drug, including appropriate and safe storage away from children, possible drug interactions, duration of therapy, importance of adherence, possible adverse effects, and expected therapeutic outcomes should be provided. Parent/caregiver education is important in both inpatient and outpatient care settings and should be reviewed at each point of care.

Because parents/caregivers are often sole providers of home care for ill children, it is important to demonstrate appropriate dose preparation and administration techniques to the caregivers before medication dispensing. First, a child should be calm for successful dose administration. Yet, calming a child is often a challenge during many methods of administration (eg, otic, ophthalmic, rectal). Parents/caregivers should explain the process in a simple and understandable form to the child because this may decrease the child's potential anxiety. In addition, it is also recommended to distract younger children using a favorite item such as toy or to reward cooperative or "good" behavior during medication administration. Helpful tips regarding administration of selected dosage forms in pediatric patients are listed in Table 2–4.[46]

Table 2–4

Helpful Tips for Medication Administration for Selected Dosage Forms[46]

Dosage Form	Recommendations
Ophthalmic drops or ointment	• Wash hands thoroughly prior to administration • Position child laying down in supine position • Avoid contact of applicator tip to surfaces, including the eye • Drops should be placed in the pocket of the lower eyelid • Ointment strip should be placed along the pocket of the lower eyelid

Otic drops	• Wash hands thoroughly prior to administration
	• Position child laying down in prone position
	• Tilt head to expose treated ear, gently pull outer ear outward, then due to age-dependent change in angle of eustachian tube:
	  • If child < 3 years of age, gently pull downward and back; apply drops
	  • If child is > 3 years of age, gently pull upward and back; apply drops

Nasal drops	• Wash hands thoroughly prior to administration • Position child laying down in supine position • Slightly tilt head back; place drops in nostril(s) • Remain in position for appropriate distribution of medication
Rectal suppository	• Similar to adult administration; challenging route for administration • For younger patients (ie, < 3 years), a smaller finger (eg, pinky finger) should be used to insert suppository
Metered-dose inhalers	• Use a spacer • For younger children, use one with a mask, be sure the mask is secured/placed closely up against the child's face, avoiding gaps between face and mask and creating a seal to ensure medication delivery • Child should take slow breaths in with each dose • Wait at least 1 minute between doses

Patient Encounter Part 3

DD is a 13-year-old adolescent boy who is brought to the clinic with a weeklong history of productive cough, rhinorrhea, and congestion. The child's temperature last night was 39°C (102.2°F) by electronic axial thermometer. Mom reports to have given the child several doses of acetaminophen, but symptoms did not improve and thus she brought him to be seen. Patient has history of allergic rhinitis and eczema. The pediatrician diagnoses DD with community-acquired pneumonia requiring antibiotic treatment and asks you to develop a treatment care plan for DD including use of cefdinir 14 mg/kg/dose by mouth divided twice a day for 10 days.

What additional information would you need to develop an appropriate treatment care plan for DD?

Mom asks you if acetaminophen was the right choice for DD's fever and pain and if other options such as aspirin could be used instead. What would you recommend for pain and fever for DD? Why?

The medical assistant provides you DD's weight as 85.8 lb (39 kg). Mom states that DD would prefer a liquid form as he is still working on swallowing pills. Cefdinir is available as a 125 mg/5 mL or 250 mg /5 mL suspension. What is the most appropriate dosage strength and calculated dose of cefdinir for DD?

Two days later, Mom calls the clinic stating that DD did not like the taste of cefdinir and would like to change to a capsule or tablet. Cefdinir comes as a 300-mg capsule. Explain whether or not this change is appropriate.

Accidental Ingestion in Pediatric Patients

Pediatric accidental ingestions most often occur in the home. Various factors account for incidence of accidental ingestions in young children, including hand-to-mouth behaviors as well as new and increased mobility resulting in easier access areas where harmful substances are stored (eg, medication cabinets). Indeed, caregivers are encouraged to use "child-safe" devices to lock closets and cabinets to reduce risk of accidental ingestions; however, this is not a substitute for appropriate caregiver supervision.

Ingested substances can vary, from household cleaning solutions to prescription and nonprescription medications. The most common exposures in children younger than 5 years were cosmetics/personal care products, analgesics, household cleaning substances, foreign bodies (eg, small toys), and topical preparations.[47] Unintentional or accidental ingestions are the most common type in younger children (ie, younger than 5 years) with fatalities possible with as little as one to two tablets/capsules of medications such as calcium channel blockers, tricyclic

Patient Care Process

Collect Information:

- For patients up to 2 years of age, review birth history, including gestational age, birth weight, medical complications, postnatal age, and corrected age.
- Review patient's past medical history, comorbidities.
- Review patient's available laboratory data (eg, serum creatinine, liver function tests).
- Review all current medication therapy, including CAM and OTC.
- Review patient's medication allergies and/or intolerances.

Assess the Information:

- Assess appropriateness of therapy. Is patient on appropriate drug therapy for current diagnoses? Are current medication doses appropriate (ie, for age, weight, etc.)? Any medications without indication?
- Evaluate patient's organ function (renal and hepatic), including use of appropriate equations (eg, bedside Schwartz).
- Assess current therapy for safety and efficacy. Is the medication effective for this patient? Is the patient experiencing any adverse effects?
- Consider available data regarding safe and effective dosing of selected drug.
- Assess patient's (or patient's caregiver) history of medication adherence and health care beliefs.

Develop a Care Plan:

- Consider available routes of administration. What is the most appropriate route? If IV medication is needed, what types of IV accesses are available? For example, does the patient have a central or peripheral line? Determine if IV medication needs to be further diluted or concentrated based on patient's comorbidities and fluid status.
- Consider ease of administration for the patient and/or caregiver. Is the dose easily measurable? Is the dosing frequency reasonable for their family schedule?
- Verify accuracy of dose calculations. Verify current weight and dosing units (e.g., mg/kg/day, mg/kg/dose). Is the dosing interval appropriate?
- Determine what drug-drug/drug-food interactions are possible with this new therapy. How can they be managed?

Implement the Care Plan:

- Communicate plan for care with patient care team.
- Educate parent/caregiver/patient regarding selected drug therapy including purpose, dose, administration, duration therapy, possible side effects, etc.

Follow-up: Monitor and Evaluate:

- Monitor signs and symptoms of clinical outcomes (improvement and decline). Measure drug serum concentrations when appropriate. Monitor for possible adverse drug events.
- Reinforce patient/caregiver education.

antidepressants, or opioids. For those age between 13 and 19 years and older, intentional exposures outnumber those classified as unintentional/accidental and include recreational and self-harm attempts.[47] Management of accidental ingestions varies depending on the ingested substance, the amount, and the age and size of the child. The American Academy of Clinical Toxicology and the AAP do not recommend the use of ipecac syrup for treatment of accidental ingestion; thus, inducing emesis is not a recommended approach for any type of ingestion.[48] Clinicians receiving calls regarding management of accidental ingestions, depending on severity of case, should direct them to the emergency department for evaluation and/or the local or regional poison control center for specific recommendations, which can reached via a universal contact number (1-800-222-1222), with additional information located through the American Association of Poison Control Centers (*www.aapcc.org*).[49]

Abbreviations Introduced in This Chapter

AAP	American Academy of Pediatrics
ACIP	Advisory Committee on Immunization Practices
bpm	Beats per minute
CAM	Complementary and alternative medicine
CDC	Centers for Disease Control and Prevention
CPOE	Computer physician order entry
ELBW	Extremely low birth weight
GA	Gestational age
GFR	Glomerular filtration rate
LBW	Low birth weight
MDI	Metered-dose inhaler
OTC	Over-the-counter
V_d	Volume of distribution (apparent)
VLBW	Very low birth weight

3 Palliative Care Management

Kelly R. Kroustos and Marc A. Sweeney

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the philosophy of palliative care including hospice care and its impact on medication therapy management.
2. Discuss the therapeutic management of palliative care patients and how it differs from and is similar to traditional patient care at the end of life.
3. List the most common symptoms experienced by the terminally ill patient.
4. Explain the pathophysiology of the common symptoms experienced in the terminally ill patient.
5. Describe the pharmacologic rationale of medication therapy used for symptom management in the terminally ill patient.
6. Recommend nonpharmacologic and pharmacologic management of symptoms in a terminally ill patient.
7. Develop a patient-specific palliative care management plan.
8. Educate patients and caregivers regarding palliative care management plan, including rationale of treatment, importance of medication adherence, and assessment and monitoring of desired outcomes.

INTRODUCTION

KEY CONCEPT According to the World Health Organization (WHO), "Palliative care is an approach that improves the **quality of life** of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual." The goal of palliative care is to achieve the best quality life for patients and their families.[1] "Palliate" literally means "to cloak." The WHO goal of achieving high quality life depends on a team approach to manage disease-related symptoms while honoring the patient's care goals.[2] Palliative care focuses on patients and their families and the challenges associated with life-threatening illness.[3] The goal is to prevent and relieve suffering by means of early identification, assessment, and treatment of pain and other physical symptoms, including associated psychosocial, emotional, and spiritual concerns.[1] Palliative medicine is rapidly becoming a well-recognized medical specialty[4] and is much needed due to the increased number of patients with chronic, slowly debilitating diseases.[2]

The term *palliative care* is frequently used synonymously with hospice and, although hospice programs provide palliative care, palliative care has a much broader application. In the United States, hospice is defined by Medicare and other third-party payers as a benefit available to individuals who have less than or equal to 6 months life expectancy if the disease runs its typical course.[2] Hospice care guidelines and regulations are primarily defined by federal regulations. Palliative care outside of the umbrella of hospice care, in contrast, is not currently regulated nor has the same reimbursement structure. Palliative care services may be provided at any point during the disease process and are not limited to the last 6 months of life; therefore, patients and families may receive palliative care services beginning at the time of diagnosis of life-limiting illness. Palliative care may be delivered in all care settings.[5] The foundation for providing quality palliative care centers around active participation of an interdisciplinary team working closely to meet patient and family goals.[6] Team members include representatives from medicine, nursing, social work, pastoral or related counseling, pharmacy, nutrition, rehabilitation, and other professional disciplines providing a holistic approach to the patient's care. KEY CONCEPT The goals of palliative care include enhancing quality of life while maintaining or improving functionality.[6,7] Palliative care should be delivered to patients from the onset of any chronic, life-altering disease. Before many of our modern medical and therapeutic advancements were developed, curative treatments were not normally available.[8] Provision of comfort was considered the mainstay for patient care. Advances in medical care, nutrition, public health, and trauma care resulted in fewer patient deaths, and medical management shifted focus from comfort to a death-denying approach, with prolonging life as the primary goal. With this shift, palliative care became less emphasized until 1967 when the first modern hospice was established in London, England. Today the palliative care philosophy attempts to combine enhanced quality of life, compassionate care, and patient and family support with modern medical advances.

EPIDEMIOLOGY AND ETIOLOGY

Currently, approximately 6100 hospice agencies care for patients across the United States.[9] In 2013, approximately 59% of hospice patients were cared for in the home, and 84% of hospice patients were older than 65 years.[9]

Palliative care for advanced lung cancer is positively correlated with increased survival and reduced risk of death in acute care settings.[10] Lung cancer patients receiving early palliative care survived 23% longer than those with delayed palliative care.[11] Early referrals to hospice appear to improve overall care of the patient and offer prolonged survival in some. The integration of palliative care prior to the patient's eligibility for hospice care may even further improve survival and quality of life and care of patients.

Because healthcare providers have an increasing recognition of palliative care benefit for patients with all life-limiting illness, increased integration of this care model has extended to other disease states beyond cancer.

PATHOPHYSIOLOGY

Understanding the pathophysiology of multiple end-stage disease states is daunting, yet in palliative care, the emphasis is less on disease state management than on assessment and appropriate treatment of associated physical, psychological, social, and spiritual symptoms. Palliative care focuses on symptom management for patients with progressive life-limiting illnesses from diagnosis through death where the pathophysiological impact of disease on a patient's symptoms may vary greatly. **KEY CONCEPT** Palliative care is appropriate for all life-limiting diseases including cancer, chronic obstructive pulmonary disease, dementia, including Alzheimer's disease, Parkinson's disease, chronic cardiac disease, stroke, renal failure, hepatic failure, multiorgan failure, diabetes mellitus, etc.

For the purpose of this chapter, pathophysiology is not a primary focus. Rather, the philosophy of managing physical, psychological, social, and spiritual symptoms to maintain quality of life and prevent suffering is discussed within the context of progressively incurable illnesses. Although palliative may coexist with aggressive disease state management to extend life, as the patient approaches the end of life, philosophy and management generally moves away from principles related to disease state management of patients where prolonging life is the goal.

CLINICAL PRESENTATION AND DIAGNOSIS

Cancer

Palliative care is commonly associated with cancer patients. Regardless of whether or not the cancer is curable, most patients have various degrees of physical, psychological, social, and spiritual symptoms that arise once a diagnosis is confirmed. Once a cancer patient has failed curative and life-prolonging therapy, prognosis and disease trajectory are easier to determine than in patients with other life-limiting diseases. The change in focus from cure to symptom control becomes apparent and therefore more acceptable. Cancer symptoms depend on both the primary tumor site and the location of metastatic spread. Symptoms may also result from the effects of cancer treatments, such as chemotherapy and radiation. (See Chapters 88–99 for specific cancers and their treatments.)

End-Stage Heart Failure

Many forms of heart disease result in sudden death; however, disease progression of heart failure is protracted, yet unpredictable. Advanced heart failure (class III–IV or stage C or D) is characterized by persistent symptoms that limit activities of daily living despite optimal drug therapy. Common symptoms include fatigue, breathlessness, anxiety, fluid retention, and pain. In heart failure, standard medication management intends to reduce progression of cardiac remodeling and is considered disease modifying. However, as patients approach the final months of life, with the exception of cholesterol-lowering agents, these same cardiac medications are also palliative and should not be discontinued prematurely without cause (Figure 3–1). Exacerbations of heart failure symptoms should be aggressively treated as long as the patient is responsive to therapy and wishes to receive treatment. In hospice, this can often be accomplished through medication

	Mortality Benefit	Functional Benefit	Renal Dosing Adjustments	Risk vs Benefit Considerations
Diuretics *(furosemide, torsemide, bumetanide)*	–	✓	✓	Continue for symptom management (edema, dyspnea) **Caution:** Dehydration, hypokalemia
Angiotensin converting enzyme inhibitors *(lisinopril, enalapril)*	✓	✓	✓	**Caution:** Dehydration, sepsis, concurrent NSAID use and renal artery stenosis can increase renal toxicity
Aldosterone antagonists *(spironolactone)*	✓	–/✓	✓	Primary benefit for reducing mortality **Caution:** Hyperkalemia risk with renal insufficiency
β-Blockers *carvedilol, metoprolol)*	✓	✓	–	Taper doses prior to discontinuation **Caution:** May cause hypotension and bradycardia
Inotrope PO *(digoxin)*	–	✓	✓	**Caution:** Digoxin toxicity (N/V, anorexia, confusion, arrhythmia)

FIGURE 3–1. Drugs, their use in Class III-IV heart failure, and their effects on mortality, hospital admissions, and functional status. Checkmark, indicating a positive impact on specified parameter, and — indicating no significant impact on specified parameter.[7,31]

manipulation in the patient's home without the need for hospitalization (see Chapter 7).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) has a prolonged and variable course. COPD Patients have numerous physician visits and hospital admissions. Palliative care treatment is directed at reducing symptoms, reducing the rate of decline in lung function, preventing and treating exacerbations, and maintaining quality of life. In end-stage COPD, bronchodilators and anti-inflammatory agents become less effective. As patients decline, the ability to appropriately use inhalers becomes more difficult. Utilizing a nebulizer to administer bronchodilators allows for more reliable drug delivery to the site of action. Symptoms of late-stage disease include wheezing, chronic sputum production, cough, frequent respiratory infections, dyspnea with exertion progressing to dyspnea at rest, fatigue, pain, hypoxia, and weight loss. Pulmonary hypertension may also occur and can lead to cor pulmonale or right-sided heart failure (see Chapter 16).

End-Stage Kidney Disease

Chronic kidney disease is progressive and leads to renal failure. In end-stage kidney disease, the only life-sustaining treatments are dialysis or renal transplant. Without treatment, kidney failure causes uremia, oliguria, hyperkalemia and other electrolyte disorders, fluid overload and hypertension unresponsive to treatment, anemia, hepatorenal syndrome, and uremic pericarditis. Symptoms associated with chronic kidney disease (stage 5) include fatigue, pruritus, nausea, vomiting, constipation, dysgeusia, muscle pain, agitation, and bleeding abnormalities. Palliative care in these patients includes the minimization of these symptoms; however, because many options for drug therapy will be cleared through the kidneys, agents should be chosen cautiously to avoid other complications (see Chapter 27).

End-Stage Liver Disease

Like kidney disease, the only treatment to prolong life in advanced liver disease is transplant. Patients with end-stage liver disease typically present with ascites, jaundice, pruritus, or encephalopathy, and, frequently, all four symptoms. Additionally, bleeding disorders are common, and bleeding esophageal or gastric varices are the cause of death in about one-third of those who die from liver disease. Palliative care in these patients focuses on the symptom management of end-stage liver disease complications.

Human Immunodeficiency Virus/Acquired Immune Deficiency Syndrome

Pharmacologic advances have changed prognosis and progression of human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS). Palliative care is predominantly directed toward patients without access to drug therapy in early stages of disease. Patients with progressed HIV/AIDS are susceptible to opportunistic infections and cancer that may hasten death. Common symptoms in individuals with HIV/AIDS at the end of life include fatigue, profound weight loss, breathlessness, nausea, gastrointestinal (GI) disturbances, and pain. The goal of palliative care in these patients is to minimize common AIDS-related symptoms (see Chapter 87).

Stroke/Cerebral Vascular Accident

Stroke results from hemorrhage or ischemia. The prognosis of cerebral vascular accident (CVA) patients is unpredictable and may be extended, resulting in caregiver fatigue. Approximately one-third of patients who have a stroke will die within 2 years. Patients with stroke deal with loss of physical and cognitive function, poststroke pain, and frequent depression. Incontinence, aphasia, **dysphagia**, and seizures are also common. Patients with dysphagia have a high incidence of aspiration pneumonia, which often is the cause of death (see Chapter 12).

Parkinson Disease

Parkinson disease is a degenerative neurologic disease with a long chronic, progressive course evidenced by akinesia, rigidity, and tremor. The goal of therapy is to reduce symptoms and maintain or improve quality of life. Palliative care provides support to both patients and caregivers as patients become more disabled, and neuropsychiatric problems arise. Frequent symptoms are skin infections and breakdown, constipation, pain, depression, hallucinations, and confusion. Individuals with Parkinson disease often die from bronchial pneumonia due to dysphagia or complication from falls (see Chapter 34).

Amyotrophic Lateral Sclerosis (Lou Gehrig Disease)

Amyotrophic lateral sclerosis (ALS) is a chronic neurodegenerative disorder characterized by progressive loss of motor neurons. The median survival is approximately 3 years from the symptom onset with less than 15% of patients surviving 10 years. Initially, symptoms of ALS present as limb weakness, with other symptoms developing in no particular order including cramps, spasticity, pain, dysarthria, sialorrhea, fatigue, insomnia, depression, fear and anxiety, involuntary emotional expression disorder, constipation, aspiration, and laryngospasm. Many patients do not have cognitive impairment; however, one-fourth to one-half of patients with ALS may have associated frontal lobe dementia. Disease progression eventually involves all systems except sphincter control and eye movement. Unless the individual has long-term mechanical ventilation, the cause of death is typically respiratory failure.

Alzheimer Disease and Other Dementia

Dementia is a progressive, nonreversible deterioration in cognitive function with associated behavioral dysfunction. Alzheimer disease accounts for most dementia cases; vascular, Parkinson disease, dementia with Lewy body, and frontotemporal dementias are less prevalent. Drug therapy targets slowing progression of cognitive symptoms and preserving patient function. As patients progress toward end-stage dementia, in addition to memory loss and personality and behavioral changes, they require assistance in basic activities of daily living such as feeding, dressing, and toileting. At this point they may not respond to their surroundings, may not communicate, or have impaired movements and dysphagia. Depression, agitation, delusions, compulsions, confusion, hallucinations, incontinence, and disruption of sleep/wake cycles are all common symptoms in end-stage dementias. Symptom assessment is challenging due to the cognitive impairment and frequent aphasia. Palliative care is not only directed toward the patient but also emotional support for those close to them (see Chapter 30).

TREATMENT

KEY CONCEPT Following a complete assessment of the patient, developing a comprehensive therapeutic plan that utilizes the fewest number of medications to achieve the highest quality of life is essential. Many times, one drug may relieve multiple symptoms, resulting in better patient care, lower costs, and decreased medications. Cost-effective drug recommendations are essential to control costs. Avoiding polypharmacy will reduce adverse drug events related to drug interactions, excessive side effects, and therapy duplication. The following list of symptoms includes common symptoms observed in palliative and end-of-life care; however, it is not comprehensive. **KEY CONCEPT** Palliative care is more than just pain management. It includes treatment of symptoms resulting in discomfort for the patient, which may include nausea and vomiting, agitation, anxiety, depression, **delirium**, dyspnea, anorexia and cachexia, constipation, diarrhea, pressure ulcers, and edema.

Note that many drugs used to treat symptoms in palliative and end-of-life care are often prescribed for unapproved uses, administered by unapproved routes or in dosages higher than recommended by the package insert. Conducting large-scale, rigorous drug studies that supply necessary information for an approved drug indication poses ethical difficultly due to the delicate nature of patients receiving palliative and/or hospice care.

Anxiety

A comprehensive review of anxiety disorders is found in Chapter 41.

▶ *Palliative Care Considerations*

- Anxiety is "characterized by apprehensive anticipation of future danger or misfortune accompanied by psychological symptoms such as worrying, vigilance, and rumination as well as by physical feelings such as tension, jitters, dyspnea, chest discomfort, or abdominal stress."[7]
- Anxiety is closely related to fear, but fear has an identified cause or source (eg, fear of death). Fear may respond more to counseling than anxiety that the patient cannot attribute to a particular fearful stimulus. Anxiety disorders are the most prevalent class of mental disorders, so it is not surprising that anxiety is a common cause of distress at life's end.

In addition to anxiety disorders, a variety of conditions can cause, mimic, or exacerbate anxiety.[12,13] **Delirium**, particularly in its early stages, can easily be confused with anxiety. Physical complications of illness, especially dyspnea and undertreated pain, are common precipitants. Significant anxiety is present in most patients with advanced lung disease and is closely related to periods of oxygen desaturation. Medication side effects, especially akathisia from older antipsychotics and antiemetics (including metoclopramide), can present as anxiety. Interpersonal, spiritual, or existential concerns can mimic and exacerbate anxiety. Patients with an anxious or dependent coping style are at high risk of anxiety as a complication of advanced illness. Short of making a diagnosis of a formal anxiety disorder, differentiating normal worry and apprehension from pathologic anxiety requires clinical judgment.

Behaviors indicative of pathological anxiety include intense worry or dread, physical distress (eg, tension, jitteriness, or restlessness), maladaptive behaviors and diminished coping, and inability to relax.[12]

Pathological anxiety may be complicated by insomnia, depression, fatigue, GI upset, dyspnea, or dysphagia.[14] Anxiety can also worsen these conditions, if they are already present. Untreated anxiety may lead to numerous complications, including withdrawal from social support, poor coping, limited participation in palliative care treatment goals, and family distress. Reassess the patient for anxiety with any change in behavior or any change in the underlying medical condition. Assessment for formal anxiety disorders or other contributing factors is key to management. A comprehensive review of insomnia may be found in Chapter 42.

▶ *Nonpharmacologic Treatment*

Regardless of treatment approach, the following principles apply. Ask questions and listen to patients' concerns and fears. Offer emotional support and reassurance when appropriate. Err on the side of treatment—be willing to palliate anxiety. Assess treatment response and side effects frequently. Aim to provide maximum resolution of anxiety and educate patients and families about anxiety and its treatments.

Psychotherapies can help manage anxiety, although availability of trained therapists willing to make home visits, and limited stamina and attention span of seriously ill patients, typically make such therapies impractical in the hospice setting. Cognitive and behavioral therapies can be beneficial, including simple relaxation exercises or distraction strategies (ie, focusing on something pleasurable or at least emotionally neutral). Encourage pastoral care visits, especially if spiritual and existential concerns predominate.

When an underlying cause of anxiety can be identified, treatment is initially aimed at the precipitating problem, with monitoring to see if anxiety improves or resolves as the underlying cause is addressed.[14]

▶ *Pharmacotherapy*

In most cases, management of pathological anxiety in the hospice setting involves pharmacologic therapies. Benzodiazepines are standard treatment; however, selective serotonin reuptake inhibitors (SSRIs), typical and atypical antipsychotics, may be appropriate based on the patient's life expectancy.[14] The primary goal of therapy for anxiety in hospice is patient comfort. Aim to prevent anxiety, not just treat it with as needed medications. Think of pain management as an analogy. As with all medications that act in the central nervous system (CNS), anxiolytics, such as benzodiazepines, should be dosed at the lower end of the dose range to prevent unnecessary sedation, particularly in the frail and elderly. However, recognize that standard or higher doses may be required. Avoid use of bupropion and psychostimulants for anxiety. Although effective for depression, they are ineffective for anxiety and may make anxiety worse. Many patients have difficulty swallowing as they approach the end of life. Lorazepam, alprazolam, and diazepam tablets are commonly crushed and placed under the tongue with a few drops of water if the liquid formulations are not readily available. Low-dose haloperidol is also used to treat anxiety in palliative care, particularly if delirium is present.[15] Chapter 41 provides more detailed information on appropriate use of anxiolytic agents.

Delirium

▶ *Palliative Care Considerations*

Delirium is very common in hospice, occurring in more than 80% of terminally ill patients, most often in the last few days of life.[11] Potential causes in the hospice setting include medical illness, dehydration, hypoxia, sleep deprivation, metabolic disturbances, sepsis, medication side effects (particularly anticholinergic agents, benzodiazepines, opioids, corticosteroids, tricyclic antidepressants), urinary retention, urinary tract infection, constipation or impaction, uncontrolled pain, or alcohol or drug withdrawal.[7,15]

A classic delirium symptom is clouding of consciousness. This can be manifested by an inability to either maintain or shift attention. Patients also have impaired cognitive functioning, which may or may not include memory disturbances. "Sundowning" is very common phenomenon at the end of life, especially in the presence of delirium. It presents as daytime sleepiness and nighttime agitation and restlessness. Another common characteristic is fluctuation in severity of delirium symptoms during the day. This can even occur within the course of a single hour or also from day to day. Patients exhibiting agitation from their delirium are easy to identify, but those who present as withdrawn and with diminished responsiveness ("quiet" delirium) are more difficult to diagnose. It is not uncommon for patients to exhibit both quiet and agitated delirium. Treatment is the same for both types. Delirium is difficult to distinguish from dementia. Delirium more commonly presents as a sudden onset (eg, hours to days), with an altered level of consciousness and a clouded sensorium. However, dementia more commonly presents gradually and with an unimpaired level of consciousness.[15]

▶ *Nonpharmacologic Treatment*

Establishing a safe, soothing environment including familiar objects such as photographs and familiar music can be helpful to calm the patient. Minimizing injury risk is important when the patient is agitated. Providing education to families and caregivers about the causes of delirium, signs and symptoms, and how to best manage it will help reduce their anxiety and distress when it occurs.

▶ *Pharmacotherapy*

The most important initial step is to determine the care goal. If possible, reverse the underlying cause of delirium to restore the patient to a meaningful cognitive status.[7,11] If the precipitating factors cannot be reversed, initiate symptom treatment. If the patient is irreversibly delirious and agitated, drug therapy is generally indicated.

Antipsychotic (neuroleptic) drugs (conventional or atypical antipsychotics) are the drugs most used to treat confusion and agitation associated with delirium. However, treatment of delirium with these drugs is "off-label." Atypical antipsychotics including risperidone, olanzapine, quetiapine, ziprasidone, paliperidone, and aripiprazole are also an option.[16]

Haloperidol, in doses less than 2 mg/day, is well tolerated and nonsedating. Doses greater than 4.5 mg/day are associated with increased extrapyramidal symptoms.[16,17] Cumulative doses of 35 mg or single intravenous (IV) doses greater than 20 mg have been associated with QTc prolongation.[18] When sedation is beneficial for terminal aggressive, agitated delirium, quetiapine provides more sedation as compared with low-dose haloperidol. When patients are bedbound and in the final stages of life, excess sedation common with quetiapine is not a concern. Haloperidol is commonly given sublingually or rectally if swallowing becomes difficult, although these are not approved administration routes. Haloperidol, but not quetiapine, can be given subcutaneously.[19]

Administering benzodiazepines alone in a patient with delirium can make the delirium and confusion worse. While addition of benzodiazepines with antipsychotics is not routinely used, delirium induced by withdrawal or untreated anxiety may benefit from addition of a benzodiazepine.[13]

Dyspnea

▶ *Palliative Care Considerations*

Dyspnea is described as an uncomfortable awareness of breathing. It is a subjective sensation, and patient self-report is the only reliable indicator. Respiratory rate or Po_1 may not correlate with the feeling of breathlessness.[20] Respiratory effort and dyspnea are not the same. While opioids do not address bronchoconstriction or bronchospasm, patients may report substantial relief of dyspnea from opioids with no change in respiratory rate. The prevalence of dyspnea varies from 12% to 74%, worsening during the last week of life in terminally ill cancer patients to between 50% and 70%. History and physical examination should be taken and reversible causes of dyspnea should be identified and treated, if present.[21–23]

Patient Encounter 1

SF is an 89-year-old woman diagnosed with metastatic breast cancer with left nodal involvement and sternal bone. Past medical history: hypertension, atrial fibrillation, asthma, depression with anxiety, and glaucoma. No known allergies. SF reports sternal pain rating 7/10 (visual analog pain scale, 0–10). Pain: deep, constant, aching, and limits movement. Breathing pain is 6/10 (visual analog pain scale, 0–10) and located in the left middle quadrant. Pain: sharp, spasmodic, worsens with deep breathing and movement. SF reports constipation, dizziness, and worsening depression and anxiety. She recently fell, and her "feet feel heavy" with 3+ pitting edema.

VS: BP 101/70 mm Hg, RR 32 breaths/min, P 88, wt 60 kg (132 lb), ht 5 ft 3 in (160 cm)

Medications: amlodipine 10 mg by mouth daily, albuterol sulfate inhaler: inhale 1 to 2 puffs by mouth every 6 hours as needed for asthma symptoms, amiodarone 200 mg by mouth daily, furosemide 20 mg by mouth twice daily for ankle edema, multivitamin by mouth once daily, latanoprost ophthalmic drops: instill one drop into both eyes once daily, hydrocodone/acetaminophen 5–325 1 tablet by mouth every 4 hours as needed, polyethylene glycol 17 g in 120 mL of water once daily, calcium carbonate 600 mg by mouth twice daily.

What are the two types of pain that SF is experiencing?

What are the other symptoms that SF is reporting during your patient encounter?

What potential drug–drug interactions may exist, and how would you monitor the patient for interactions?

What may be contributing to SF's report of dizziness and leading recent fall?

What medications should be added, changed, or discontinued?

List nonpharmacologic interventions that the practitioner could make to improve the care of SF.

▶ *Nonpharmacologic Treatment*

Provide information, anticipate and proactively prepare the patient and family for worsening symptoms. Identify and attempt to minimize triggers that cause episodes of dyspnea. Educate patient and family regarding treatment of dyspnea, including the use of opioids and benzodiazepines for dyspnea-associated anxiety. Prevent isolation and address spiritual issues that can worsen symptoms. Encourage relaxation and minimize the need for exertion.

Reposition to comfort, usually to a more upright position or with the compromised lung down. Avoid strong odors, perfumes, and smoking in the patient's presence or in proximity. Improve air circulation/quality: provide a draft, use fans, or open windows and adjust temperature/humidity with air conditioner or humidifier.

▶ *Pharmacotherapy*

If no treatable causes can be identified, or when treatments do not completely alleviate distressing symptoms, opioids are first-line agents for treating dyspnea.[21,23,24] Opioids suppress respiratory awareness, decrease response to hypoxia and hypercapnia, vasodilate, and have sedative properties. Low-dose opioids (eg, starting oral dose of morphine ~5 mg) have been shown to be safe and effective in the treatment of dyspnea. Opioid doses should be titrated judiciously. Once an effective dose of an opioid has been established, converting to an extended-release preparation may simplify dosing. When using opioids, anticipate side effects and prevent constipation by initiating a stimulant laxative/stool softener combination.

Nebulized opioids for treatment of dyspnea are controversial. Study results have been inconsistent.[22,23] Nonrandomized studies, case reports, and chart reviews describe anecdotal improvement in dyspnea using nebulized opioids; however, several controlled studies using nebulized opioids have provided inconclusive or negative results.[21,22]

Nebulized furosemide appears effective for dyspnea refractive to other conventional therapies.[24] The hypothesized mechanism of action of nebulized furosemide is its ability to enhance pulmonary stretch receptor activity, inhibition of chloride movement through the membrane of the epithelial cell, and its ability to increase the synthesis of bronchodilating prostaglandins.[24]

Because anxiety can exacerbate dyspnea, benzodiazepines and antidepressants having anxiolytic properties are frequently beneficial. Not all dyspnea is caused by low oxygen saturation. However, oxygen therapy is useful and beneficial for dyspnea if hypoxia is present.

For known etiologies of dyspnea, consider the following:

Bronchospasm or COPD exacerbation: Albuterol, ipratropium, and/or oral steroids are effective for symptom management. Nebulized bronchodilators are more effective than handheld inhalers in patients who are weak and have difficulty controlling breathing.

Thick secretions: If cough reflex is strong, loosen secretions by increasing fluid intake. Guaifenesin may thin secretions; however, its efficacy in the absence of hydration is controversial. Nebulized saline may also help loosen secretions. If the patient is unable to cough, hyoscyamine, glycopyrrolate, or scopolamine patch can effectively dry secretions.[21,23] Oral glycopyrrolate is preferred since it has less propensity to cause the anticholinergic side effect of confusion.

Anxiety associated with dyspnea: Consider benzodiazepines (eg, lorazepam, diazepam).

Effusions: Thoracentesis may be necessary.

Low hemoglobin: Red blood cell transfusion (controversial) or erythropoietin (rarely used in hospice but might have larger role in palliative care).

Infections: Antibiotic therapy as appropriate.

Pulmonary emboli: Anticoagulants for prevention and treatment or vena cava filter placement (rarely used in hospice but might have a larger role in palliative care).

Rales due to volume overload: Reduction of fluid intake or diuretic therapy as appropriate.

Patient Encounter 2

KP is a 74-year-old man admitted to the palliative care service with a diagnosis of moderate Alzheimer disease. Comorbidities include type 2 diabetes mellitus and hyperlipidemia. KP is widowed, resides in the community. He smokes one ppd and consumes two to four beers per day. No known drug allergies. Related symptoms: disorientation to time and place with repeated questioning, difficulty performing, and withdrawal from daily tasks, complex actions and social engagements. Recent weight loss of 25 pounds (11 kg) over 3 months.

VS: BP 125/50 mm Hg, RR 20 breaths/min, P 88, wt 54.5 kg (120 lb), ht 5 ft 6in (168 cm)

Medications: metformin 1000 mg by mouth twice daily, glimepiride 2 mg by mouth once daily, atorvastatin 10 mg by mouth daily, psyllium 1 teaspoonful by mouth dissolved in 8 oz (240 mL) of water twice daily for constipation, donepezil 5 mg by mouth daily.

What parameters should be assessed prior to making changes to or adding additional interventions for KP's current situation?

What medication(s) could be added, changed, or discontinued?

What are some nonpharmacologic interventions for treating KP's symptoms of disorientation, frequent questioning, difficulty with daily tasks, and decline in social engagement?

Nausea and Vomiting

A comprehensive review of nausea and vomiting may be found in Chapter 21.

▶ *Palliative Care Considerations*

Up to 71% of palliative care patients will develop nausea and vomiting with approximately 40% experiencing these symptoms in the last 6 weeks of life. Chronic nausea can be defined as lasting longer than a week and without a well-identified or self-limiting cause, such as chemotherapy, radiation, or infection.[3] Four major mechanisms are correlated with stimulation of the vomiting center (Figure 3–2). Potentially reversible causes of nausea and vomiting should not be overlooked. Causes of chronic nausea in end-of-life patients may include autonomic dysfunction, constipation, antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), other drugs, infection, bowel obstruction, metabolic abnormalities (eg, renal or hepatic failure, hypercalcemia), increased intracranial pressure, anxiety, radiation therapy, chemotherapy, or untreated pain.[23,25,26]

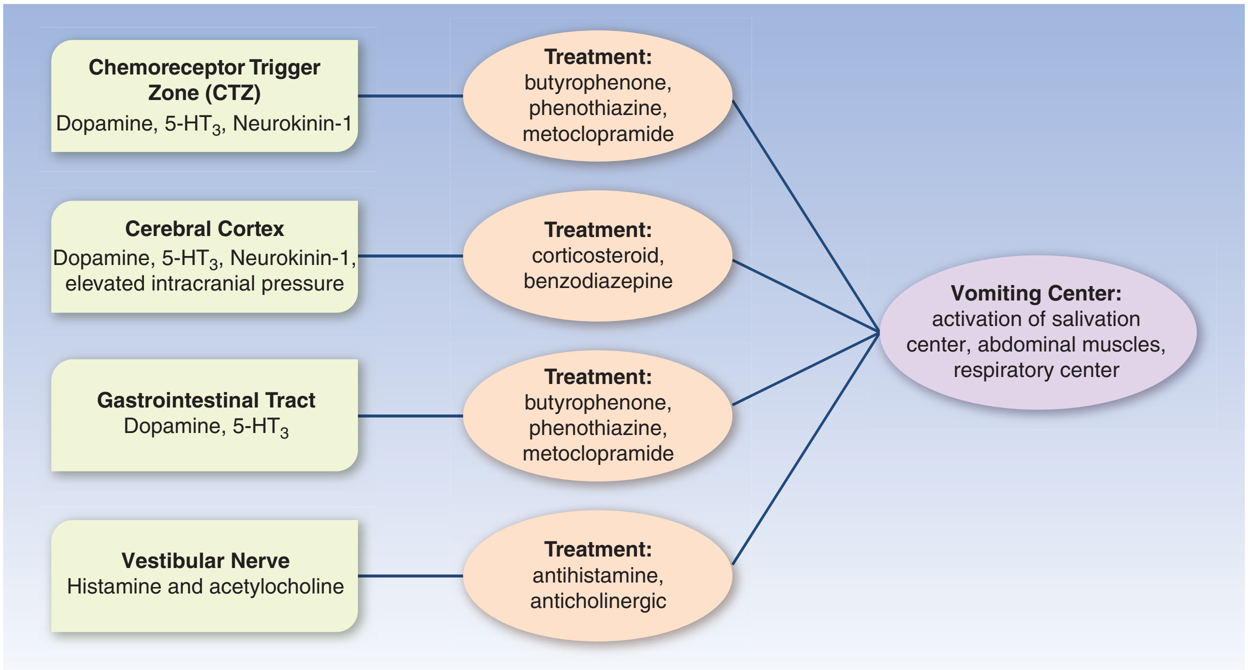
▶ *Nonpharmacologic Treatment*

Relaxation techniques may prove beneficial. Strong foods or odors should be avoided and eliminate offending medications.

▶ *Pharmacotherapy*

Clinical features of nausea and vomiting should guide the choice of antiemetics used (for a more comprehensive review, see Chapter 21).

Chemoreceptor trigger zone (CTZ)-induced nausea and vomiting are caused by chemotherapeutic agents, bacterial toxins, metabolic products (eg, uremia), and opioids. Dopamine (D_2),



Chemoreceptor Trigger Zone (CTZ)
Dopamine, 5-HT3, Neurokinin-1
Cerebral Cortex
Dopamine, 5-HT3, Neurokinin-1, elevated intracranial pressure
Gastrointestinal Tract
Dopamine, 5-HT3
Vestibular Nerve
Histamine and acetylocholine
Treatment: butyrophenone, phenothiazine, metoclopramide
Treatment: corticosteroid, benzodiazepine
Treatment: butyrophenone, phenothiazine, metoclopramide
Treatment: antihistamine, anticholinergic
Vomiting Center: activation of salivation center, abdominal muscles, respiratory center

FIGURE 3–2. Mechanisms and associated neurotransmitters involved in nausea and vomiting.[7,25,28]

serotonin (5-HT), and neurokinin-1 are the primary neurotransmitters involved in this process. Therapy is based on blocking D_2 with D_2-antagonists including butyrophenones (eg, haloperidol), phenothiazines, and metoclopramide.

Due to receptor specificity, serotonin_3 (5-HT_3) antagonists such as ondansetron, granisetron, dolasetron, and palonosetron have limited usefulness in nausea and vomiting at the end of life.[7,25] They are typically indicated with emetogenic chemotherapy and up to 10 to 14 days posttreatment. Aprepitant is a neurokinin-1 antagonist indicated for the treatment of nausea due to highly emetogenic chemotherapy in combination with a 5-HT_3 antagonist and corticosteroid. Aprepitant should not be used as monotherapy.[23]

Cerebral cortex–induced nausea and vomiting can be caused by anxiety, taste, and smell, and also secondary to increased intracranial pressure. Corticosteroids decrease intracranial pressure due to tumor involvement. Corticosteroids can be effective in nonspecific nausea and vomiting. The mechanism of action is unknown. Anxiolytics, such as benzodiazepines, are used to treat anxiety and "anticipatory" gustatory and olfactory stimulation.[23]

Vestibular nausea and vomiting is triggered by motion. Opioids can sensitize the vestibular center, resulting in movement-induced nausea. Since histamine and acetylcholine are the predominant neurotransmitters, antihistamines and anticholinergics are the drugs of choice in movement-induced nausea and vomiting.

GI tract stimulation occurs through vagal and sympathetic pathways. These pathways are triggered by stimulation of mechanoreceptors or chemoreceptors located in the gut. Gastric stasis, GI obstruction, drugs, metastatic disease, bacterial toxins, chemotherapeutic agents, and irradiation may cause nausea and vomiting. Glossopharyngeal or vagus nerve stimulation in the pharynx by sputum, mucosal lesions, or infection (eg, *Candida*) can also evoke nausea. The major neurotransmitters in the upper GI tract are D_2, acetylcholine, and 5-HT. Metoclopramide is a 5-HT_4 agonist and increases gastric motility above the jejunum, whereas anticholinergics decrease GI spasticity and motility in nausea induced by gut hyperactivity. In high doses, metoclopramide also acts as a 5-HT_3 antagonist.[7,23]

Autonomic failure causes gastroparesis resulting in anorexia, nausea, early satiety, and constipation. Delayed gastric emptying occurs in patients with diabetes mellitus, chronic renal failure, and neurological disorders. Malnutrition, cachexia, lung and pancreatic cancers, HIV, radiotherapy, and drugs such as opioids, anticholinergics, antidepressants, and vasodilators have been associated with autonomic failure and resulting chronic nausea, poor performance, tachycardia, and malnutrition. Evaluate underlying causes, including multiple drugs that may cause gastroparesis. If drug therapy is indicated, metoclopramide is effective in improving gastric emptying.[7]

GI irritation can cause nausea and vomiting due to generalized gastritis, gastroesophageal reflux disease (GERD), or peptic ulcer disease. Histamine_2 (H_2) antagonists or proton pump inhibitors (PPIs) are considered the drugs of choice for ongoing gastritis.

Refractory cases of nausea and vomiting often require judiciously selected combinations of medications from different classes (eg, various combinations of haloperidol, metoclopramide, lorazepam, and dexamethasone).

Pain

A comprehensive review of pain management may be found in Chapter 35.

► *Palliative Care Considerations*

According to the SUPPORT study, 74% to 95% of very ill or dying patients still experience uncontrolled pain.[26] Conducting a comprehensive pain assessment is key to choosing appropriate interventions. Palliative care patients must be evaluated for anxiety, depression, delirium, and other neurological influences that may heighten a patient's awareness or response to pain.

▶ Nonpharmacologic Treatment

Nonpharmacologic treatment is essential. Physical, complementary, and cognitive behavioral interventions reduce the perception of pain and decrease the dose requirements of medications. Examples of such strategies may include providing education, massage, ice, heat, physical therapy, music therapy, imagery, pet therapy, and psychotherapy.

▶ Pharmacotherapy

Pain should be assessed thoroughly and frequently, especially at the onset of treatment. The WHO approach to pain management addresses nociceptive pain (see Chapter 35). Although opioid analgesics are not always necessary or appropriate for all types of pain, most patients with cancer-related pain require opioids. For chronic, constant pain, around-the-clock dosing of analgesics (preferably long-acting agents) is usually necessary and preferred.[27] When titrating opioid doses, increase daily maintenance doses by 25% to 50% if patients routinely require three or more breakthrough doses per 24 hours as a result of around-the-clock maintenance dose failure. The around-the-clock maintenance doses should not be increased if breakthrough doses are used only for incident pain, such as increased activity or dressing changes.

Fentanyl transdermal patches may be appropriate in some; however, many end-of-life patients experience fat and muscle wasting and dehydration, resulting in reduced and variable absorption. Fentanyl transdermal patches have a slow onset of action, contributing to difficulty in dose titration.[7]

Only short-acting opioids should be used for breakthrough pain (eg, immediate-release morphine, oxycodone, and hydromorphone are common examples). The dose of short-acting opioids for the treatment of breakthrough pain should be equal to 5% to 20% of the total daily maintenance dose. Frequencies for breakthrough dosing should not exceed the following:

- **Oral:** Every 1 to 2 hours
- **Subcutaneous:** Every 20 to 30 minutes
- **IV:** Every 8 to 20 minutes

Monitor for and appropriately treat common side effects of opioids, including constipation, nausea and vomiting, itching, and transient sedation. Because constipation occurs with all chronic opioid therapy, prevention is imperative. Stimulant laxatives (senna or bisacodyl) with or without a stool softener (docusate) are the drugs of choice.[7] Myoclonus, delirium, hallucinations, and hyperalgesia are possible signs of opioid-induced neurotoxicity and require rotation to another opioid or dose reduction. Respiratory depression is uncommon with the appropriate opioid dose. However, if dangerous opioid-induced respiratory depression does occur, small doses (0.1 mg) of the μ receptor antagonist naloxone are appropriate and can be repeated as necessary. The goal is to increase respirations to a safe level while preventing the patient from experiencing a loss of pain control.

Different types of pain may require specific types of analgesics or adjuvant medications. Identification and treatment of these separate pain types will help avoid unnecessary opioid dose escalations and opioid side effects. Examples of pain types commonly seen in patients with advanced illness are as follows. See Figure 3–3 for medication options.

Visceral pain (nociceptive pain induced by stretching or spasms of visceral organs including the GI tract, liver, and pancreas) should be treated with an adjuvant such as an anticholinergic agent or, if inflammation is associated with the pain, corticosteroids.

Bone pain (metastatic site of cancer) is best treated with NSAIDs or corticosteroids in addition to standard opioid therapy.

Neuropathic pain (pain caused by damage to the afferent nociceptive fibers) can be managed with tricyclic antidepressants, antiepileptic drugs, tramadol, tapentadol or *N*-methyl-D-aspartate antagonists, such as ketamine. Methadone is an opioid μ-agonist that has a role in neuropathic pain given its added *N*-methyl-D-aspartate antagonist activity. Methadone has a very long half-life compared to most other opioids, except buprenorphine. It should be used with caution and under the close supervision of clinicians experienced in its use for pain management.

Terminal Secretions

▶ Palliative Care Considerations

Terminal secretions, or death rattle, is the noise produced by the oscillatory movements of secretions in the upper airways in association with the inspiratory and expiratory phases of respiration.[28,29] As patients lose their ability to swallow and clear oral secretions, accumulation of mucus results in a rattling or gurgling sound produced by air passing through mucus in the lungs and air passages. The sound does not represent any discomfort for the patient. However, the sound is sometimes so distressing to the family that it should be treated. Terminal secretions are typically seen only in patients who are obtunded or are too weak to expectorate. Drugs that decrease secretions are best initiated at the first sign of death rattle because they do not affect existing respiratory secretions. These agents have limited or no impact when the secretions are secondary to pneumonia, pulmonary congestion, or edema.[30]

▶ Nonpharmacologic Treatment

Position the patient on their side or in a semiprone position to facilitate drainage of secretions. If necessary, place the patient in the Trendelenburg position (lowering the head of the bed); this allows fluids to move into the oropharynx, facilitating an easy removal. Do not maintain this position for long due to the risk of aspiration. Oropharyngeal suctioning is another option but may be disturbing to the patient and visitors. Fluid intake can also be decreased, as appropriate.[23,30]

▶ Pharmacotherapy

Anticholinergic drugs remain standard therapy for prevention and treatment of terminal secretions due to their ability to effectively reduce future production of secretions.[28–30] Drugs used for this indication are similar pharmacologically, and one can be selected by anticholinergic potency, onset of action, route of administration, alertness of patient, and cost. The most used anticholinergic agents are atropine, hyoscyamine, scopolamine, and glycopyrrolate.

Anticholinergic side effects include blurred vision, constipation, urinary retention, confusion, delirium, restlessness, hallucinations, dry mouth, and heart palpitations. Unlike the other anticholinergics, glycopyrrolate does not cross the blood–brain barrier and is associated with fewer CNS side effects, and it is often preferred if the use of anticholinergic intervention is prolonged for more than 7 to 10 days. Glycopyrrolate is a potent drying agent when compared with other agents and has the potential to cause excessive dryness.[30]

Advanced Heart Failure

▶ Palliative Care Considerations

Heart failure symptoms at the end of life may include hypotension, volume overload, edema, and fatigue. Patients should be

Pharmacologic Adjuvants: Nociceptive Pain	
Bone Pain *(inflammatory)*	
Nonsteroidal anti-inflammatory drug (NSAID)	
Ibuprofen (Motrin)[a] Naproxen (Naprosyn)[a] Celecoxib (Celebrex)[b] Meloxicam (Mobic)[b]	- Often first line for untreated diffuse bone pain - Similar efficacy among NSAIDs; however, the risks of GI bleeding, GI ulcers, renal toxicity, and cardiovascular concerns are higher among the nonselective NSAIDs - Selective NSAIDs have less GI effects, but retain risk of renal toxicity
Bisphosphonates	
Zolendronic acid (Zometa) Pamidronate (Aredia) Ibandronate (Boniva)	- Role in treating diffuse bone pain - Intravenous administration with renal monitoring - Monitor: osteonecrosis of the jaw, follow-up with dental evaluation
Steroids	
Dexamethasone (Decadron) Methylprednisolone (Medrol) Prednisone (Deltasone)	- May be preferred over NSAIDs for diffuse bone pain in patients experiencing anorexia and fatigue - Burst and taper recommended for rapid pain control - Monitor: edema, glucose, insomnia, GI upset - Less edema with mineralcorticosteroid - Administer doses earlier in the day with food to avoid insomnia and GI upset
Visceral Pain	
Anticholinergic/Antispasmodics	
Dicyclomine (Bentyl) Glycopyrolate (Robinul IV) Hyoscyamine (Levsin) Scopolamine (Transderm Scop)	- Monitor: *(especially in elderly)* constipation, dry mouth, confusion, dizziness, urinary retention - Steroids may also be used concurrently for visceral pain with associated inflammatory processes (ie, pleuritic pain, capsular organ pain, diffuse intestinal cancer) - Often used short term for treatment of terminal secretions “death rattle”
[a]Nonselective NSAID [b]COX-II selective NSAID	

FIGURE 3–3. Pharmacologic adjuvants for the treatment of bone pain and inflammatory pain.[7,23,26]

assessed to confirm that symptoms are related to heart failure rather than other disease states to ensure appropriate treatment.[31]

Goals for advanced heart failure treatment differ from traditional heart failure management. Drug therapy focuses on symptom management rather than improving mortality. Prevention of cardiovascular disease through cholesterol reduction is no longer necessary.

▶ *Nonpharmacologic Treatment*

Patients should maintain a comfortable position with feet elevated to minimize lower leg fluid accumulation. Minimizing high-salt foods and limiting fluid intake can help reduce fluid accumulation. At this stage in heart failure, comfort becomes the primary initiative.

▶ *Pharmacotherapy*

As patients approach the end of life, it is difficult to determine when certain medications for heart failure should be dose reduced or discontinued. The following general principles may help serve as a guide. However, patient history, prognosis, and current condition should be evaluated to determine appropriateness.

If a patient becomes symptomatic due to hypotension, angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blocker (ARB), and/or β-adrenergic blocker doses should be reduced or discontinued. For β-adrenergic blockers, in particular, this should be done gradually to avoid significant clinical deterioration. If volume overload occurs or persists while taking β-adrenergic blocker therapy, consider tapering off the medication. Likewise, for patients experiencing fatigue while taking a β-adrenergic blocking agent, consider tapering the dose *only if* their heart rate does not increase with exertion. Consider discontinuing the ACE inhibitor (or the angiotensin receptor blocker) if the patient’s renal function deteriorates (eg, cardiorenal syndrome).

In patients with excessive fluid overload where sodium and water intake restrictions are not effective or not possible, consider increasing the diuretic dose. However, vascular dehydration can occur in some patients with end-stage heart failure if the dose of diuretic is excessive.

Digoxin toxicity is common; therefore, patients should be carefully monitored and therapy adjusted or discontinued as appropriate. The symptoms of digoxin toxicity include complaints of anorexia, nausea and vomiting, visual disturbances, disorientation, confusion, or cardiac arrhythmias.[31]

Hydroxymethylglutaryl coenzyme-A (HMG-CoA) reductase inhibitors (and other cholesterol-lowering medications) are likely to have a long-term effect rather than a palliative effect.

Figure 3–1 provides a list of agents that improve functional status in advanced heart failure patients.

OUTCOME EVALUATION

KEY CONCEPT Involving the patient, family, and caregivers in the development of the therapeutic plan demonstrates responsible palliative care. Before implementation of drug therapy, the patient, family, and caregiver should be involved with decision making. The practitioner should provide information about all reasonable options for care so that the patient, family, and caregivers can collaborate with the healthcare team to meet their combined goals. **KEY CONCEPT** Positive therapeutic outcomes include resolution of symptoms while minimizing adverse drug events. When treating symptoms pharmacologically, adverse drug events must be avoided or minimized to prevent negative outcomes.

Patients with life-limiting diseases have emotional and spiritual issues deserving attention by trained professionals. Addressing these concerns and providing support and coping skills can dramatically reduce medication requirements for symptom control. Psychosocial and spiritual support is not only directed toward the patient in palliative care but also supports the family during the time of the illness and after the death of their loved one.

KEY CONCEPT Patient and caregiver education is vital to ensuring positive outcomes. If the patient and caregiver are unaware of the purpose and goals for interventions used in palliative medicine, adherence to regimens will be hindered and outcomes compromised. Education regarding the role and value of the palliative care team will allow the patient and family to understand why palliative care is important to their overall quality of life. Patients will achieve the best possible outcomes when practitioners incorporate the interdisciplinary palliative care approach to care early in the disease progression of patients with life-limiting illnesses.

Patient Encounter 3

JM is a 45-year-old man diagnosed with colon cancer. He received palliative chemotherapy with localized radiation for a few months with the last chemotherapy and radiation administered 4 weeks ago. The interventions were unsuccessful in limiting tumor growth, which has now metastasized to liver and brain. JM has jaundice with mild ascites with no pruritus. JM's chief complaint today is uncontrolled nausea and vomiting, which worsens upon awakening and is unresponsive to antiemetics. The nausea improves throughout the day. The oncologist prescribed ondansetron 8 mg by mouth every 8 hours as needed. JM has taken six doses over 3 to 4 days without improvement in his morning nausea. Comorbidities: hypertension, depression with recent uncontrolled anxiety. Allergy: codeine (reaction unknown). Medications: tramadol 50 mg 1 to 2 tablets by mouth every 4 to 6 hours as needed for pain, ibuprofen 200 mg 1 to 2 tablets by mouth every 4 to 6 hours as needed for pain, ondansetron 8 mg by mouth every 8 hours as needed for nausea.

What are potential causes of JM's nausea and vomiting? Based on this differential list, what questions would you ask JM during your assessment of his nausea and vomiting?

What potential drug–drug interactions and side effects exist in this patient?

What medications could be added, changed, and/or discontinued?

How does the patient's reported allergy to codeine impact potential treatment options?

Patient Care Process

Collect Information:

- Evaluate physical examination, review of systems and relevant laboratory findings and assess for symptoms related to or worsened by their current hospice diagnosis.
- Perform medication reconciliation (prescription, OTC medications, herbal).
- Determine goals as related to the hospice care plan.
- Identify cultural, spiritual, or ethnic traditions that impact patient care and incorporate those aspects into the plan of care.

Assess the Information:

- Ensure medications confer functional status benefit rather than only survival (see Figure 3–1) and that this supports the patient's goals.
- Establish realistic medication outcomes prior to initiating or titrating a medication for palliative care.
- Verify prescription coverage or institutional formulary when adding medications.
- Provide preventative care recommendations (ie, immunization, annual health screening, etc.) and discuss health benefits.

Develop a Care Plan:

- Based on prognosis of a health condition, determine if continuing medication for preventative or long-term management is appropriate.
- If laboratory monitoring is discontinued, medications with a narrow therapeutic index may be discontinued.
- Ensure medications are appropriate for the patient's functional status.
- Evaluate adherence strategies and monitor for side effects.
- Before adding a medication to treat symptoms, ensure that the symptom is not attributable to current medications.

Implement the Care Plan:

- Involve the patient, family, and caregivers in development of pharmacologic/nonpharmacologic strategies based on patient's goals.
- Share patient preferences, priorities, and goals with healthcare providers.
- Communicate resuscitation preferences with caregivers and healthcare providers.

Follow-up: Monitor and Evaluate:

- Monitor results following initiation of drug therapy, and discuss findings in context to symptom prioritization, goals, and outcomes.
- Continuous evaluation of therapy as functional status (ie, ambulation, swallowing, continence) changes, and ensure safe and effective medication use.
- Encourage the patient, family, and caregivers to contact the hospice or palliative team with questions.
- Bimonthly reviews of the patient's medical condition, medications, and goals occur during hospice interdisciplinary meetings.

Abbreviations Introduced in This Chapter

5-HT	5-Hydroxytriptophan (serotonin)
ACE	Angiotensin-converting enzyme
ALS	Amyotrophic lateral sclerosis
ARB	Angiotensin receptor blocker
CHF	Chronic heart failure
COPD	Chronic obstructive pulmonary disease
CTZ	Chemoreceptor trigger zone
CVA	Cerebrovascular accident
ESRD	End-stage renal disease
GERD	Gastroesophageal reflux disease
HMG-CoA	Hydroxymethylglutaryl coenzyme-A
NSAID	Nonsteroidal anti-inflammatory drug
PEG	Percutaneous endoscopic gastrostomy
PPIs	Proton pump inhibitors
SSRI	Selective serotonin reuptake inhibitor
WHO	World Health Organization

4 Critical Care Pharmacotherapy

Brittany D. Bissell and Brian W. Gilbert

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Understand the function and role of an intensive care unit (ICU).
2. List the healthcare members that comprise a critical care or intensive care unit team.
3. Differentiate components that comprise an intensive care unit not seen on general floor.
4. Identify key areas in which critical care healthcare providers have impact in patient care.
5. Explain the differences in types of vascular access utilized in critically ill patients for administration of fluids and medications.
6. Formulate a recommendation for nutrition as well as subsequent glycemic control management in the ICU.
7. Discuss indications for neuromuscular blockade in the critically ill patients.
8. Contrast mechanical ventilation modes and parameters of invasive mechanical ventilation.
9. Identify risk factors and prevention strategies for stress ulcers.
10. Design a pain management plan for the critically ill patients.

INTRODUCTION

KEY CONCEPT The intensive care unit (ICU) is a designated place within an institution that is highly specialized and sophisticated, dedicated to managing critically ill patients with potentially recoverable diseases who would benefit from close observation and treatment. There are various types of ICUs including those dedicated to the management of patients with, but not limited to, medical, surgical, traumatic, pediatric, cardiac, or neurological conditions. Typically, the ICU is staffed and equipped for the highest level of acuity possible, given the illness of patients, with designated teams trained in **critical care medicine**.

Patients within the ICU typically have more invasive indwelling devices (eg, intravenous catheters) and procedures, require higher levels of respiratory support than patients on general floors, and have a higher severity of illness. The illness of these patients often leaves them immobile, more **obtunded**, at risk for increased multiorgan failure, and malnourished, requiring frequent monitoring and, often, more nutritional support. Overall, the main functions of an ICU and critical care team are to provide optimal therapies and adequate monitoring for those who may have a high risk of sudden death.

While each specialized ICU may have some slight variations, they all will be equipped to handle mechanical ventilation, circulatory support, renal replacement therapies, and management of shock. The specialized services offered in the ICU are staffed for continuous service, 24 hours a day, should a patient's condition decline. Additionally, there are times a patient may not require the equipment listed above but have disease states or be placed on pharmacologic therapies that necessitate close monitoring, that is not possible on general wards. Each ICU will have different criteria for admission and the realization that patients have high acuity, need for close monitoring, and have a reversible disease state.

Since ICUs are staffed with continuous complex equipment, services, and personnel, they often can incur the highest financial burden on institutions. Therefore, patients are often prioritized for ICU admission to ensure they are not so sick that their care would be futile and, conversely, they are sick enough to have resources allocated toward their recovery that could not be provided elsewhere.[1] Admissions to the ICU can be planned or emergent. For example, a patient undergoing a coronary artery bypass grafting is often a planned admission, whereas, a patient suffering from a traumatic brain injury will require an emergency admission. Formal criteria for admission will likely be institution specific but should be at the discretion of the ICU, general floor, and hospital administration team to ensure patients are being treated at the optimal level of care. Similarly, there are no formal discharge criteria. Given the greater cost associated with ICU beds, patient needs are constantly evaluated to identify those who no longer require the higher intensity of care. Once the acute illness has stabilized and strenuous monitoring or therapy is no longer required, patients are often transitioned to a lower level of care. Similarly, once a patient reaches the point of medical futility, they may be transferred from the ICU into a palliative or comfort care unit.

While the immediate illness of a patient who has been discharged from the ICU may subside, the long-term effects of critical illness has been a focus of clinicians in recent years. **Post-intensive care syndrome** (PICS) describes the disability that is noted after discharge from the ICU and critical illness.[2] Impairments which have been described include, but are not limited to, issues with cognition, mental health disabilities, and recurring physical ailments, specifically neuromuscular weakness. Since PICS has been reported to occur in up to 25% of all ICU survivors, clinician's efforts are aimed at mitigating not only death and morbidity in the short term but also how best to prevent ailments associated with ICU admission long term.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that over 5 million patients are admitted to the ICU within the United States annually with this number expected to rise.[3] The majority of admissions that require ICU care are adult patients with respiratory failure requiring ventilator support, acute myocardial infarction, intracranial hemorrhage or acute ischemic stroke, patients requiring cardiovascular procedures, and sepsis with shock.

The American Hospital Association Hospital Statistics system 2015 survey reported there are 2862 acute care registered hospitals with 2814 of these institutions having at least one ICU bed.[4] In the decade between 2000 and 2010 annual critical care medicine costs increased by 92% from $56.6 billion to $108 billion which represented 0.72% of the entire US gross domestic product.[5] Multiorgan failure, cardiovascular compromise, and sepsis are the leading causes of death within the ICU in the United States.[6] The pharmacotherapies offered within the ICU oftentimes contribute a large percentage of an institution's budget.

ROLES OF VARIOUS HEALTHCARE PROFESSIONALS IN ICUs

The management of critically ill patients requires a robust pool and broad range of healthcare providers who have developed a skill set to aid in the treatment of this subset of patients. Historically, paternalistic medicine, where the physician is regarded as the ultimate authority on the care of the patient, has since been shifted to allow for a team approach while also promoting more autonomy to patients in the decisions of their care. While physicians can often be seen as the "coach" of the team, each member serves a unique role utilizing their highly trained skill set. **KEY CONCEPT** While each ICU team will be constructed differently, the Society of Critical Care Medicine (SCCM) recommends the team that consists of an intensivist, physician assistant or advanced practice registered nurse, critical care nurse, pharmacist, registered dietitian, respiratory therapist, occupational and physical therapist, chaplain, and support staff.[7]

The intensivist is a physician who is trained to care for critically ill patients; they often have subspecialty training in surgery, internal medicine, neurology, pediatrics, nephrology, pulmonary/critical care, or anesthesiology. As the head of the care team the intensivist is responsible for overseeing all aspects of patient care while relying on the rest of their healthcare providers to maximize therapies in each respective area. Their primary role includes, but is not limited to, obtaining medical histories, ordering, and interpreting different diagnostic tests and performing various medical procedures in caring for critically ill patients. In addition to patient care duties, the intensivist often is responsible for the training of younger physicians including interns, residents, and fellows dedicated to the care of critically ill patients.

A physician assistant or advanced practice registered nurse within the ICU acts as an extension of the intensivist. Under intensivist supervision, these midlevel practitioners can perform many of the same functions as the intensivist. Many institutions do not have 24-hour intensivist support, and physician assistants and nurse practitioners can provide their skill sets in the hours an intensivist may not be present. In recent years, advances in technology have allowed for electronic ICU coverage for smaller institutions who may not have an intensivist present during the day, as well as coverage at night.

The critical care nurse is the most visible bedside healthcare provider serving as a liaison between the patient, family, and ICU team. The nurse skill set includes, but is not limited to, obtaining and monitoring samples for laboratory tests, placement of intravenous lines, administration of medications, assessing vital signs, and executing the daily plans developed by the ICU team. Critically ill patients are hyperdynamic requiring extensive monitoring and treatments which necessitate nurse to patient ratios that are lower compared to general floors.

The critical care pharmacist provides pharmacotherapeutic expertise to the ICU team. The scope of what a critical care pharmacist entails has been outlined by the American Society of Health-System Pharmacists, SCCM, and American College of Clinical Pharmacy.[8] The critical care pharmacist is responsible for all aspects of drug therapy management including interpreting test and diagnostic data to recommend therapeutic options, dose optimization, medication reconciliation, monitoring for drug–drug or drug–disease interactions, and education to healthcare providers or patients. Additionally, as many members of the ICU team constantly rotate on or off the critical care service, the pharmacist often is the member who is able to provide key information on the history or management of the patient. Lastly, the critical care pharmacist has a tremendous role in managing pharmacological therapies as it relates to transitions of care, such as transitioning patients from parenteral to oral treatments. Patients are initiated on medications during the acute illness that may not be appropriate once the process has subsided; therefore, the pharmacist's perpetual review of the medication profile can be crucial to prevent inappropriate therapies from reaching the patient or medication errors.

During critical illness, patients often have complex caloric and other nutritional needs that are evaluated by a registered dietitian. Nutritional needs are assessed not only for the appropriate caloric totals but appropriate combination of macro- and micronutrients. In conjunction with a critical care pharmacist, dietitians work to provide patients with enteral or parenteral feeding goals. The registered dietitian interprets laboratory results and diagnostic tests to ensure appropriate caloric needs are met.

Frequently, patients with critical illness develop respiratory distress or failure that requires various forms of oxygenation or ventilator support. A respiratory therapist works in conjunction with the critical care team to support these needs with various forms of supplemental oxygen, noninvasive mechanical ventilation, or invasive forms of mechanical ventilation. The respiratory therapist, in conjunction with the intensivist or nurse, will follow protocols to adjust or support the oxygenation or ventilatory needs of the patient.

A large portion of the management of critical illness is to ensure survival; however, the quality of life post illness is just as important. Physical therapists work to ensure appropriate muscle, bone, tissue, and nerve function to improve daily life activities. Occupational therapists work with patients to help regain life skills to ensure that their activities of daily living are maximized. Early mobility, with physical therapists, and continued focus on living as independently as possible, by occupational therapists, has been a growing area of research in critical care. Speech pathologists are trained specialists who work with patients in the management of communication and swallowing disorders secondary to critical illness.

During critical illness there is a tremendous amount of emotional support needed for the patient, family, and ICU team.

Patient Encounter Part 1

A 62-year-old man presents to the neurological ICU after experiencing a massive ischemic stroke to his middle cerebral artery. In the emergency department, the patient received intravenous thrombolytic therapy as well as endovascular thrombectomy of the clot. While unable to speak due to his stroke, his previous admissions showed his wife was his surrogate and did not have advanced directives in place.

What information presented would warrant this patient to have an ICU admission?

Which healthcare providers do you believe should be a part of this patient's neurological ICU team?

Emotional and spiritual support is often provided by a chaplain or, at a minimum, organized so that the patient's or family's spiritual needs are met during the time of critical illness. The chaplain has a large role during end-of-life care to support the needs of the patient, family, and those involved in the care of the patient.

Lastly, there are numerous support staff that aid the ICU team during the management of critical illness. Environmental services, child life specialists, hospital informatics, and many more are needed to have a functioning ICU.

INTRAVENOUS ACCESS

KEY CONCEPT Establishment of intravenous (IV) access is essential for care of critically ill patients. Venous access is a direct route into the bloodstream for administration of medications, fluid resuscitation, delivery of parental nutrition, to administer nonpharmacologic treatments such as dialysis, or to obtain blood for analysis or noninvasive hemodynamic monitoring. Types of venous access devices (VADs) include peripheral IV lines, midline peripheral lines, peripherally inserted central catheters (PICCs), and central catheters.[9] Peripheral lines are most often placed in the arm or hand as well as in the foot. Guidelines recommend rotating these sites every 72 to 96 hours to prevent phlebitis.[9] Central catheters terminate in the veins within the thoracic cavity and are indicated for the administration of medications which may cause harm if administered peripherally, such as vesicants (examples include calcium chloride, hypertonic saline, and vasopressors or chemotherapy). Further, central catheters are placed for administration of intravenous products in large quantity or over a longer period of time, for long-term access for procedures, or when peripheral access cannot be obtained.

Midline peripheral catheters are alternatively placed within the antecubital vein and extend roughly 20 cm long, allowing for a longer duration of retention (1–4 weeks) as they are at less risk of failure from displacement compared to shorter peripheral lines. However, as the tips of these catheters terminate prior to the central veins, their use has fallen out of favor secondary to an increase in PICCs. While central venous catheters are typically placed within the internal jugular, subclavian, or femoral vein, a PICC is a central line that is placed peripherally in the basilica, brachial, or cephalic vein but terminates in a central vein. A PICC can be in place up to 6 months. While skin-tunneled catheters and implanted ports are considered types of central access, most patients in the ICU receive nontunneled catheters given they are intended for more short-term use. Catheters range in length and diameter, ranging typically from 14 gauge (2.1 mm diameter and 45 mm length) to 26 gauge (0.6 mm diameter with 19 mm length) and are color coded. Selection of catheter is determined based on patient anatomy, provider preference/expertise, overall desired use of the catheter, and device risk. Wider diameters are necessary for faster or large infusion volumes but can be at higher risk of complications.[10,11] Complications of VAD include infection, thrombosis, **pneumothorax**, **hematoma**, among others.[11]

An alternative access site is intraosseous (IO). This catheter is placed directly into the bone marrow using a drill, providing a noncollapsible venous entry. This mode should only be used when IV access is not obtainable. Locations for access include the proximal femur, proximal humerus, and the tibial tuberosity. All medications can be administered via IO; however, **pharmacodynamics** and **pharmacokinetics** can be altered.

PHARMACOKINETICS AND PHARMACODYNAMICS

KEY CONCEPT Multiple pharmacokinetic aspects may be altered within the ICU population. Within critical illness, decreased subcutaneous or gastrointestinal perfusion may occur secondary to shock or vasopressor use.[12] Because of altered perfusion, in combination with the use of enteral nutrition, decreases in area under the curve (AUC) for some medications are seen. Drug distribution can be altered within the critically ill for a variety of reasons. Decreases in cardiac output from shock or mechanical ventilation can decrease drug distribution. Poor peripheral perfusion can result in a reduction in free drug concentration at local tissues. Fluid resuscitation can increase volume of distribution for hydrophilic medications, decreasing peak concentration.[12] Reductions in serum albumin and increases in α1-acid glycoprotein can result in alterations in free drug concentrations (eg, phenytoin). Hepatic blood flow can be reduced while hepatic enzymes can be inhibited and/or induced by critical illness or commonly administered medications, resulting in potential for both reduction and increase of low extraction ratio medications. Regarding elimination, roughly 25% of patients with critical illness present in acute kidney injury (AKI), decreasing the clearance of renally eliminated drugs.[12] Alternatively, patients can present with augmented renal function that increases clearance. The use of renal replacement therapies for AKI can have a variable effect on clearance depending on type of therapy and drug (see Chapter 26).

Regarding pharmacodynamics, doses of medications are titrated or monitored based on clinical parameters, such as blood pressure, sedation, and pain. Most studies of pharmacodynamics in this population have centered on antimicrobials as they do not have a an effect that can be visually monitored clinically and are often prescribed within the ICU.[13] An increasing amount of evidence supports prolonged versus standard interval administration of time-dependent antibiotics (such as 3-hour cefepime or meropenem infusions vs 30-minute infusions).[13] Further, increasing evidence supports the use of vancomycin continuous infusion given the potential increase in AUC/minimum inhibitory concentration (MIC) ratio. Aminoglycosides or other purely concentration-dependent antibiotics rely on high maximum concentration/MIC ratios. Given the pharmacokinetic alterations in critically ill patients, these anti-infectives may require higher empiric dosing than a noncritically ill population.

INVASIVE AND NONINVASIVE VENTILATION

KEY CONCEPT Mechanical ventilation, the provision of an external source of ventilation and often oxygenation, is used frequently within the ICU for patients presenting in respiratory failure and can be either noninvasive or invasive.[14] Noninvasive ventilation, such as bilevel positive airway pressure (BiPAP) or continuous positive airway pressure (CPAP), is oxygen supplementation administered without placement of an endotracheal tube (ETT). BiPAP, when worn continuously, requires ICU level of care for risk of aspiration. Alternatively, nighttime BiPAP can be worn on general medical floor. Noninvasive ventilation can decrease invasive ventilation (endotracheal intubation), decreasing complications, such as ventilator-associated pneumonia as well as death, and decreasing overall duration of stay.[14] Noninvasive ventilation can be provided via a nasal mask, helmet, or an oronasal mask (facial mask), with the latter being the most common. Guidelines currently recommend noninvasive ventilation for patients with hypercapnia secondary to an exacerbation of chronic obstructive pulmonary disease, cardiogenic edema, immunocompromised, postoperative, palliative care, trauma, postextubation in high-risk patients, and weaning in hypercapnia, all in the setting of acute respiratory failure.[15]

Invasive ventilation can be performed via an ETT or tracheostomy tube. The ETT allows for ventilator support while also providing airway protection. Breaths on the mechanical ventilator are administered via triggering, defined as the initiation of a breath, and cycling, which is simply defined as the end of a breath. Breaths are classified as volume, pressure, or time cycled. Volume breaths end after a certain volume is delivered; pressure breaths end after a certain pressure is reached; and time cycles end dependent on a prespecified duration.[16] Mechanical ventilation can be either full support, delivering all ventilatory needs, or partial support, acting as a supplement to the patient's own respiratory effort. Important parameters for the mechanical ventilator can be found in Table 4–1. A full review of mechanical ventilation is beyond the purpose of this chapter. Endotracheal intubation also uniquely provides an additional route of drug administration for medications. Medications that can be administered via the ETT include naloxone, atropine, vasopressin, epinephrine, lidocaine, and others. Inhalation solutions and metered-dose inhalers (MDIs) can be administered via the ventilation circuit but not dry powder inhalers.

After initial noninvasive airway approaches have been exhausted, clinicians may consider endotracheal intubation for invasive ventilation that will likely require **rapid sequence intubation** (RSI). RSI is an airway procedure that aims to reduce the incidence of complications of placing an endotracheal tube. During the procedure agents are utilized to induce an amnestic state while also causing muscle relaxation to allow for easier passage of the tube to the lungs. Commonly utilized medications for RSI include propofol, ketamine, etomidate, midazolam, fentanyl for induction, and rocuronium, vecuronium, and succinylcholine for paralysis.

Table 4–1

Common Ventilator Parameters

Parameter	Definition	Normal Range
Tidal volume	Volume of air inhaled or exhaled during a normal respiratory cycle	6–8 mL/kg
Respiratory rate	Breaths given per minute	8–12 breaths/min
Fio$_2$	Fraction of inspired oxygen	21% room air
I/E ratio	Ratio of inspiratory to expiratory time	1:2
PEEP	Pressure within the lungs after exhalation phase to increase alveoli diffusion	5 cm H_2O (0.5 kPa)
Peak pressure	Pressure at end of inspiration	40 cm H_2O (3.9 kPa)
Plateau pressure	Pressure in alveoli between inspiration and expiration	< 30 cm H_2O (2.9 kPa)

I/E, inspiratory: expiratory ratio; PEEP, positive end expiratory pressure.

While listed as paralysis with induction, it is important to note that paralysis without induction should never occur. When deciding the appropriate agents for RSI, the healthcare provider must take into consideration numerous confounders including patient's vital signs, comorbidities, medication pharmacokinetics, and pharmacodynamics. Table 4–2 gives an overview of the commonly utilized medications for paralysis and induction during RSI. Understanding appropriate pharmacokinetic, pharmacodynamic, and adverse events profiles can aid clinicians at selecting the ideal agent for their patient.

PAIN, AGITATION, DELIRIUM, AND SLEEP

Pain, agitation, delirium, immobility, and sleep (PADIS) management in patients within the ICU is complex. Each modality is highly individualized to the patient and is determined by a multitude of factors including, but not limited to, illness severity, comorbidities, concurrent medications, and patient demographics. Practice guidelines have continued to evolve as the understanding of the pathophysiology of critical illness changes with the approach to PADIS.[17]

Patients experience pain in a highly individualized manner. Acute, chronic, or acute-on-chronic pain can manifest in different ways, and understanding that the source of pain, whether it be somatic, visceral, or neuropathic pain (see Chapter 35), also produces phenotypically separate patterns can be quite challenging for management. Pain itself, can be considered as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[17] ICU clinicians will rely on a patient's self-reported pain; however, if a patient is unable to communicate the experience to providers, this does not negate the fact they may still be experiencing pain and can be assessed by other objective tools such as the Critical Care Pain Observation Tool or Behavioral Pain Scale. There are negative consequences associated with untreated pain, therefore, the PADIS guidelines attempt to standardize the treatment of pain with a multimodality pharmacological approach. The utilization of opioids, such as fentanyl, morphine, and hydromorphone, remains the cornerstone of treatment for pain in the ICU for mechanically ventilated and nonmechanically ventilated patients. However, as opioids have known adverse drug events, like oversedation, respiratory depression delirium, hypotension, and decreased gastrointestinal (GI) motility, the guidelines have promoted the use of a multimodal approach to pain. Concurrent treatments such as acetaminophen, nonsteroidal anti-inflammatory drugs, lidocaine, ketamine, and neuropathic pain medications (eg, gabapentin, pregabalin) have roles in select patients at reducing daily **morphine equivalents**. Patients often will receive combinations of these therapies via the intravenous, oral, rectal, or even transdermal routes. **KEY CONCEPT** The practice of analgesia-first sedation, or **analgosedation**, is a sedative-sparing technique which has shown improved ventilator-free days as well as reductions in ICU length of stay. Fentanyl is the most common opioid used in the United States for analgesic sedation. In addition to pharmacologic management of pain there are recommendations for nonpharmacologic therapies such as music, pet,

Table 4–2

Commonly Utilized Induction and Paralysis Agents

Agent	Utilized for Induction or Paralysis	Dosing	Adverse Reactions
Midazolam	Induction	0.2–0.3 mg/kg IV	Respiratory depression, hypotension
Etomidate	Induction	0.3 mg/kg IV	Adrenal suppression
Propofol	Induction	1–2 mg/kg IV	Hypotension, bradycardia, respiratory depression
Ketamine	Induction	0.5–1.5 mg/kg IV	Increased secretions, nystagmus, laryngospasm
Succinylcholine	Paralysis	1–1.5 mg/kg IV	Hyperkalemia, bradycardia, malignant hyperthermia
Vecuronium	Paralysis	0.1 mg/kg IV	Caution with hepatic or renal dysfunction
Rocuronium	Paralysis	0.6–1.2 mg/kg IV	Caution with hepatic or renal dysfunction

massage, temperature control, and relaxation techniques, which are beyond the scope of this chapter.

Anxiety is quite prevalent within the ICU, especially in mechanically ventilated patients, and sedatives are often needed to reduce the stress associated with routine ICU care. As previously discussed, patients within the ICU often have an analgesia-first approach to sedation but, if anxiety is not relieved by this approach, agents like benzodiazepines, propofol, or dexmedetomidine are utilized in the mechanically ventilated patient. Validated scales, such as the Richmond Agitation-Sedation Scale (RASS) or Riker Sedation-Agitation Scale (SAS), are utilized to assess the degree of sedation. A paradigm shift has occurred in the management of critically ill mechanically ventilated patients from utilizing deep levels of sedation, considered to be comatose, to lighter levels, or arousable levels, of sedation which has improved clinical outcomes. However, deep levels of sedation are needed for refractory status epilepticus, paralysis, or refractory elevations in intracranial pressures. The PADIS guidelines recommend utilizing nonbenzodiazepines, such as propofol or dexmedetomidine, to maintain a light goal of sedation and to minimize delirium.

Delirium is a clinical diagnosis that is detected utilizing the Confusion Assessment Method for the ICU scale (CAM-ICU) and is associated with worse outcomes, such as increased associated healthcare costs, hospital, ICU length of stays, and mortality. At this time there are no Food and Drug Administration (FDA)-approved treatments for delirium, and management strategies include trying to prevent delirium by reducing benzodiazepine utilization, patient reorientation, improving sleep hygiene, early mobilization, and lighter sedation strategies.

Proper sleep and sleep hygiene within the ICU can serve an important role. Patients in the ICU can experience sleep disturbances, including disruptions in normal circadian rhythms, from their critical illness as well as being in a noisy environment, not conducive to sleep due to disruption, light patterns, and patient monitoring. By minimizing noise and light disturbances, ICU clinicians may improve sleep patterns. Currently, the PADIS guidelines provide no pharmacotherapy recommendations for improving sleep patterns.

GLYCEMIC CONTROL

KEY CONCEPT Optimal glycemic control within the critically ill patients has been an evolving concept for decades. Hyperglycemia is common in the setting of the stress response. Endogenous inflammation and corticosteroids can result in elevation of blood glucose values. The consequences of poor glucose control are infection and poor wound healing. Studies that signaled potential benefit of tighter glucose control (< 110 mg/dL [6.1 mmol/L]), however, were contradicted by a much larger study that demonstrated higher mortality with glucose goals less than 100 mg/dL (5.6 mmol/L) compared to a target of less than 180 mg/dL (10 mmol/L).[18–20] This is likely attributed to the higher incidence of hypoglycemia with intensive glucose control in the larger study. Hypoglycemia has the potential to worsen autonomic function, alter blood flow and composition, while also altering immune cell mediation and release as well as vasoconstriction. Moderate hypoglycemia (41–70 mg/dL [2.3–3.9 mmol/L]) is associated with a 40% increase in mortality, while severe hypoglycemia (< 41 mg/dL [2.3 mmol/L]) has been associated with a doubled risk of death.[21]

Of growing interest is the concept of glycemic variability, or glucose fluctuations, within the critically ill patients rather than set values for hyper- and hypoglycemia. Glycemic variability has yet to be definitively defined, and its causative role in outcomes is unknown.[22] For this reason, guidelines currently recommend initiation of insulin therapy after two consecutive blood glucose values greater than 180 mg/dL (10 mmol/L) to reach a goal of less than 180 mg/dL (10 mmol/L), with glucose checks every 1 to 2 hours.[23] Guidelines also recommend the utilization of an insulin infusion over subcutaneous dosing while cautioning against the use of point-of-care capillary glucose testing over plasma testing given potential inaccuracy given physiologic changes in this population.

STRESS ULCER PROPHYLAXIS

Upper gastrointestinal bleeding is a known consequence of acute illness secondary to changes to the gastroduodenal mucosa. Inflammatory changes, splanchnic hypoperfusion, and altered microcirculation result in an altered mucosal barrier, increasing potential for gastrointestinal bleeding.[24] The significance of these changes is less clear. While historic cohorts demonstrated an incidence of overt bleeding, defined as hematemesis, frank blood or coffee-grounds in aspirate, or melena, between 5% and 25%, the incidence of clinically important bleeding (CIB) is between 0% and 5%. CIB is overt bleeding with the addition of one or more of the following:

1. Blood pressure drop of 20 mm Hg or more in 24 hours.
2. An orthostatic increase in pulse of at least 20 beats/min and decrease in systolic blood pressure of 10 mm Hg.
3. A decrease in hemoglobin of 2 g/dL (20 g/L; 1.24 mmol/L) or moreover a 24-hour period or transfusion or 2 units of red blood cell transfusion within 24 hours.
4. An invasive intervention required, such as vasopressors or endoscopy.

Critically ill patients are at the highest risk of CIB with two risk factors independently associated with gastrointestinal bleeding:

Table 4–3

Risk Factors for Stress-Related Mucosal Changes

Independent	Relative
Coagulopathy, defined as platelet count < 50,000 /mm^3 (50×10^9/L, INR > 1.5, or PTT > 2 × control value	Spinal cord injury Multiple trauma Hepatic failure
Respiratory failure requiring mechanical ventilation ≥ 48 hours	Thermal injury > 35% body surface area Partial hepatectomy Head injury with Glasgow coma score < 11 History of gastric ulcer or bleed within 1 year Sepsis/septic shock ICU stay exceeding 1 week Occult or overt bleeding for 1 week Corticosteroids

ICU, intensive care unit; INR, international normalized ratio; PTT, partial thromboplastin time.

mechanical ventilation for 48 hours or longer and coagulopathy. Other relative risk factors can be found in Table 4–3.[25]

Guidelines recommend the initiation of prophylaxis against CIB in the presence of an independent risk factor or two other risk factors within the ICU. Notably, these guidelines were established over two decades ago, with growing concern for overutilization of prophylactic regimens and potential for harm in the setting of low incidence of CIB. Stress ulcer prophylaxis has been shown to decrease the incidence of overt bleeding with mixed evidence on impact for CIB. Choices for prophylaxis include histamine-2 receptor antagonists and proton pump inhibitors. Previously evaluated choices, including antacids and sucralfate, have fallen out of favor secondary to administration difficulties or lack of efficacy. Studies evaluating these agents show a slight benefit of proton pump inhibitors therapy over histamine-2 receptor antagonists for decreasing incidence of bleeding overall.[26] No difference in adverse events has been routinely found between groups.

Increasing attention has been given to the usefulness of enteral nutrition in preventing bleeding of patients receiving enteral nutrition. Early studies of CIB were performed prior to data demonstrating benefit of early feeding in this population. As standards of care have evolved to include early enteral nutrition, recent evidence has sought to evaluate its use over pharmacologic prophylaxis. In patients receiving enteral nutrition, current data support continuing pharmacologic prophylaxis at the time to decrease incidence of CIB; however, it is unclear if this has any impact on clinical outcomes such on clinically important events or mortality.[27]

THROMBOPROPHYLAXIS

Disruption in normal hemostatic functions occur regularly in the critically ill patient populations. Venous thromboembolism (VTE) is a general term where patients experience inappropriate clot formation causing deep vein thrombosis (DVT) or pulmonary embolisms (PEs). A PE typically occurs after embolization of a lower extremity DVT but can occur even without the presence of a DVT. The incidence rate of VTE is largest in those with the highest acuity, specifically in patients with traumatic injuries or septic shock.[28,29] The prophylaxis against VTE development is vital to the critically ill patient as it can reduce mortality. KEY CONCEPT Risk factors for the development of DVT or PE may be stratified by modifiable or nonmodifiable risk factors (Table 4–4). A risk assessment tool that has been validated to predict VTE in medical patients, the Padua Score, is often utilized to help stratify patients at low and high risk for inappropriate clot formation.[30] The score assesses factors which place patients at higher risks for VTE development such as reduced mobility, advanced age (≥ 70 years), obesity, previous VTE, recent trauma or surgery, known hematological conditions, heart or respiratory failure, acute coronary syndrome, acute ischemic stroke, active infection, and ongoing treatment with hormonal pharmacologic therapies.

Heparinoids, such as low-molecular-weight heparin (LMWH) and unfractionated heparin (UFH), are the most widely utilized thromboprophylaxis agents administered in critically ill patients. Multiple factors are utilized when deciding on whether to utilize LMWH or UFH in the critically ill patient population and which dose to administer. Type of critical illness, renal function, and body habitus are just a few of the deciding factors when selecting a heparinoid for VTE prophylaxis.[31] For patients in the surgical or trauma setting LMWH, such as enoxaparin, is preferred over UFH and typically dosed as enoxaparin 30 mg subcutaneously every 12 hours. Dose adjustment is based on body habitus or anti-Xa levels. Medical patients or those with renal dysfunction primarily receive 5000 units of UFH subcutaneously every 8 hours, however, may be dose adjusted again for body habitus or enoxaparin 40 mg subcutaneously once daily.

In addition to heparinoids, there is an increased interest in utilizing the direct oral anticoagulants (DOACs) in the critically ill patient population including their use for VTE prophylaxis. However, when compared to the heparinoids, the DOACs have shown no difference in VTE occurrence while increasing bleeding risk.[32] At this time DOACs should not be utilized instead of heparinoids for thromboprophylaxis in critically ill patient populations while in the inpatient setting.[31,32]

Fondaparinux at 10 mg administered subcutaneously or a continuous infusion of IV argatroban are at times utilized in clinical scenarios where heparinoids are contraindicated such as heparin-induced thrombocytopenia.

In addition to chemical VTE prophylaxis, patients should also receive mechanical prophylaxis with agents such as sequential compression devices (SCDs). An SCD is an inflatable sleeve that primarily rests on the patient's lower legs and is then inflated, which promotes blood perfusion rather than venous stasis, a known risk factor for VTE development. In addition to mechanical motion the inflation provides, the increased blood velocity decreases tissue factor release, increases fibrinolysis, and releases endogenous heparin from the endothelium.[33,34] While

Table 4–4

Example of Risk Factors for the Development of Venous Thromboembolism

Nonmodifiable Risk Factors	Modifiable Risk Factors
Factor V Leiden or hematological disorders	Immobility
Age > 40 years	Medications
Familial history of thrombosis	Obesity
Oncological disorders	Transfusion related
Male sex	Surgery or trauma

SCDs certainly have numerous benefits, they should not be the sole therapy for prevention of VTE in critically ill patients unless chemical prophylaxis is contraindicated, such as patients who are actively hemorrhaging.

Prevention of VTE in critically ill patients poses a unique challenge in that clinicians must weigh the risk of thromboprophylaxis with bleeding risk. Clinicians should evaluate the factors associated with the patient's risk of thrombosis with risk of bleeding while continually monitoring laboratory values and clinical criteria to hold or administer thromboprophylaxis. For example, patients with traumatic brain injury are at high risk for the development of VTE, but anticoagulation could cause hematoma expansion within the brain. A clinician must understand when the risk outweighs the benefit and if those risk and benefits change throughout a patient's illness.

BOWEL PROPHYLAXIS

KEY CONCEPT Critically ill patients experience numerous disruptions in normal homeostatic functions, including abnormalities within their GI tract. Irregularities in bowel motility can occur in critically ill patients secondary to acute illness, bed rest, medications, and dietary variances.[35] Constipation, during critical illness, has been reported to occur in up to 83% of patients, which may affect important clinical outcomes such as mechanical ventilation, ICU length of stay, or even mortality by contributing to increased intra-abdominal pressures, ileus, or prevented ventilator weaning.[36] While diarrhea can occur in critically ill patients, it is not as prevalent and often linked with an infectious etiology or the result of an adverse drug event.

Definitions of constipation vary but can be thought of as the lack of defecation over a specific time period (typically less than three stools per week). Constipation has been associated with increased abdominal distension, pain, diet intolerance, vomiting leading to aspiration, and obstructions.[37] Common agents used to treat constipation include laxatives (eg, polyethylene glycol, bisacodyl, or senna) and, in certain cases, prokinetic agents like metoclopramide. These agents would ideally be administered prior to constipation symptoms occurring as prophylaxis. Opioids are commonly utilized within critically ill patient populations and can be associated with a phenotypically different type of constipation than a patient who has a bowel obstruction. Initially management of constipation in critical illness will consist of bulk forming or osmotic laxatives, such as, psyllium or polyethylene glycol, with the addition of a stool softener, such as docusate. If response is not achieved after the addition of these agents, stimulants, such as senna are reasonable options.

In addition to selecting the appropriate agents as a bowel prophylaxis, proper regimens to ensure euglycemia, electrolyte and fluid management, and adequate enteral feeding can be used to mitigate ICU-associated constipation. Lastly, early mobility exercises improve clinical outcomes including those associated with GI motility.[38]

NEUROMUSCULAR BLOCKADE

Neuromuscular blockade, or pharmacologic paralysis, can be used for a variety of reasons within the ICU aside from RSI, including acute respiratory distress syndrome (ARDS) and therapeutic hypothermia, also known as code chill, following cardiac arrest. Currently, use of neuromuscular blockade is not recommended for status asthmaticus while no recommendations are made for its use for elevated intracranial or intraabdominal pressure.[39] Neuromuscular blockers are initiated only after a deep level of sedation is documented. Neuromuscular blockers can be divided into two types: depolarizing and nondepolarizing. Because of the adverse event profiles in combination with issues surrounding organ dysfunction within the critically ill patients, cisatracurium (nondepolarizing) is usually selected first line in this population as it is not hepatically metabolized or renally excreted (Hoffman elimination). Because of its slower onset of effect, cisatracurium is not used in emergent scenarios such as RSI.[40] Neuromuscular blockade is titratable based on disease-specific parameters or depth of paralysis. Depth of paralysis can be monitored using a peripheral nerve stimulator. This device delivers four electrical impulses at a time to the ulnar or facial nerves and assesses response. No twitches in response to stimulation would mean complete paralyzation while four twitches in response would be no, or minimal, paralyzation. The neuromuscular blocker dose is titrated based on twitch response.

Complications of neuromuscular blockade include prolonged weakness, corneal abrasions, and thrombosis. For this reason, patients require monitoring and use of prophylactic regimens such as eye lubrication and VTE prophylaxis.

Patient Encounter Part 2

A 62-year-old man presents to the neurological ICU after experiencing a massive ischemic stroke to his middle cerebral artery. In the emergency department, the patient received intravenous thrombolytic therapy as well as endovascular thrombectomy of the clot. While unable to speak due to his stroke, his previous admissions showed his wife was his surrogate and did not have advanced directives in place. He is intubated for airway protection; additionally, the attending begins to discuss goals of care given the patient's debilitating stroke and options in terms of recovery.

What therapies should we consider for this patient now that they are intubated?

If the patient requires paralysis during mechanical ventilation, what supportive care must be considered?

FEEDING AND NUTRITION

Nutrition can be administered either via an enteral (via a feeding tube into the stomach) or parenteral (IV) route, with the latter reserved for situations where enteral nutrition is not feasible or possible. Nutrition supplementation is started early in poorly nourished patients but can be delayed up to 7 days following admission in patients at low nutritional risk. Enteral nutrition (EN) (see Chapter 101), if it is possible, should be initiated within 24 to 48 hours of ICU admission.[41] Delaying can worsen risk of gastromucosal changes, bacterial translocations, and ileus. The contraindications to EN are bowel obstruction, perforation, mesenteric ischemia, or major GI bleeding. Typically, EN can be started at roughly 25% to 50% of the caloric goal, increasing to target over 72 hours, up to 1 week. While a variety of formulations exist for EN, there is no evidence to support the utilization of one over another. Patients who have trouble tolerating EN can be supported with placement of their feeding tube after the pylorus or with prokinetic agents to increase gut motility. Patients should roughly be given 25 kcal/kg/day (105 kJ/kg/day) of EN with 1 to 2 g/kg of protein accounting for a significant portion of caloric intake.

There are considerations to make for special populations. Patients with renal failure complicated by electrolyte abnormalities may warrant renal-specific formulations, while immune-modulating formulas may be helpful in the trauma-surgical population. Patients who have diarrhea should be started on tube feeds with fiber or small peptides, and fluid-restricted formulations can be considered in those patients with volume overload. In obese patients, a lower caloric need is necessary, roughly 11 to 14 kcal/kg/day (46–59 kJ/kg/day) or 22 to 25 kcal/kg/day (92–105 kJ/kg/day) of ideal body weight, once a body mass index exceeds 50. In the obese, protein should be administered at 2 to 2.5 kcal/kg/day (8–10.5 kJ/kg/day). Refer to Chapters 100 and 101 for further information on nutritional support.

END-OF-LIFE CARE/COMFORT CARE

There are times that the interventions performed by the ICU team are ultimately unsuccessful or would be futile to pursue. Comfort care therapy is a compassionate part of the end-of-life process that aims to prevent or relieve discomfort, suffering, or pain to improve the quality of life for a patient. The decision to pursue comfort care or end-of-life management involves a physician and the patient, if able, or caregivers who know the advanced directives of the patient.[42] After all curative therapies have been exhausted or have been deemed ineffective, the attending physician will typically begin discussing goals of care with the patient, caregivers, and team. Should the patient be incapable of making decisions on goals of care, and no caregivers are available, the discussion will include other providers involved in the patients care. In some discussions, the ethics team may be involved.

Comfort care management can be vital to ensure the patient does not have protracted pain or discomfort during the dying process. Sedatives, such as lorazepam, opiates, such as morphine, and steroids, such as dexamethasone, are often utilized to relieve anxiety, pain, or inflammation-related discomfort. Atropine or glycopyrrolate can be administered orally or intraocular to minimize secretions. In addition to pharmacologic therapies, nonpharmacologic therapies have a role at managing anxiety, pain, and depression. Aromatherapy, music therapy, and pet therapy are just a few of the different strategies that have shown success

Patient Encounter Part 3

A 62-year-old man presents to the neurological ICU after experiencing a massive ischemic stroke to his middle cerebral artery. In the emergency department, the patient received intravenous thrombolytic therapy as well as endovascular thrombectomy of the clot. While unable to speak due to his stroke, his previous admissions showed his wife was his surrogate and did not have advanced directives in place. He is intubated for airway protection; additionally, the attending begins to discuss goals of care given the patient's debilitating stroke and options in terms of recovery. Family decides to continue full care; however, after intubation, the patient becomes hemodynamically unstable requiring vasopressors.

What considerations need to be made for the pharmacotherapy regimen given the acute change?

What type of questions would you consider in determining goals of care for this patient?

Patient Care Process

Collect Information:

- Collect past medical history as well as home medication reconciliation.
- Gather pertinent laboratory values, particularly regarding organ function and perfusion.
- Evaluate IV fluids, current medication list, and nutrition prescriptions. Identify current lines and devices and pertinent parameters, such as dialysis or mechanical ventilation.
- Evaluate vital signs, such as fluid balance, blood pressure, oxygenation, and daily weights.

Assess the Information:

- Ensure that all medications are dosed for organ dysfunction, such as liver failure or renal dysfunction.
- Assess whether IV lines are appropriate based on current medication list.
- Evaluate need for additional regimens, such as stress ulcer prophylaxis or DVT prophylaxis.
- Assess whether patient infusions and medications are targeting appropriate goals and whether such is being achieved.
- Evaluate current goals of care, ranging from primary problem to end-of-life care.

Develop a Care Plan:

- Discuss plan of care with team and patient-specific considerations.
- When possible, discuss options with patient and patient's family.
- Determine appropriate plan based on current laboratory results, vital signs, and other patient-specific parameters.
- Implement prophylaxis in patients at risk of complications.
- Determine appropriate monitoring parameters for current goals of care.

Implement the Care Plan:

- Deliver recommendations to the interdisciplinary team.
- Assess orders for changes necessary to medication dosing or to end target goals (ie, target mean arterial pressure or blood glucose).
- Relay information to next shift to ensure continuity of care.

Follow-up: Monitor and Evaluate:

- Continue to evaluate pertinent laboratory values, particularly regarding organ function and perfusion.
- Evaluate medication profile and consider discontinuation of medications not clinically necessary.
- Monitor changes in intake and output, vital signs, such as blood pressure, oxygenation, and daily weights.
- Evaluate trajectory of clinical support needed, such as dialysis, mechanical ventilation, and other devices.

in the end-of-life process in conjunction with pharmacologic therapies.[43] While the pharmacologic and nonpharmacologic therapies listed above are not all encompassing, they do represent a cornerstone of the end-of-life comfort care management.

The end-of-life process, like critical care, should incorporate those with specialized training in the management of dying patients in the form of palliative care physicians, nurses, physician assistants, chaplains, pharmacists, and social workers. Effective communication and expectation management are a crucial aspect of the end-of-life process, which can require having in-depth conversations with patients who may not have acknowledged their own mortality. Open dialogue about the end-of-life process can reduce fear, anxiety, and even depression associated with it. Standard institutional protocols can create a systematic approach to the care of end-of-life patients; however, targeted goals of therapy, as it relates to the end-of-life process, should be assessed daily from the team, patient, or caregivers. Lastly, screening may occur during the comfort care process for organ procurement in select patients. Further information about this care can be found in Chapter 3.

The end-of-life or comfort care process is vital to ensuring patients are relieved from suffering during the dying process. Communication, training, and team-based guidance on goals of care can ensure optimal comfort treatment in the patient's most vulnerable state.

Abbreviations Introduced in This Chapter

AUC	Area under the curve
AKI	Acute kidney injury
ARDS	Acute respiratory distress syndrome
CIB	Clinically important bleeding
DOAC	Direct oral anticoagulation
DVT	Deep vein thrombosis
EN	Interal nutrition
ETT	Endotracheal tube
ICU	Intensive care unit
IV	Intravenous
LMWH	Low-molecular-weight heparin
MIC	Minimum inhibitory concentration
PADIS	Pain, agitation, delirium, immobility, and sleep
PICS	Post-intensive care syndrome
PICC	Peripherally inserted central catheter
PE	Pulmonary embolism
PPI	Proton pump inhibitor
RSI	Rapid sequence intubation
SCCM	Society of Critical Care Medicine
SCD	Sequential compression device
UFH	Unfractionated heparin
VAD	Venous access devices
VTE	Venous thromboembolism

Global Health and Travel Medicine

Sonak D. Pastakia, Alyssa P. Gould,
Benson N. Njuguna, and Jeffrey W. Hall

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discern the difference between equality and equity.
2. Explain the social determinants of health and their contribution to health outcomes.
3. Identify the main contributors to the global burden of disease.
4. Contrast benefits and possible harms of cross-cultural health work.
5. Discuss neglected tropical diseases and the different treatment approaches used to manage them.
6. Discuss the different components of medication access to optimize health outcomes.
7. Describe the key components of a pretravel consultation.
8. Summarize the advantages and disadvantages of four antimalarial prophylactic regimens.
9. Explain the difference between prophylactic and self-directed therapy for traveler's diarrhea.
10. Identify two reasons for urgent evaluation of returned travelers with illness.

INTRODUCTION

Global health is an effort to reduce health inequities for people all over the world. Prior to the 1800s, average life expectancy was 30 to 40 years globally. Since then, advancements in agriculture, economics, public health, medicine, and society have led to dramatic improvements in health, including increased life expectancy and decreased under-five mortality (Figure 5–1). However, significant variations persist across different world regions, underlined by health inequities.[1,2]

The field of global health rose in part from a recognition of these inequities, aiming to alleviate them. Numerous international development organizations, philanthropic foundations, academic medical centers, and development consulting firms have consistently devoted economic and/or human resources to global health practice. This includes, but is not limited to, the United States Agency for International Development (USAID), United Kingdom Agency for International Development (UKAID), Swedish International Development Cooperation Agency (SIDA), German Agency for International Cooperation (GiZ), Japan International Cooperation Agency (JICA), United Arab Emirates International Development Cooperation, the Gates and Rockefeller foundations, and Family Health International 360 and Management Sciences for Health. Government-based organizations have typically provided the most aid with the United States providing the most funding in terms of absolute amount of overseas development assistance and Sweden providing the highest percentage of gross national income as seen in Figure 5–2.[3]

KEY CONCEPT Of note, global health does not necessarily refer to high-income countries supporting lower-income ones, as this is problematic for several reasons. It creates a false perception that high-income countries are at the center of the world and everything outside of those borders is considered "global," a misnomer that presents a challenge for defining who a global health practitioner is. For example, should a South Africa-born pharmacist who practices in South Africa consider themself to be a global health pharmacist? Furthermore, it is clear that health disparities also exist within high-income countries. For example, while overall life expectancy for a baby born in 2016 in the United States is 78.6 years and higher than the worldwide average,[1] some counties within the United States have a much lower life expectancy of only 56.3 years,[4] worse than the average life expectancy in low-income countries of 63.8 years.[5]

It is for these reasons that the term health equity will be used throughout this chapter to refer to the borderless pursuit of improving health for populations around the world. This moniker more accurately describes the disparities than a term defined by country borders that diseases do not respect. Unsurprisingly, regions with lower life expectancies tend to also have subpar economic stability, educational opportunities, food insecurity, relatively less-safe neighborhoods, and suboptimal healthcare access. Furthermore, the drivers of these health inequities are similar across the world. This chapter will provide a better understanding of these broader determinants. This chapter will also provide representative examples of how these disparities are manifested around the world, with illustrative descriptions of efforts to address them in a culturally contextualized fashion. This approach will facilitate discussion of novel approaches to address determinants of health alongside more traditional healthcare system approaches that can be applied regardless of the practice setting or discipline.

EQUITY VERSUS EQUALITY

KEY CONCEPT When trying to understand the concept of global health equity, it is important to differentiate equity from equality. Equality focuses on treating all people the same regardless of other factors, while equity considers the circumstances of each individual

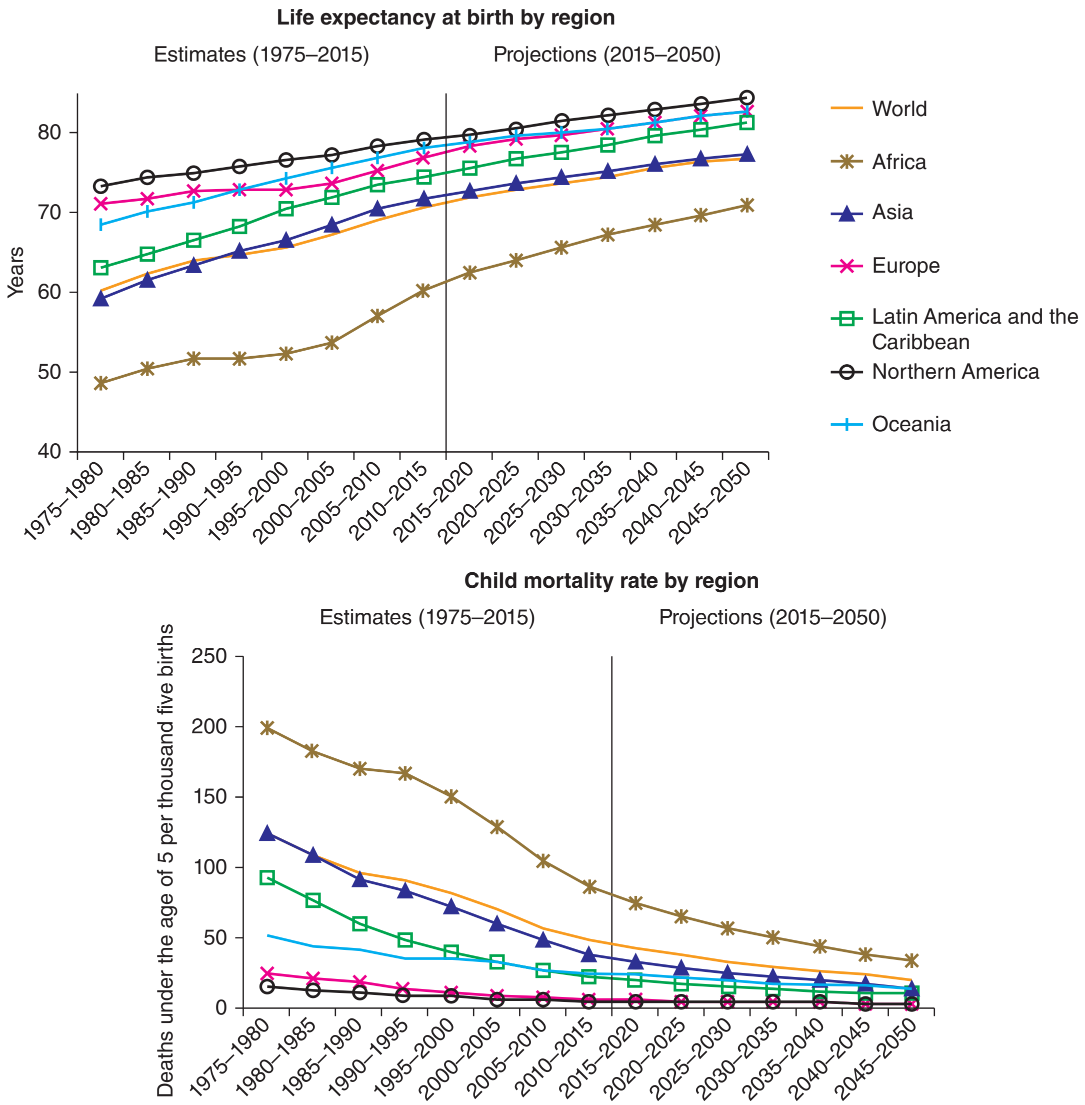

FIGURE 5–1. Estimated and projected life expectancy at birth and child mortality rate by region between 1975 and 2050. Reproduced with permission from World Population Prospects 2017 - Data Booklet United Nations, Department of Economic and Social Affairs, Population Division; 2017. Report No.: Contract No.: (ST/ESA/SER.A/401).

and attempts to allocate resources and solutions based on each individual's particular context. The difference in an approach focused on equality and equity is illustrated in Figure 5–3.

The top image shows how each individual receives a chair to have a seat at the table. While this reflects equal treatment of the three individuals, it does not consider their needs or circumstances. In this scenario, only one individual has a functional seat at the table while the infant and individual in a wheelchair do not. The bottom image exemplifies an approach focused on equity where the three individuals are provided with different seating options that fit their context. The normally abled adult still receives a chair; however, the infant receives a high chair to prevent them from falling, and the individual in the wheelchair receives no chair and instead has space for their wheelchair so they can sit at the table.

HEALTHCARE SYSTEM: A CASE EXAMPLE FROM THE UNITED STATES

The US healthcare system provides a representative example of health inequities across the globe. Large segments of the population, especially those with lower financial means, are priced out of accessing various aspects of care. As illustrated in Figure 5–4, equality in the US healthcare system is promoted by having all populations rely on the same system for their healthcare needs. Despite accessing the same system, low-income populations have limited access to primary care services and disproportionately rely on emergency room-based care.[6] This dynamic ultimately leads to increased costs within the healthcare system. More expensive emergency room visits are used to manage needs, which could be more effectively managed through outpatient visits.[7] In contrast, high- and middle-income populations with employer-based health insurance in the United States have better geographical and financial access to primary care and preventive services. These limit their reliance on the costlier emergency room-based care.[6] In addition to the challenges low-income populations face with accessing healthcare services, they also face a disproportionate burden of other health-related challenges. These include, but are not limited to, economic instability, insecure housing, poor educational choices, and limited nutritional options.

To counter this, US federal and state agencies have introduced a variety of initiatives to strive for more equitable access

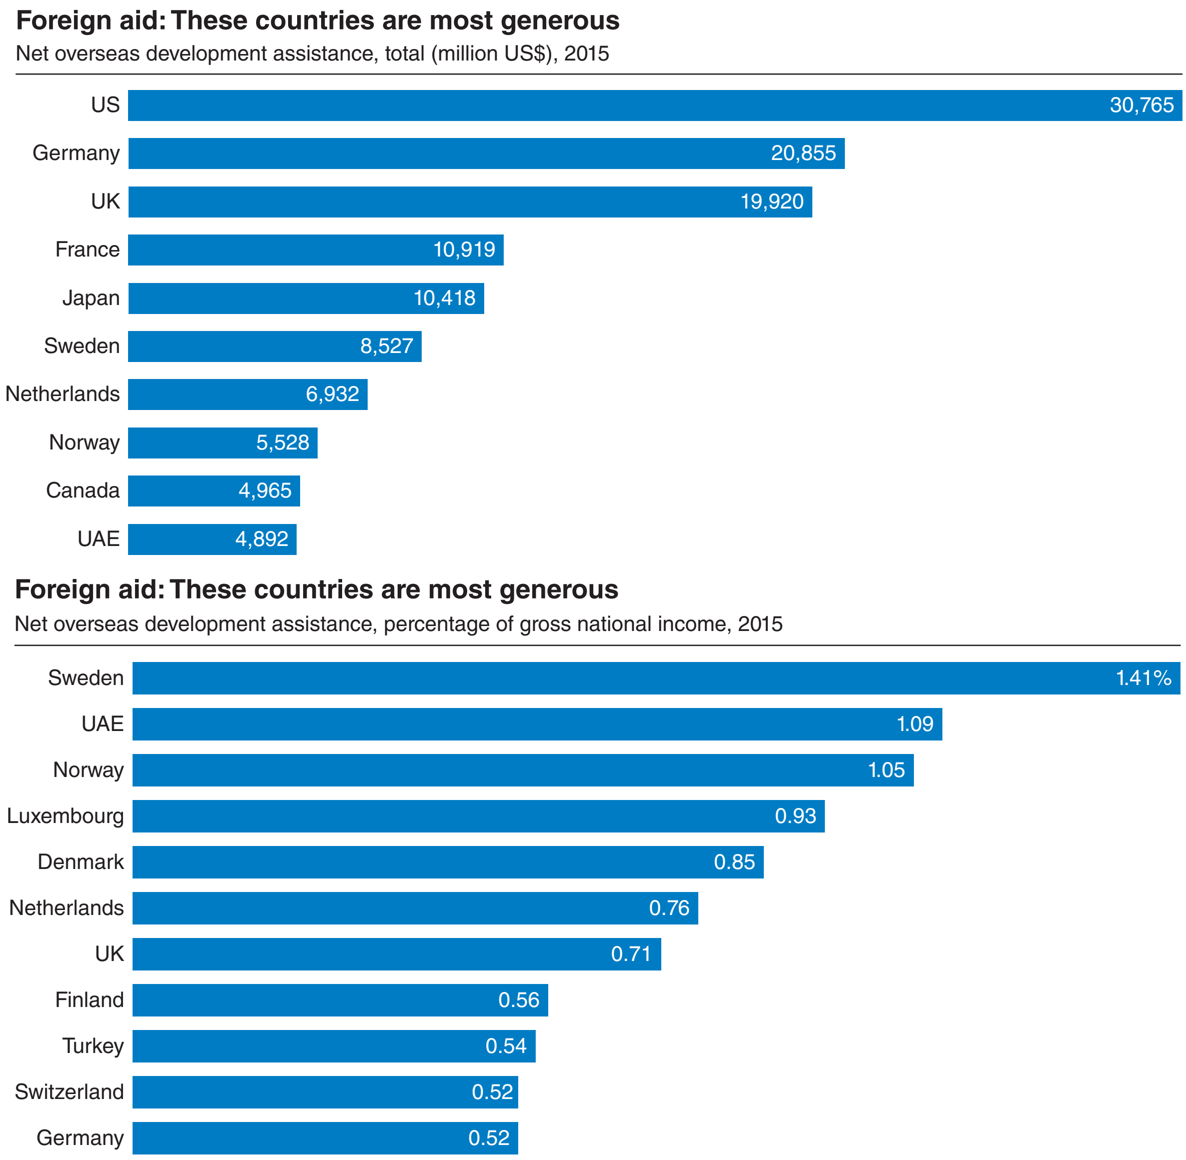

FIGURE 5–2. Foreign aid by high-income countries in terms of absolute financial support (in $) and percentage of gross national income (%). Reproduced with permission from Myers J. Foreign aid: These countries are the most generous 2016 [cited 2020 Aug 15].

to health across the different economic strata of the population as illustrated in Figure 5–5. Programs such as the Affordable Care Act and the associated Medicaid expansion to cover additional low-income populations have addressed these inequities by increasing access to health insurance for low-income populations. While these programs have helped provide low-cost insurance to millions of Americans, many of these programs include high deductible, lean plans, which insure against high-cost healthcare expenses. However, many of these non-Medicaid insurance plans still require significant copays for outpatient visits which leads to relatively lower uptake of primary care services. Increases in the uptake of primary care services have been seen, however, they still lag behind higher-income populations with more comprehensive insurance plans as seen in Figure 5–5.[8,9]

There are also efforts to address other aspects of health beyond direct clinical care to assist low-income populations. This includes, but is not limited to, programs like Temporary Assistance for Needy Families (TANF) (frequently referred to as welfare), Supplemental Nutrition Assistance Program (formerly known as food stamps), and Affirmative Action to promote good faith efforts to advance enrollment in higher education and job opportunities for historically underrepresented segments of the population. While many fail to recognize the government assistance services provided to high- and middle-income populations, these populations also benefit from government aid in the form of home mortgage interest deductions, preferential tax cuts, and school voucher programs that facilitate school choice.

Despite these efforts to promote equity, dramatic differences still exist in health outcomes across different socioeconomic strata. While there has been progress in improving access to clinical care, recent estimates suggest that direct clinical care is responsible for only 20% of the health outcomes of the US population, with other social determinants of health being responsible for the majority of health outcomes as seen in Figure 5–6.[10]

The Social Determinants of Health

KEY CONCEPT The social determinants of health include both the healthcare system and "the conditions in which people are born, grow, live, work, and age" as defined by the World Health Organization (WHO). The WHO definition further explains that "these circumstances are shaped by the distribution of money, power, and resources at global, national, and local levels. The social determinants of health are mostly responsible for health inequities—the unfair and avoidable differences in health status seen within and between countries."[11] The social determinants of health are characterized by the Centers for Disease Control and Prevention (CDC) as relating to economic stability, education, neighborhood and built environments, school and community contexts, and the healthcare system. Some organizations, such as the Kaiser Family Foundation, specifically draw attention to the importance of food and describe many of the contributors of the social determinants of health as seen in Figure 5–6.[12]

The impacts of these social determinants of health have been consistently illustrated in numerous studies that show the correlations between these factors and health outcomes.[11–15] Several illustrative examples come from research done in the United States.

As seen in the combination of illustrations and graphs in Figure 5–7a–d, different social determinants of health play an outsized role in determining health outcomes of the population. The impact of neighborhood, physical environment, community, and social context is illustrated through an analysis of the life expectancy within the city of New Orleans in Louisiana, United States.[16] As seen in Figure 5–7a, there is a 25-year disparity

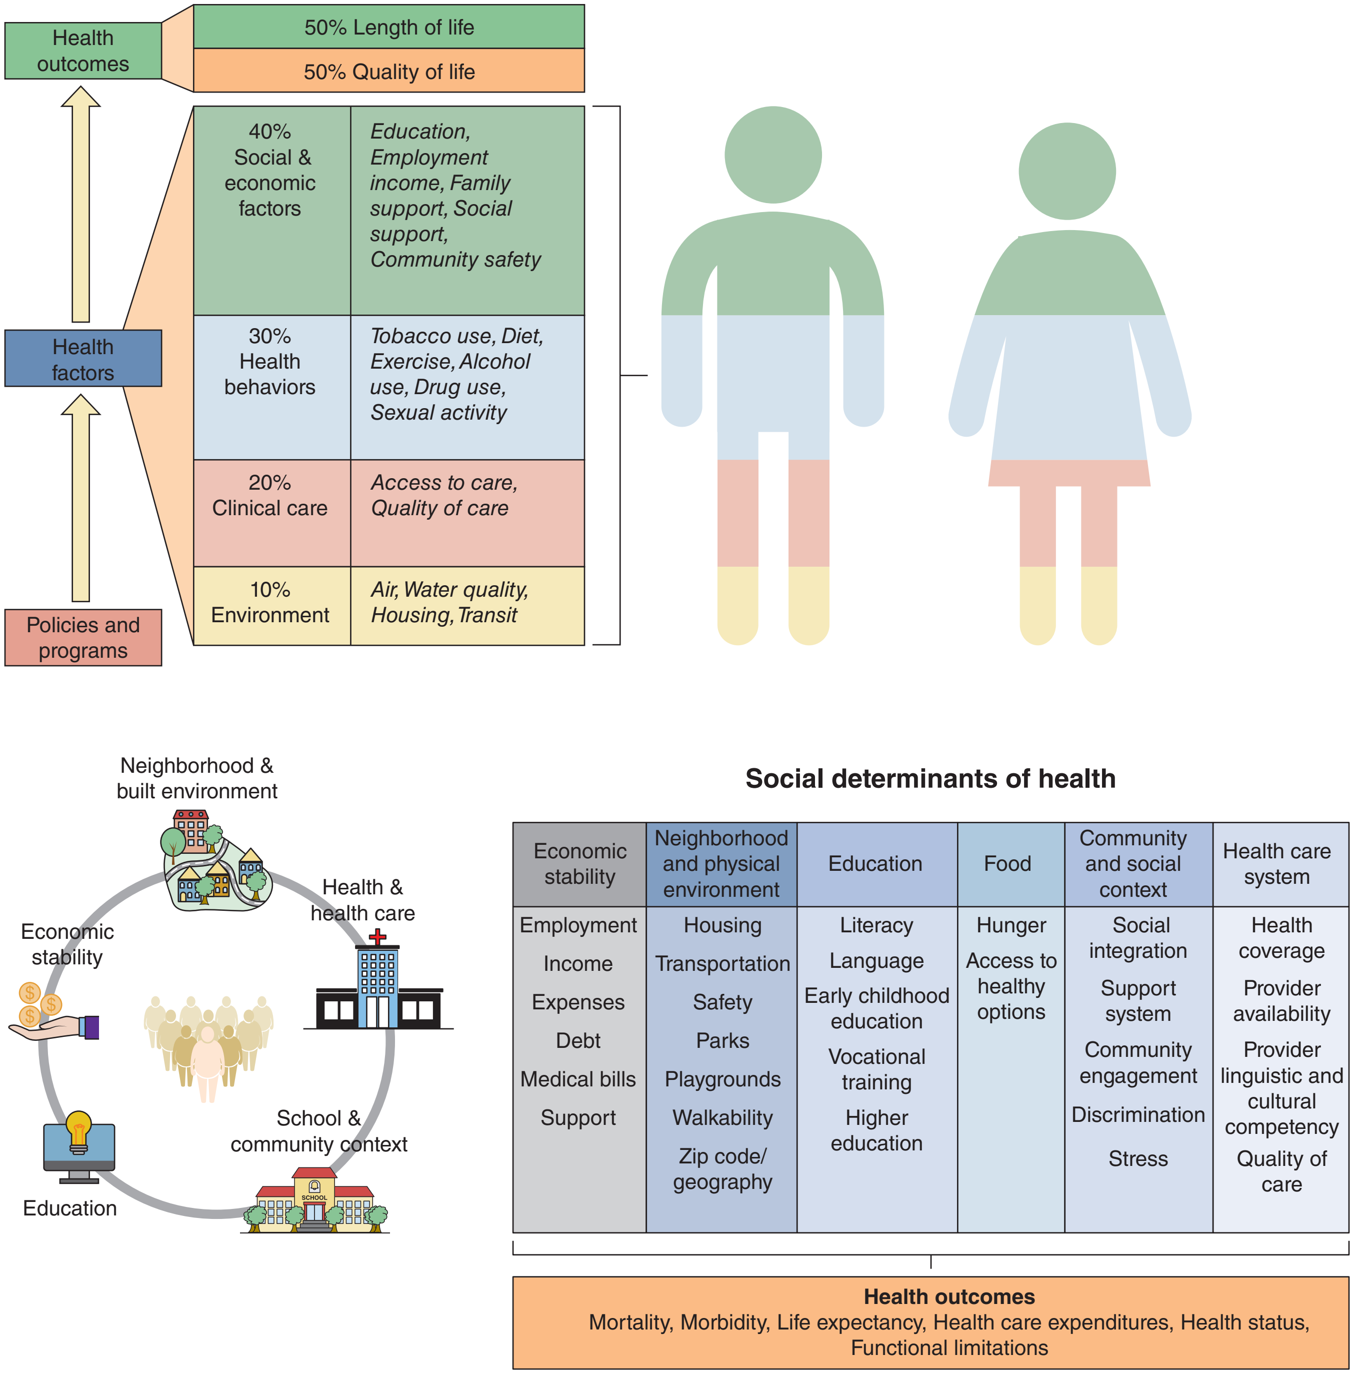
in life expectancy based simply on which part of New Orleans you were born in.[16] National data from the United States highlight the impact of the financial situation of parents on the health of their children as families with the highest levels of poverty have the greatest proportion of children with "less than very good health" and highest proportion of children who are overweight or obese, as seen in Figure 5–7b.[16] In Figure 5–7c, the impact of ethnicity and family income on health is illustrated as non-Hispanic black individuals in the United States tend to have a higher proportion of people in poor/fair health at all levels of income. Lastly, Figure 5–7d illustrates the impact of educational attainment on health, as the proportion of adults who have poor/fair health for each ethnicity goes up as the level of educational attainment they have achieved goes down.[16,17]

The WHO established a commission to drive greater progress in addressing social determinants of health. While the need for this focused effort is especially pronounced in low- and middle-income countries (LMICs), which tend to have relatively less progress on social determinants of health, high-income countries have also realized the importance of addressing these factors and have completed numerous population level studies. KEY CONCEPT Studies from the United States assessing determinants of health have found that socioeconomic factors, physical environment, and health behaviors are responsible for 40%, 10%, and 30% of health outcomes respectively, with clinical care being responsible for only 20%.[10] Similarly, in the United Kingdom and Canada, clinical care was only responsible for 10% and 25%, respectively, of healthcare outcomes while socioeconomic factors, genetics, environment, and health behaviors were responsible for the rest.[15,18] Because of the growing awareness of the importance of social determinants of health on outcomes, it is important that consideration for social determinants of health be incorporated into all aspects of the healthcare system including pharmacy.[19] Table 5–1 provides representative examples of the incorporation of social determinants of health into pharmacy services from programs around the world.

For additional descriptions of how social determinants of health impact the health of populations around the world, the WHO commission on Social Determinants of Health has prepared case studies on over 30 countries (https://www.who.int/sdhconference/resources/case_studies/en/).

Global Burden of Disease

An understanding of the importance of the aforementioned social determinants of health is crucial to appreciate the burden of disease for different regions around the world. While it is difficult to sufficiently describe the situation in every country, there are several examples that help illustrate the key trends when assessing the global burden of disease. As seen in Figure 5–1, LMICs, especially those in Africa, continue to have the lowest life expectancy at birth. Fortunately, however, this region is in the midst of a promising upward trajectory. Life expectancy has improved from 50.4 in the year 2000 to 61.3 in 2018 as this region transitions from facing excess preventable mortality from infectious diseases



50% Length of life	
50% Quality of life	
40% Social & economic factors	*Education, Employment income, Family support, Social support, Community safety*
30% Health behaviors	*Tobacco use, Diet, Exercise, Alcohol use, Drug use, Sexual activity*
20% Clinical care	*Access to care, Quality of care*
10% Environment	*Air, Water quality, Housing, Transit*

Social determinants of health

FIGURE 5–6. Illustration of the different social determinants of health, their contribution to health outcomes, and representative examples.

to now facing a growing burden of noncommunicable diseases much like the rest of the world.[5,20]

Figure 5–8 illustrates these transitions in burden between noncommunicable diseases and neonatal, maternal, and communicable diseases. **KEY CONCEPT** Noncommunicable diseases such as ischemic heart disease have risen in their contribution to disability-adjusted life years (DALYs—the sum of healthy years of life lost due to illness or its consequences in the form of disability or premature death[20]), while communicable infectious diseases like HIV and tuberculosis were a much bigger negative contributor to DALYs in 2007 than they are in 2017. This transition, along with the dramatic increase in life expectancy in Africa over the past two decades, is due, in small part, to the collaborations which have been established in response to these diseases.

The most notable of these international collaborations is the remarkable response to the HIV epidemic through the President's Emergency Plan for AIDS Relief (PEPFAR). In 2003, President George W. Bush authorized an unprecedented $15 billion investment in global health over 5 years with support from both major US political parties (ie, Republicans and Democrats) and the American public. At the time, this program instantaneously became the largest financial contribution from any government to address a health crisis in another region. The initial authorization of the PEPFAR program required funding recipients to collaborate with

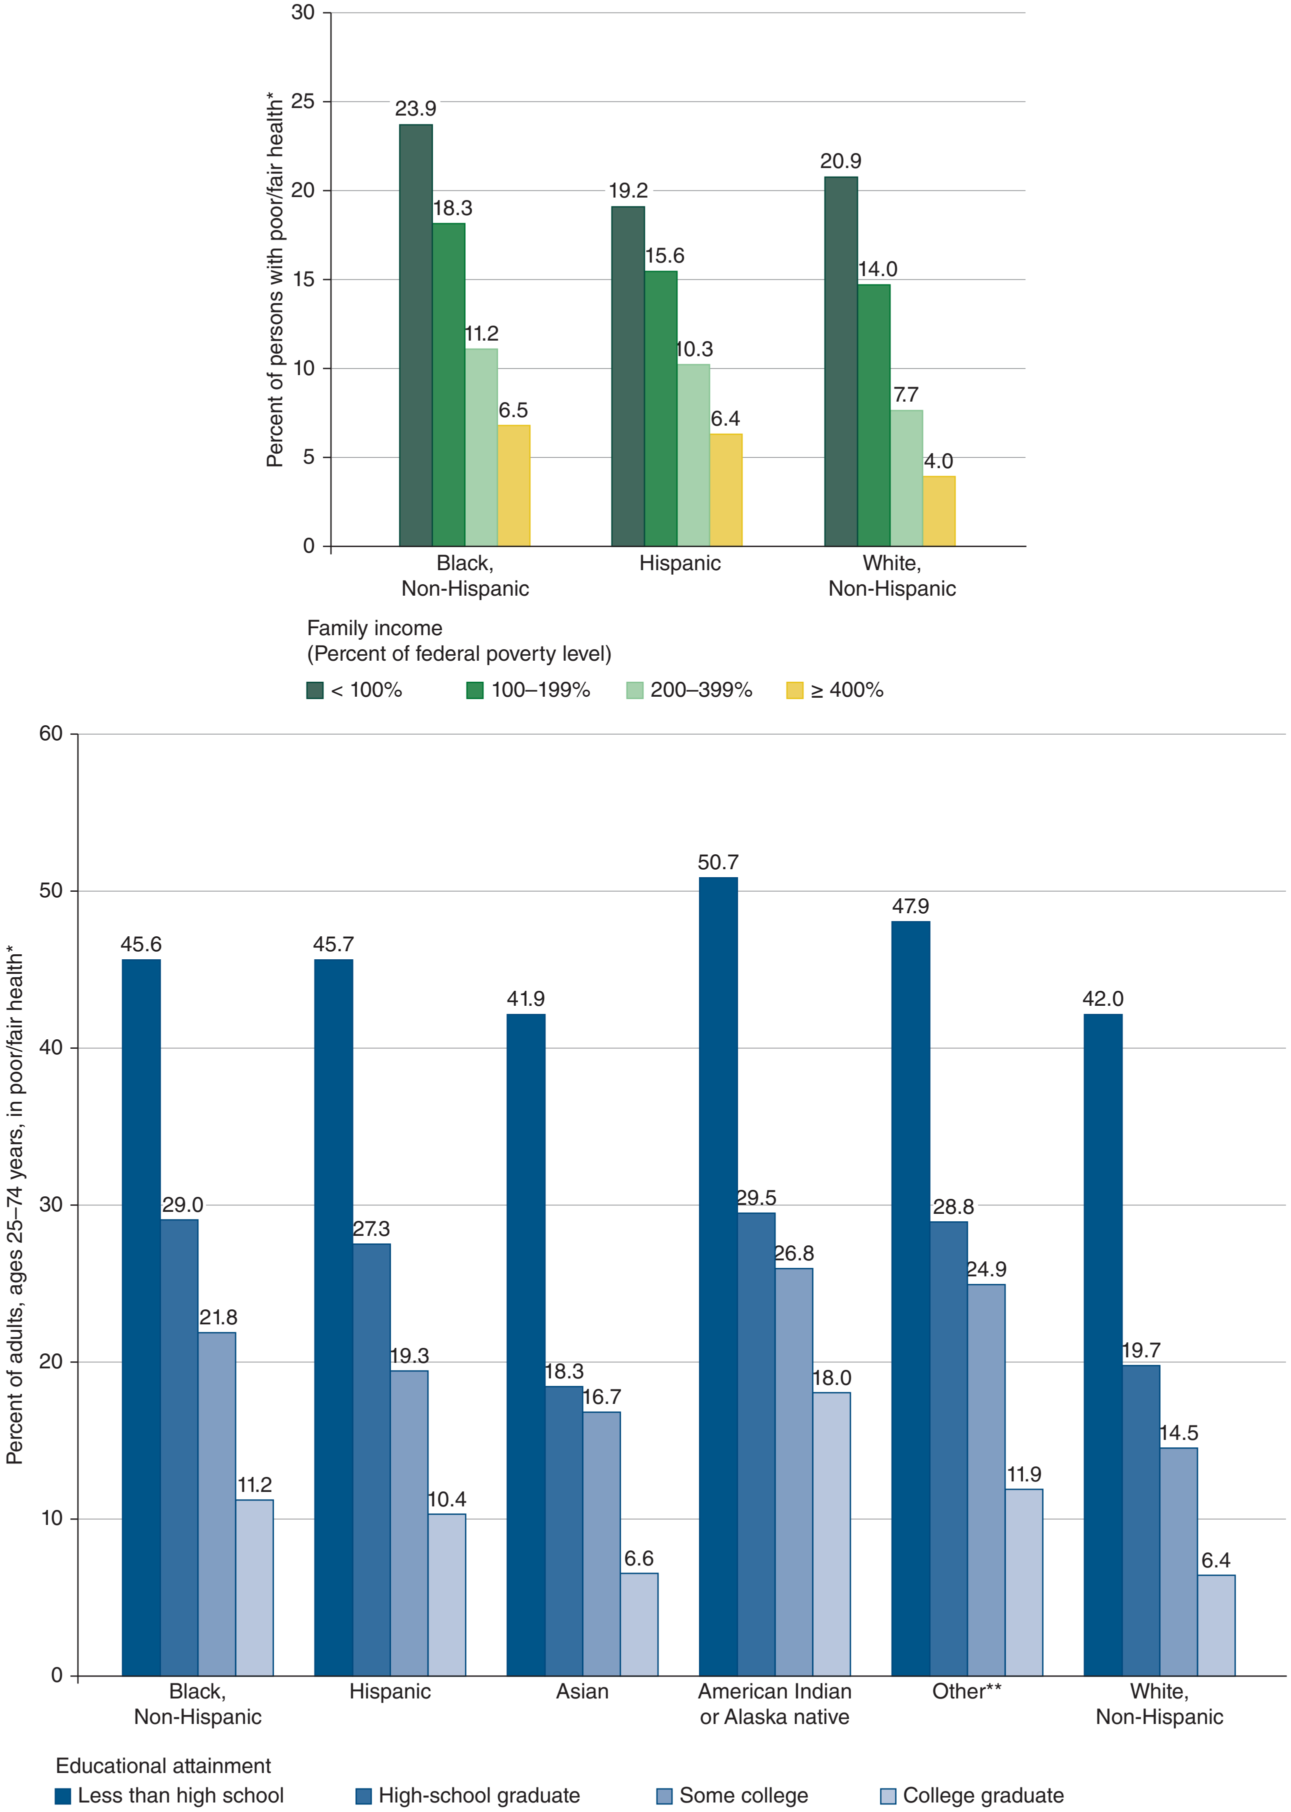

FIGURE 5–7 (Continued)

Table 5–1

Representative Examples of Pharmacotherapy Integration with Other Social Determinants of Health

	Location of Study	Brief Description of Initiative	Social Determinants of Health Addressed	Key Outcomes Observed
Victor RG et al.[93]	United States	Black male patrons of black-owned barbershops were randomized participants to a hypertension control program where pharmacists adjusted medications at the barbershop and trained barbers to provide education. Participants in the control group only received education from their barbers.	Community context	Patients in the pharmacist care group experienced statistically significant reductions in blood pressure (27 mm Hg vs 9.3 mm Hg).
Pastakia et al.[94]	Kenya	Bridging Income Generation through Group Integrated Care (BIGPIC)—community events were held for rural Kenyan communities where attendees received information on microfinance, agribusiness, and healthcare services. Interested participants then formed community groups where they could participate in microfinance activities, agriculture cooperatives, and receive portable care services (consultation, laboratories, and medications) from an interdisciplinary team of local practitioners working with the ministry of health.	Economic stability, neighborhood and physical environment, education, food, community and social context	Statistically significant improvements in participation in care were seen along with statistically significant reductions in blood pressure control with patients demonstrating a 21 mm Hg reduction in systolic blood pressure.
Palazuelos D et al.[95]	Haiti, Kazakhstan, Lesotho, Liberia, Malawi, Mexico, Peru, Rwanda, Sierra Leone	Partners in Health (www.pih.org) revamps healthcare systems around the world. Central to their model is the integration of community health workers (accompagnateurs) who assist with a wide range of activities (education, supply chain support, medication deliveries, adherence support, counseling, screening, home visits) across different disease states.	Community context	Haiti—100% clinical cure rate for tuberculosis patients Mexico—doubling of the odds of sustaining clinical control for diabetes and hypertension beyond 2 years Malawi—83% 12-month survival after chemotherapy for patients with Kaposi sarcoma and HIV Lesotho—no maternal deaths in first 2 years Rwanda—92.3% retention with 97.5% with a viral load less than 500 copies/mL among people living with HIV
Jackson C et al.[96]	India	In order to address the growing burden of tuberculosis and multidrug-resistant tuberculosis, Operation Asha (OpAsha) has developed a community health worker-based model to track directly observed therapy by using digital fingerprints to document the receipt and consumption of tuberculosis medications.	Community and social context	OpAsha was able to achieve treatment success rates (84.9%) comparable to the national average for India despite working exclusively with disadvantaged populations predominantly residing in urban slums.
Ali GK. (Sudan)[97] Murakami et al. (Lao)[98] Manji et al. (Kenya)[99] Uzochukwu et al. (Nigeria)[100]	Sudan, Lao, Kenya, Nigeria	Revolving Drug Fund (RDF) pharmacies have been established in multiple countries to serve as a parallel or backup to the ministry of health supply chain to minimize stockouts for patients seeking care in the public sector.	Community context, affordability of healthcare services	Sudan—achieved 97% availability of essential medicines through the RDF Lao—87% of outpatients could fill their prescriptions Kenya—availability of essential medicines was increased from < 50% in three facilities to > 90% in the first three RDF pharmacies Nigeria—centers with RDF pharmacies had greater average availability of essential medicines (35.4 vs 15.3, $p < 0.05$)

Global, regional, and national disability-adjusted life-years (DALYs) for 359 diseases and injuries and healthy life expectancy (HALE) for 195 countries and territories, 1990–2017: a systematic analysis for the Global Burden of Disease Study 2017. The Lancet. 2018;392(10159):1859–922.

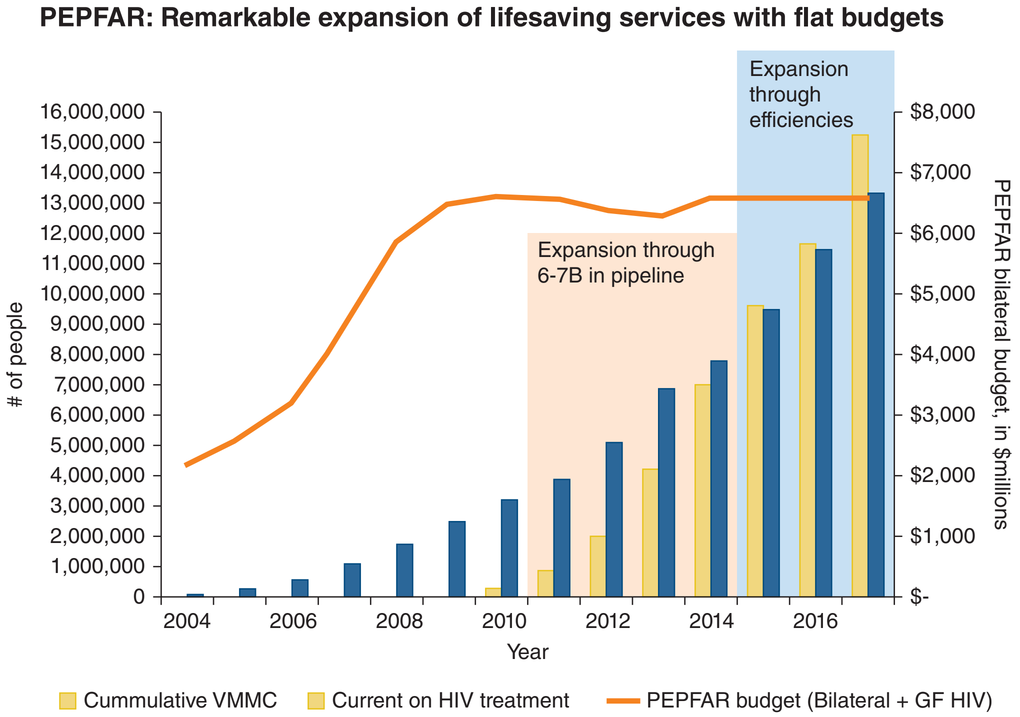

FIGURE 5–9. PEPFAR funding commitments and reach by year. (VMMC, voluntary medical male circumcision; GF, global fund.) From PEPFAR 2018 Annual Report to Congress. U.S. Department of State Office of the U.S. Global AIDS Coordinator and Health Diplomacy, April 2018. https://www.state.gov/wp-content/uploads/2019/08/PEPFAR-2018-Annual-Report-to-Congress.pdf.

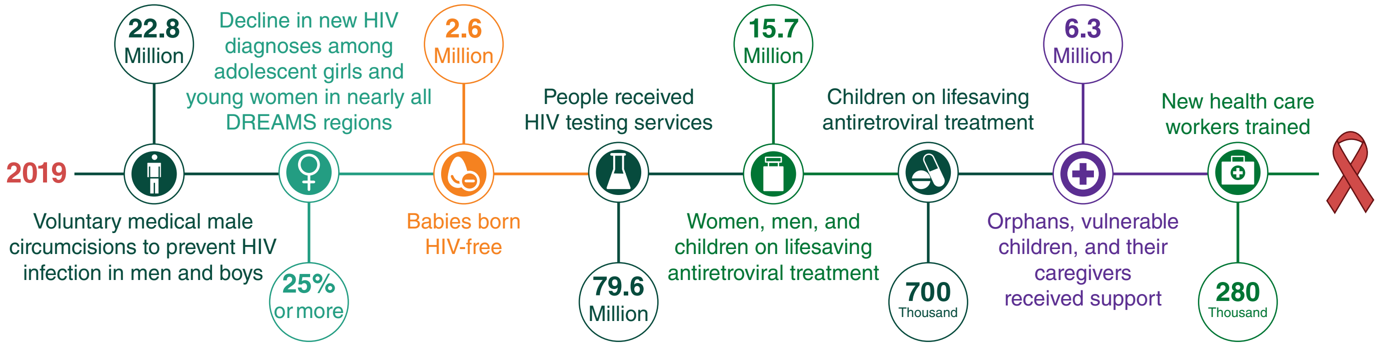
North American organizations including academic institutions. This investment has helped seed many of the academic collaborations, which have now grown to expand beyond HIV.

While US funding for the PEPFAR is now declining as seen in Figure 5–9, many efficiencies in program activities have helped sustain and expand the impact of this investment. As seen in the 2019 PEPFAR annual report in Figure 5–10, 79.6 million people have received HIV screening, and 15.7 million people are on lifesaving antiretroviral treatment across PEPFAR-supported countries. This success has supported the realistic hope that PEPFAR-supported countries can end the HIV epidemic by 2030 by consistently meeting the 90-90-90 targets (ie, 90% of the people living with HIV knowing their HIV status, 90% of the people living with HIV on antiretroviral therapy, 90% of the people receiving antiretroviral therapy achieving virological suppression). PEPFAR has reinforced the importance of these targets in hastening the end of the HIV epidemic by advocating that countries attempt to reach 95% for each of the three domains. This will continue to reduce the number of new infections below 200,000 per year and limit the future burden of HIV.

Other notable examples of international funding collaborations focused on infectious diseases include, but are not limited to, the Global Alliance for Vaccines and Immunizations (www.gavi.org) (GAVI), the President's (US) Malaria Initiative (www.pmi.gov), and The Global Fund to Fight AIDS, Tuberculosis, and Malaria (www.theglobalfund.org). Throughout human history, there have been numerous other viral epidemics besides HIV, as seen in Table 5–2. These epidemics have had devastating effects on the morbidity and mortality faced by populations around the world with entire populations being decimated as viruses have rapidly spread throughout certain regions. While these partnerships have helped us envision an end to the HIV epidemic, many of these same strategies could help us combat other viral illnesses and prevent the high mortality seen in past epidemics.[21] As we continue to manage the challenges with the recent COVID-19 pandemic, it is important that we adopt



2019
22.8 Million
Voluntary medical male circumcisions to prevent HIV infection in men and boys
Decline in new HIV diagnoses among adolescent girls and young women in nearly all DREAMS regions
25% or more
2.6 Million
Babies born HIV-free
People received HIV testing services
79.6 Million
15.7 Million
Women, men, and children on lifesaving antiretroviral treatment
Children on lifesaving antiretroviral treatment
700 Thousand
6.3 Million
Orphans, vulnerable children, and their caregivers received support
New health care workers trained
280 Thousand

FIGURE 5–10. PEPFAR impact metrics as of 2019. From The United States President's Emergency Plan for AIDS Relief Latest Results United States Department of State 2020 [updated June 16, 2020; cited 2020 June 16]. Available from: https://www.pepfar.gov/funding/results/index.htm.

Table 5–2

Notable Epidemics and Pandemics since the Middle Ages[101]

Starting Year	Event	Geographic Extent	Estimated Direct Morbidity or Mortality	Estimated Economic, Social, or Political Impact
1347	Bubonic plague (Black Death) pandemic	Eurasia	30%–50% mortality of the European population	Likely hastened end of the feudal system in Europe
Early 1500s	Introduction of smallpox	Americas	More than 50% mortality in some communities	Destroyed native societies, facilitating the hegemony of European countries
1881	Fifth cholera pandemic	Global	More than 1.5 million deaths (9.7 per 10,000 persons)	Sparked attacks on Russian tsarist government and medical officials
1918	Spanish flu influenza pandemic	Global	20–100 million deaths (111–555 deaths per 10,000 persons)	GDP loss of 3% in Australia, 15% in Canada, 17% in the United Kingdom, 11% in the United States
1957	Asian flu influenza pandemic	Global	0.7–1.5 million deaths (2.4–5.1 deaths per 10,000 persons)	GDP loss of 3% in Canada, Japan, the United Kingdom, and the United States)
1968	Hong Kong flu influenza pandemic	Global	1 million deaths (2.8 deaths per 10,000 persons)	US$23–US$26 billion direct and indirect costs in the United States
1981	HIV/AIDS pandemic	Global	More than 70 million infections, 36.7 million deaths (WHO Global Health Observatory data)	2%–4% annual loss of GDP growth in Africa[a]
2003	SARS pandemic	4 continents, 37 countries	8098 possible cases, 744 deaths	GDP loss of US$4 billion in Hong Kong SAR, China; US$3–US$6 billion in Canada; and US$5 billion in Singapore
2009	Swine flu influenza pandemic	Global	151,700–575,500 deaths (0.2–0.8 per 10,000 persons)	GDP loss of US$1 billion in the Republic of Korea
2012	MERS epidemic	22 countries	1879 symptomatic cases, 659 deaths	US$2 billion loss in the Republic of Korea, triggering US$14 billion in government stimulus spending
2013[b]	West Africa Ebola virus disease epidemic	10 countries	28,646 cases, 11,323 deaths	US$2 billion loss in Guinea, Liberia, and Sierra Leone
2015	Zika virus pandemic	76 countries	2656 reported cases of microcephaly or central nervous system malformation	US$7–US$18 billion loss in Latin America and the Caribbean

[a] Studies of the effects of HIV/AIDS on per capita gross national product have found smaller effects.

[b] The West Africa Ebola virus outbreak occurred from 2013 to 2016, but the peak and international response efforts began in 2014.

GDP, gross domestic product; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; MERS, Middle East respiratory syndrome; SARS, severe acute respiratory syndrome.

Note: List of events is illustrative rather than exhaustive. All US dollar amounts are rounded to nearest billion. From Jamison DT, Gelband H, Horton S, et al., editors. 2017. Disease Control Priorities: Improving Health and Reducing Poverty. third edition, volume 9. Washington, DC. The International Bank for Reconstruction and Development/The World Bank. doi: 10.1596/978-1-4648-0527-1. License: Creative Commons Attribution CC BY 3.0 IGO.

successful historic strategies while avoiding the mistakes, which have led to excess morbidity/mortality and preventable economic losses.

Noncommunicable Diseases

Since the early 2000s, an epidemiological transition that has accompanied urbanization has occurred. This has led to a rise in noncommunicable diseases (NCDs) and a reduction in the burden on communicable diseases. As seen in Figure 5–8, NCDs are the leading causes of death and disability, responsible for 73% of deaths and 61% of DALYs globally, and disproportionately so in LMICs.[22,23] Eighty percent of global NCDs are among LMIC individuals, and 80% of premature deaths (ie, deaths occurring before age 70) from NCDs occur in LMICs. The net effect of rising NCDs in LMICs is a dual burden of disease that puts significant strain on the health system. For example, in Africa, while 29% of DALYs in 2017 were attributable to NCDs, these were still second to communicable, maternal, neonatal, and nutritional disorders. In addition, incident cases of HIV/AIDS remain highest in Africa.[24] Further, recent infectious pandemics such as Ebola and COVID-19 are notable for exposing existing deficiencies on LMIC health systems.[25]

Inequities in access to quality health care contribute to the disproportionate burden: morbidity and mortality of NCDs in LMICs.[26] Equitable access incorporates four key domains. First, health services should be made available to a population in need. Consideration in this domain should factor in the availability of health workers and health facilities, geographical considerations, and the associated direct and indirect costs of physically accessing the services. Second, available services must be usable by the population, that is, they must be both affordable and acceptable. Third, health services should be available in a timely fashion to enable prevention, management, and treatment of disease in order to prevent unnecessary death and disability. Fourth, and overarching the three domains above, that access is equitable—enabling all those in need to receive health services.[27] Limited access to health care pervades LMICs, with emerging diseases like hypertension and diabetes having lower control rates than high-income countries. Access to standard drugs such as statins for primary and secondary prevention of cardiovascular disease is also low. Capacity for screening, diagnosis, and treatment of common cancers (eg, cervical) is limited in LMICs. Key causes for the above include lack of access to necessary evidence-based interventions such as essential medicines. This is particularly problematic given that NCDs require lifelong treatment and surveillance for disease complications. Catastrophic healthcare spending—that is, healthcare spending that risks a household's ability to meet their basic needs relative to their income—occurs in 60% to 92% of LMIC households in which an NCD diagnosis has been made.[28,29]

The connection between ill health and socioeconomic disparity, its causes, and consequences on overall health is an important consideration in clinical practice. It informs prevention, diagnosis, and treatment decisions in the various contexts. Standard evidence-based treatments and interventions recommended for specific clinical indications may be inaccessible in a specific setting (see Patient Encounter 1) necessitating use of less ideal, yet suitable alternatives. If a key goal of global health practice is to improve population health, greater understanding of these drivers and results will increase effectiveness of practice by aligning service delivery to contextual needs and available resources. While less ideal alternatives may sometimes have to be utilized due to these constraints, healthcare practitioners and the healthcare system at large must ensure that continuous efforts are made to optimize access to the preferred treatment for each individual patient.

Patient Encounter 1

EK is a 28-year-old woman, weight 61 kg, admitted for management of new-onset atrial fibrillation at a cardiac care unit in a referral hospital in Western Kenya. She has underlying rheumatic heart disease, one of the leading causes of cardiovascular disease (CVD)-related DALYs among young patients in LMICs, with severe mitral regurgitation and heart failure with preserved ejection fraction and is on regular follow-up at the outpatient cardiac clinic.[20] At her last visit 4 days ago, she was noted to have an irregular heart rate at 145 beats/min. Her home medications before this admission were oral furosemide 40 mg once daily and once monthly benzathine penicillin 1.2 million unit injection for secondary prophylaxis of rheumatic fever. She is a single mother of two children who are both in primary school. She runs a small shop that provides the family income, just enough for her family's subsistence, children's education, her medicines, and her inpatient health insurance plan. Her health insurance does not cater for outpatient treatment or home medications. On day 4 of her hospital stay, EK is eager to be discharged, as her shop has had to remain closed while she has been in the hospital as she has no one to run it. The medical team believes she is stable enough for discharge but would like to put in place an anticoagulation plan because of her new-onset atrial fibrillation and mitral valve disease. She is currently on oral furosemide 40 mg once daily, oral metoprolol succinate 25 mg once daily, and subcutaneous enoxaparin 60 mg twice daily. While reviewing the current guidelines for management of atrial fibrillation, you note that either a direct oral anticoagulant (DOAC) such as rivaroxaban or a vitamin K antagonist such as warfarin may be appropriate for her atrial fibrillation and mitral regurgitation. The referral hospital has a busy anticoagulation monitoring service, but EK lives approximately 3 hours away by public transport. Rivaroxaban is also available but costly. At the hospital, a month's prescription is priced at about a third of her current monthly income, and if available, is likely to be two times higher in private pharmacies closer to her home.

What additional considerations would you need to make in discussing EK's options with her and the clinical care team?

What are the trade-offs this patient is being forced to consider?

What is the best way forward for EK's anticoagulation discharge plan?

MATERNAL AND CHILD HEALTH

KEY CONCEPT While infectious diseases have been the main funding priority for international donors over the last three decades, development funding focused on addressing the maternal and child health needs of populations has consistently been shown to be one of the most impactful investments in improving the long-term productivity and economic performance of LMICs.[30,31] These broader improvements are tied to improvements in several key metrics which include, but are not limited to, (1) maternal mortality ratio, (2) fertility rate, and (3) unmet needs for family planning.

The maternal mortality ratio is the main measure used to judge progress in health care for pregnancy-related needs. This ratio is calculated by taking the number of maternal deaths in a calendar year and dividing it by the number of live births for the same period multiplied by 100,000. As seen in Figure 5–11, maternal mortality remains highest in the low-income classification countries in Africa while high-income countries tend to have the lowest maternal mortality ratios.

A closer examination of trends for high-income countries in Figure 5–12 illustrates the higher maternal mortality ratio experienced by pregnant mothers in the United States compared to their high-income country peers.

Efforts to improve the maternal mortality ratio, especially in LMICs, often focus on the three delays model that suggests maternal mortality is related to delays in (1) deciding to seek care, (2) reaching the healthcare facility, and (3) receiving care.[32]

The total fertility rate is an important metric which has considerable ramifications for the economic growth of countries. Between 2010 and 2015, the average global fertility rate was 2.5 live births per woman. If the fertility growth is too low (< 2.1 live births per woman), the current population is unable to replace the parents' generation (ie, below replacement fertility). However, if the fertility rate goes too high without concomitant economic growth and increased employment opportunities, the growth in population frequently worsens the economic outlook for the country and especially for women as they take on more child rearing responsibilities and become more dependent on income from spousal partners trying to find economic opportunities in a more competitive job market.[33]

Because of the growing understanding of the impact of fertility rate on economic growth, the proportion of women with unmet family planning needs has become an important target to promote development in Africa and other LMICs with elevated fertility rates (see Figure 5–13). Studies have consistently demonstrated the cost-effectiveness of this investment, and increasing access to family planning remains a time-tested and proven intervention in improving health and economic outcomes.[34]

Furthermore, increased access to family planning reduces the need for provider-assisted and unsafe abortions.[35]

Access to family planning has also been estimated to reduce maternal deaths by 44% or 272,040 each year. If the unmet needs for contraception were addressed, an additional 29% or 104,000 maternal deaths could be prevented each year.[36]

ALGRAWANY

Breast and Cervical Cancer—Diseases of Disparities

These two prominent cancers in women highlight the many disparities in health described throughout this chapter. Globally, the majority of women who die from breast and cervical cancer live in low- and middle-income countries with many of these deaths being preventable. In contrast, most women living in high-income countries who develop these cancers will survive. This contrast is especially stark for cervical cancer where numerous preventative strategies have demonstrated effectiveness and are readily available in high-income countries. As seen in **Figure 5–14**, Africa faces a disproportionate burden in terms of the incidence of new cases and an exceptionally high mortality rate compared to all other regions of the world. This is due to a combination of socioeconomic factors which have limited the widespread scale up of (1) vaccination against harmful strains of human papillomavirus (HPV), (2) routine screening through Pap smear testing or visual inspection with acetic acid, and (3) access to effective chemotherapy and/or radiotherapy where appropriate.

In contrast, Figure 5–14 illustrates the higher incidence of breast cancer in high-income countries where women tend to live longer, which increases their likelihood of developing breast cancer over their lifetime. However, women in low- and middle-income countries, especially those in Africa, experience a higher mortality rate than women with breast cancer in high-income countries. This disparity is largely due to earlier diagnosis combined with greater access to effective chemotherapy and radiotherapy in high-income countries. Urgent action is needed to protect the health of women from these cancers as they currently take the lives of three times as many women each year than complications from pregnancy and childbirth.[37]

Fortunately, recent efforts from organizations like GAVI to increase access to HPV vaccine in LMICs are gaining traction, and countries are now making demonstrable headway in increasing vaccine uptake and averting preventable cervical cancer–related morbidity and mortality.

GLOBAL PROGRAMS

Medication Access

The right to health, including access to essential medicines, is a fundamental human right; however, an estimated 2 billion people have no access to essential medicines.[38] KEY CONCEPT Three major barriers to medication access—availability, accountability, and adherence—are summarized in **Figure 5–15**.[39] To help tackle the first barrier of *availability*, WHO released the initial version of their Essential Medicines List (EML) in 1977 with subsequent revisions published every 2 years. This EML includes medications that are considered safe, effective, and cost-effective and satisfy the priority healthcare needs of the population. It is intended to serve as a model list for countries to use when developing national EMLs, akin to a suggested national formulary. In response to rising global antibiotic consumption, WHO more recently added the Access, Watch, Reserve (AWaRe) classification of antibiotics to the EML framework to help promote antimicrobial stewardship and combat development of resistance. While the EML has increased

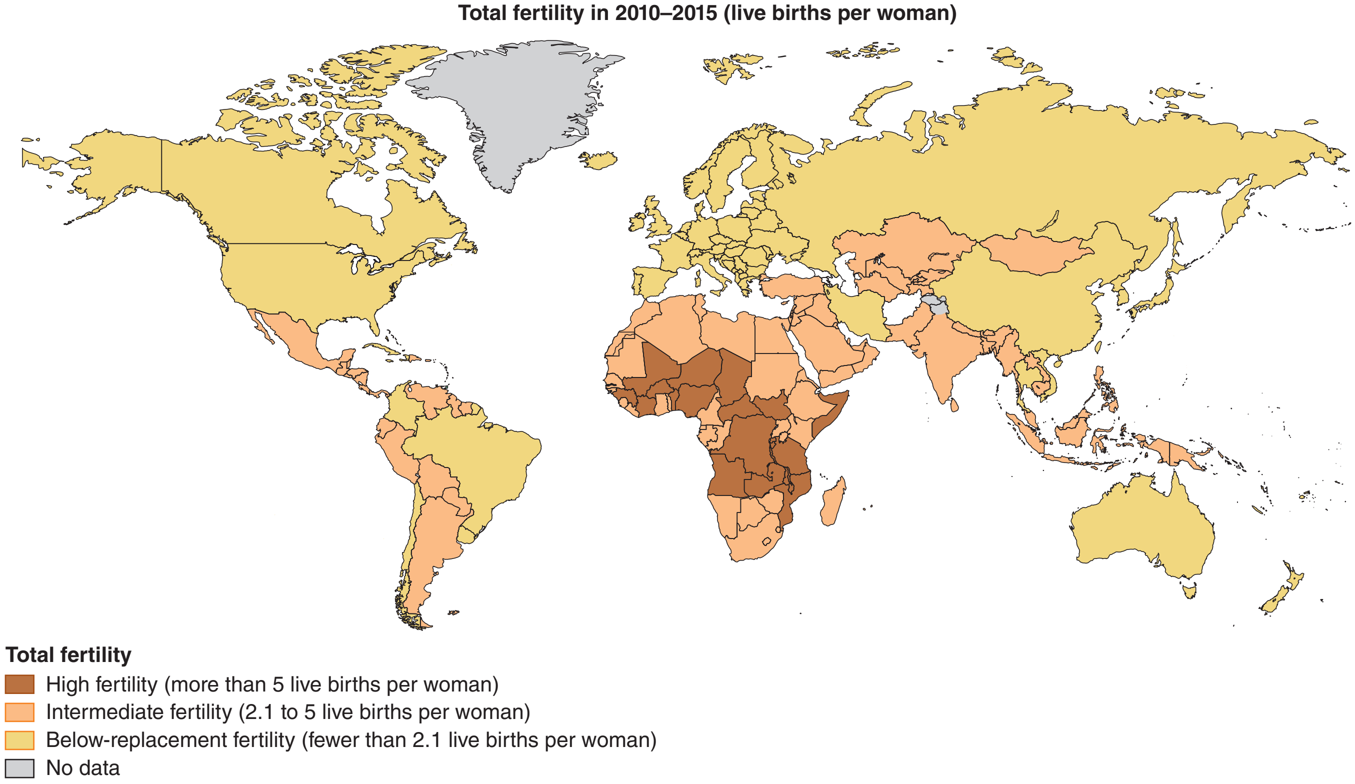
access in some countries, numerous gaps in medication availability remain in many regions, as a lack of infrastructure has hindered the practical implementation of this guidance.[40,41] Underresourced multitier supply chains and poor operations management within a pharmacy or hospital also limit availability. Facilities often lack reliable inventory systems to track and forecast medication use and inconsistent financial means, making it difficult to identify the optimal time to order before the available supply is depleted.[39] These systems frequently lack real-time documentation and reporting, which contributes to delayed or inconsistent procurement.

A lack of *accountability* for upholding standards of quality assurance perpetuates limited access to medications. This is exacerbated by complicated supply chains with multiple tiers between initial drug acquisition and end user, as each tier places blame on another step in the chain when something goes awry.[39,42] In order to cut costs and maximize profit, wholesalers and distributors are often compelled to purchase the cheapest available medicine



Total fertility in 2010–2015 (live births per woman)
Total fertility
High fertility (more than 5 live births per woman)
Intermediate fertility (2.1 to 5 live births per woman)
Below-replacement fertility (fewer than 2.1 live births per woman)
No data

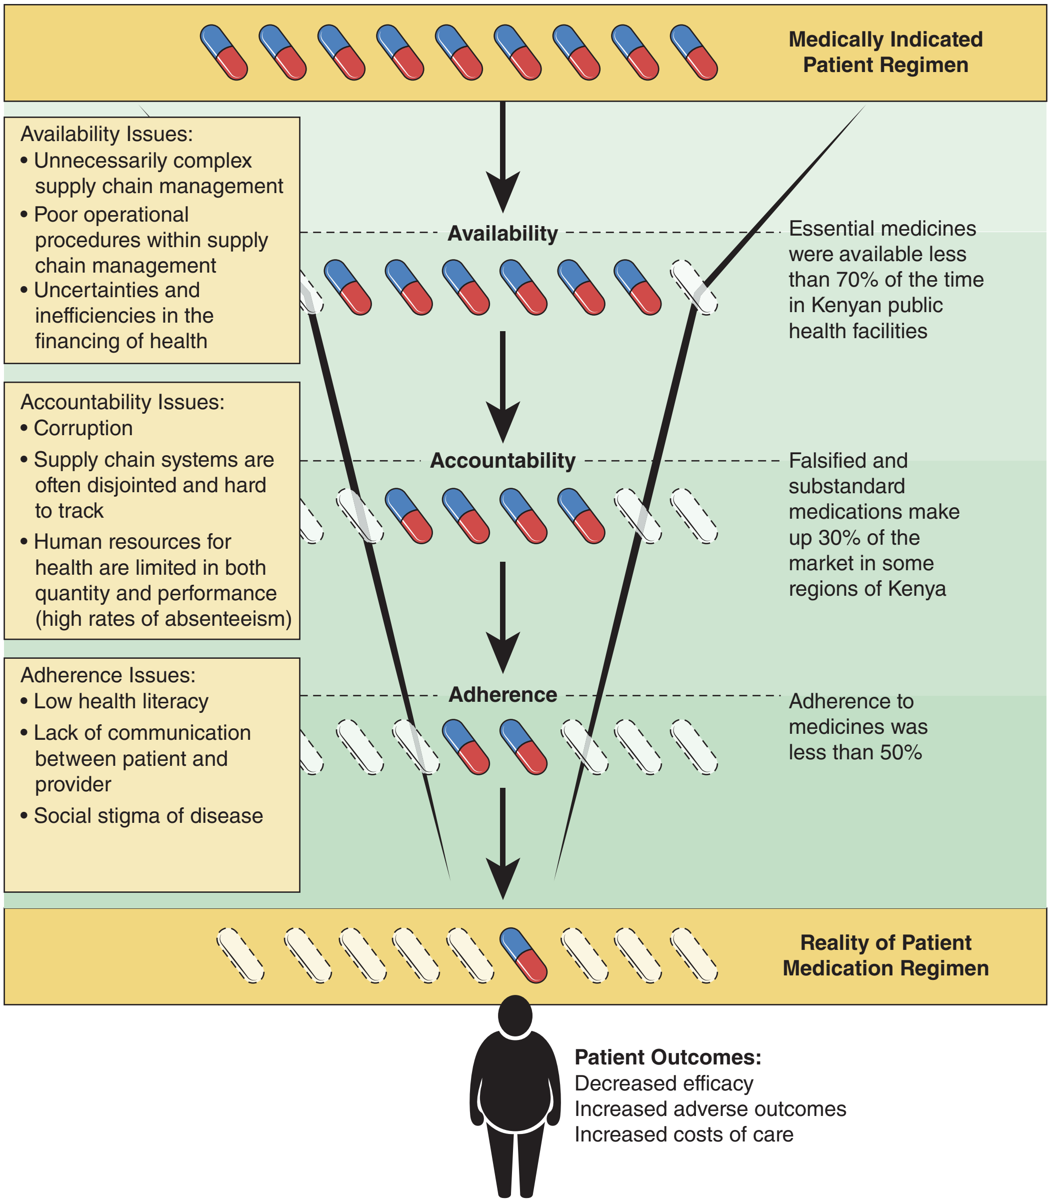
FIGURE 5–14. Breast and cervical cancer incidence and mortality rate for countries and territories. From Ginsburg O, Bray F, Coleman MP, et al. The global burden of women's cancers: a grand challenge in global health. The Lancet. 2016;389(10071):847–860.



Medically Indicated Patient Regimen
Availability Issues:
• Unnecessarily complex supply chain management
• Poor operational procedures within supply chain management
• Uncertainties and inefficiencies in the financing of health
Availability
Essential medicines were available less than 70% of the time in Kenyan public health facilities
Accountability Issues:
• Corruption
• Supply chain systems are often disjointed and hard to track
• Human resources for health are limited in both quantity and performance (high rates of absenteeism)
Accountability
Falsified and substandard medications make up 30% of the market in some regions of Kenya
Adherence Issues:
• Low health literacy
• Lack of communication between patient and provider
• Social stigma of disease
Adherence
Adherence to medicines was less than 50%
Reality of Patient Medication Regimen
Patient Outcomes:
Decreased efficacy
Increased adverse outcomes
Increased costs of care

including from sources with unproven validity who may not have completed the appropriate registration and manufacturer processes.[39] Due to poor infrastructure and a lack of regulatory bodies to enforce good manufacturing practices, many LMICs are unable to hold the culprits responsible or stop counterfeit medications from infiltrating the supply chain.[43] Countries with poor pharmacovigilance systems have the greatest risk of impact from substandard or falsified (SF) medications.[44] Not only do SF medications contribute to worse clinical outcomes due to not providing the intended drug/dose to achieve the desired therapeutic outcome, but they undermine people's trust in the legitimacy of the health system.[44] A review and meta-analysis of 265 studies estimated the overall prevalence of counterfeit medications to be 13.6% across LMICs, ranging from 13.7% in Asia to 18.7% in Africa.[44] Antimicrobials are the most commonly SF medication class, leading to concerns not only for a lack of appropriate therapy but also for potential development of resistance with subtherapeutic doses (for more information on the importance of providing an optimal antimicrobial regimen, see Chapter 72). A study assessing the quality of amoxicillin and amoxicillin/clavulanate across retail and private hospital pharmacies in Nairobi, Kenya found that almost 40% of analyzed drugs did not comply with quality standards.[45] In particular, SF antimalarials lead to significant morbidity and mortality in LMICs. The estimated prevalence of SF antimalarials in select African countries ranged from 10.3% in Zambia to 22% in Uganda, and a 10% reduction in poor-quality antimalarials would avoid an estimated $578 million in Nigeria.[46]

Medication access does not stop once the drug reaches the patient—patient *adherence* is another key component. It is estimated that 50% of patients are nonadherent to prescribed medication regimens.[38] One of the most prominent factors associated with medication nonadherence is financial burden, including cost of medication, provider visit, and transportation to clinic and

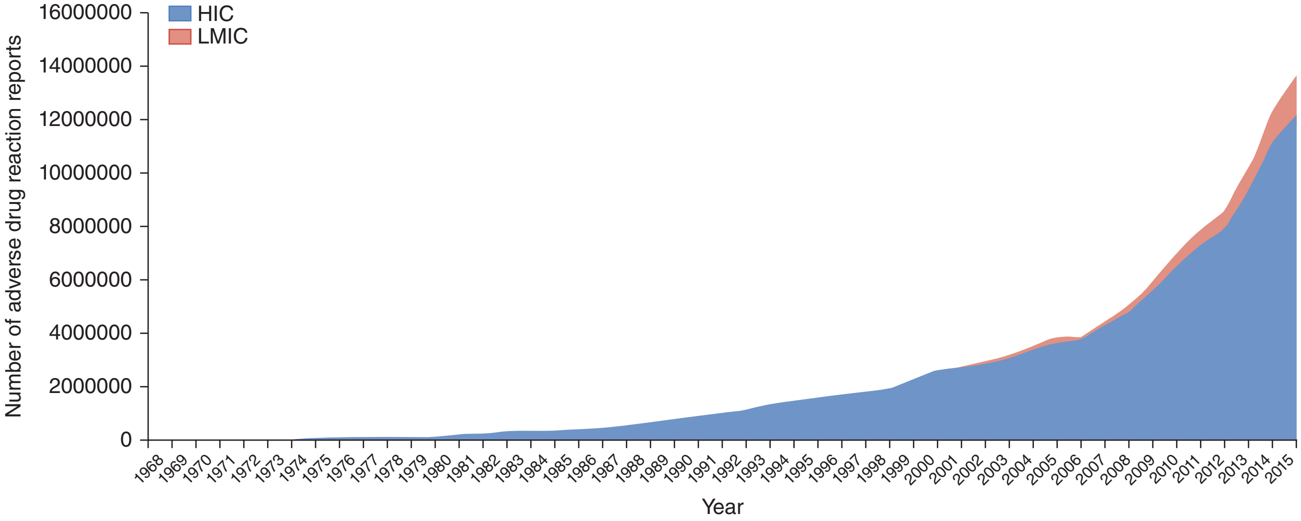

FIGURE 5–16. Number of adverse drug reaction reports in high- versus low- and middle-income countries. Reproduced with permission from Wirtz VJ, Hogerzeil HV, Gray AL, et al. Essential medicines for universal health coverage. The Lancet. 2017;389(10067):403–476.

pharmacy.[39] When medications are not covered by insurance or a national health system, and patients have to pay out of pocket, they may be unable to afford the prescribed therapy or may resort to obtaining a medication from an unlicensed supplier such as in a street market.[47] Factors associated with the regimen itself also play a role. Complex medication regimens with a significant pill burden or those requiring numerous doses per day have been shown to reduce patient adherence.[39,48] Studies have shown once-daily antiretroviral therapy regimens have improved adherence compared to twice-daily regimens.[49,50] Medication-related adverse effects are also a barrier to adherence and have been associated with a twofold increased risk of nonadherence.[39] The challenge of adverse effects in LMIC settings is further complicated by the limited availability of data describing the incidence of side effects in their populations as most of the data come from high-income countries as seen in Figure 5–16.[51] Of more than 10 million individual safety reports submitted to a global pharmacovigilance database as of 2015, less than 10% were from LMICs.

Overall, there are numerous barriers contributing to the lack of medication access for disadvantaged populations. While there are initiatives in place intended to reduce these disparities, additional work is needed to maximize health outcomes from appropriate pharmacotherapy. In particular, treatments for neglected tropical diseases (NTDs) deserve greater focus to lower disease burden and increase quality of life. While this section focused on increasing the availability, accountability, and adherence to medications for common diseases, there are many neglected tropical diseases that occur more commonly in LMICs and lack therapeutic options.

Neglected Tropical Diseases

NTDs are a group of 20 communicable diseases that are estimated to affect over 1.5 billion people per year, particularly those with low socioeconomic status (Table 5–3).[52] While they primarily affect impoverished communities in developing countries, the developed world is not immune to NTDs: a study in rural Alabama found that 35% of participants had stool samples positive for hookworm.[53,54] The morbidity burden of NTDs far outweighs that of mortality, leading to reduced quality of life manifesting in a variety of ways.[52] Physical impairment or disfigurement may lead to stigmatization and social discrimination and ultimately higher rates of mental health conditions such as depression.[55] Physical impairment may also reduce ability to work or for children to attend school, leading to loss of productivity. Healthcare costs often worsen the financial hardship of people living with NTDs. In Malawi, people with lymphatic filariasis have been shown to earn more than 50% less per week than those without the disease.[56] Billions of dollars are lost annually due to reduced productivity, perpetuating the cycle of poverty for nations plagued with endemic NTDs.[52] The projected economic gain from increased productivity with the end of five NTDs, that is, onchocerciasis, lymphatic filariasis, schistosomiasis, trachoma,

and soil-transmitted helminths, is $127 billion between 2021 and 2030, equating to a net benefit of $42.8 for every dollar invested during the same time period.[57]

NTDs have historically received little global attention. They were not explicitly described in the 2000 Millennium Development Goals (MDGs). Although they were intended to fall under "other diseases" within MDG 6, this goal was largely focused on HIV/AIDS, malaria, and tuberculosis.[58] Since 2010, WHO has released numerous reports outlining comprehensive plans for eliminating NTDs.[59] The most recent report summarizes considerable progress in the past decade, such as near eradication of dracunculiasis and the elimination of at least one NTD in 40 countries or regions, before providing revised recommendations for further impact.[60] NTDs are also now specifically mentioned within the Sustainable Development Goals (SDG 3.3 aims to end epidemics of NTDs).[61] The sustainable development goals (SDGs) (shown in Figure 5–17) consist of 17 interconnected goals to achieve by 2030. They are intended to expand upon the progress made by the MDGs and are applicable to all nations rather than only developing countries. Compared to the MDGs, the SDGs are more comprehensive and place a greater emphasis on an integrated approach for attainment.

▸ *Mass Drug Administration*

Preventive chemotherapy for diseases that can be treated pharmacologically is one of the more successful NTD interventions. Preventive chemotherapy is typically accomplished by treating entire populations via mass drug administration (MDA) or to specific at-risk groups via targeted treatment.[62,63] The goals of these programs are to treat those with infection, prevent development of additional morbidity, and interrupt disease transmission.[52,63] Treatment is typically provided by community drug distributors and may be offered anywhere from every few months to years, depending on the disease endemicity of the region as described in Table 5–4.[62] Five NTDs most amenable to control via MDA are onchocerciasis, lymphatic filariasis, trachoma, schistosomiasis, and soil-transmitted helminths. Largely due to robust donation programs by pharmaceutical companies, MDA initiatives combatting NTDs are incredibly economical with an estimated cost of less than $ 0.50 per person per year.[53] To date, MDA has primarily been provided via vertical programs targeting a single disease state. More recently there has been an effort to move away from siloed, disease-specific programs in favor of integrated delivery of health services to sustain ongoing success.[60] Vertical programs often perform parallel functions of one another, providing duplicative therapies across common populations.[64] Alternatively, integration of multiple NTD targets within a single campaign improves efficiency, increases the impact of health interventions, alleviates the burden on health systems and communities, and reduces costs compared to vertical programs.[53,64,65] Other non-MDA strategies that help combat NTDs which may be incorporated into MDA campaigns include education around water, sanitation, and hygiene (WASH), vector control, zoonosis, and integrated disease management.[66]

▸ *Priority Review Voucher Programs*

One of the primary concerns regarding MDA programs involves the potential for antimicrobial resistance when only one drug is used for a given disease, as evidenced by the emergence of chloroquine resistance during malaria eradication efforts in the 1960s. Research and development (R&D) of novel agents to treat NTDs

Table 5–4

Neglected tropical diseases amenable to mass drug administration[62,102]

Disease	Causative Organism(s)	Transmission	Common Symptoms	Therapy	Frequency of MDA	Prevention
Onchocerciasis (river blindness)	*Onchocerca volvulus*	Blackflies	Ocular changes (punctate or sclerosing keratitis, optic atrophy, etc.), subcutaneous nodules, pruritus	**Ivermectin** 150 mcg/kg × 1 dose Moxidectin 8 mg × 1 dose	Every 6–12 months	Vector management
Lymphatic filariasis	*Wuchereria bancrofti, Brugia malayi, Brugia timori*	Mosquitoes	Often asymptomatic; lymphangitis, localized pain and swelling, lymphedema, hydrocele	*Regions with coendemic onchocerciasis:* **Ivermectin** 150 mcg/kg × 1 dose PLUS **albendazole** 400 mg × 1 dose *Regions without coendemic onchocerciasis:* **Diethylcarbamazine** (DEC) 6 mg/kg × 1 dose PLUS **albendazole** 400 mg × 1 dose	Every 12 months	Vector management
Schistosomiasis (bilharzia)	*Schistosoma* spp.	Contaminated freshwater	*Acute*: Pruritus, fever, myalgia, headache, abdominal pain, cough *Chronic*: Urogenital symptoms (hematuria, urinary frequency and burning, bladder cancer) and intestinal symptoms (abdominal pain, diarrhea, rectal bleeding, hepatomegaly)	**Praziquantel** 40–60 mg/kg divided in 2–3 doses × 1 day	Depends on local prevalence	Environmental improvements (water, sanitation, hygiene)
Trachoma	*Chlamydia trachomatis* serotypes A, B, Ba and C	Body fluids, flies	Conjunctivitis (redness, irritation, discharge), conjunctival scarring, trichiasis, blindness	**Azithromycin** 20 mg/kg (max 1 g) × 1 dose Tetracycline 1% ointment twice daily × 6 weeks Surgery if trichiasis present	Every 12 months	Facial cleanliness, environmental improvements (water, sanitation, hygiene)
Soil-transmitted helminths (particularly ascariasis, trichuriasis, and hookworms)	*Ascaris lumbricoides, Trichuris trichiura, Necator americanus*, and *Ancylostoma duodenale*, among others	Fecal–oral route, penetration through skin (typically bare feet)	Often asymptomatic; diarrhea or constipation, weight loss, abdominal pain, small bowel obstruction, rectal prolapse, anemia, protein deficiency, cough	**Albendazole** 400 mg or **mebendazole** 500 mg × 1 dose Ivermectin 150–200 mcg/kg × 1 dose Surgery in severe cases	Every 6–12 months based on prevalence	Environmental improvements (water, sanitation, hygiene), use of footwear

Data from Montresor A, Gabrielli AF, Chitsulo L, et al. Preventive chemotherapy and the fight against neglected tropical diseases. Expert Rev Anti Infect Ther. 2012;10(2):237–242 and Addisu A, Adriaensen W, Balew A, et al. Neglected tropical diseases and the sustainable development goals: an urgent call for action from the front line. BMJ Glob Health. 2019;4(1):e001334.

is greatly needed; however, there is little motivation for pharmaceutical companies to devote funding to diseases that are likely to have minimal return on investment. For this reason, the priority review voucher program was created to provide financial incentives for sponsors of NTD therapies.[67] If a company brings a new drug to market that fills a gap in therapy related to NTDs, they are awarded a voucher, which may either be used for expedited review of any subsequent new drug application or may be sold to another company, often for millions of dollars.[67,68] While the program is not without criticism, six new NTD therapies have come to market due to the priority review voucher program.[68] Moxidectin, which was shown to be superior to ivermectin for onchocerciasis in clinical trials, received FDA approval in 2018 and is the first new onchocerciasis drug to come to market in over 20 years.[69] Furthermore, all revenue from moxidectin sales will be used to support further access to the drug and R&D on other novel NTD therapies.[69] Additional incentives for R&D are urgently needed to drive control and elimination of NTDs.

INTERNATIONAL PARTNERSHIP PRINCIPLES

Context Matters

Global health practice occurs in various and varied contexts—in terms of geography, setting, culture, organizational structures, resources, and capabilities.[70] While it is common to extrapolate global health experiences in one setting to another, it is important to recognize that even between settings within the same country, contexts can be significantly different. International partners practicing **cross-culturally** need adequate preparation on what the context holds, in addition to being willing and open to learn more while at practice and collaboration.[71]

KEY CONCEPT Culture, resources, and capabilities are key contextual considerations to keep in mind and applicable at both the micro- (individual, organizational) and macro level (health system, population level). Cultural competence is the ability to understand, communicate with, and effectively interact with people and systems across cultures; in global health practice, this includes respecting diverse values, beliefs, and feelings from patients and their families, as well as those of local health practitioners. Resources refer to the preventive, diagnostic, and treatment options available, while capabilities refer to how and to what extent individuals can utilize these resources, and in the context of global health, to achieve health and well-being. Taken together, resources and capabilities play particular prominence to access issues; that is, to what extent health resources are equitably available, usable (affordable and acceptable), and can be leveraged in a timely fashion to avert death and disability.[27]

Understanding the context in global health promises more effective partnership in several ways. Firstly, collaboration may be smoother as cultural faux pas and gaffes, which may create friction between partners, are less likely to be made. Secondly, problems and their root causes may be more clearly comprehended. One is less likely to project their own point of view toward a health problem—be it at the individual level or health system level—and solutions are more likely to be appropriate and acceptable. For example, in resource-limited settings, cost of medicines is often highlighted as a barrier to medication adherence, with potential solutions such as providing access to free medicines proposed. Unfortunately, such programs have at times failed to improve adherence. Root causes, however, include patient deprioritization of the need for medicines, particularly in asymptomatic patients such as in uncomplicated hypertension.[72] In such an instance, given competing priorities for personal resource use, the **opportunity cost** of adherence may be perceived to be higher by a patient and its benefits negligible. Therefore, a more effective intervention would target improving the patient's understanding of the need for adherence.

True Collaboration in Problem Solving Through Bilateral Learning

A prevailing mindset in global health has been the need to deliver solutions developed and demonstrated to work in high-income settings to target foreign LMIC settings. This knowledge and skills transfer may be what is needed in some instances; for example, training on use of a new health technology, which may be novel in the LMIC setting but the visiting global health practitioner has wide experience with its use in their high-income home country. However, it is inappropriate to assume that one-way knowledge and skills transfer is required in all situations. Given the context considerations described above, differences in care delivery between home and target settings should not be assumed to be a result of knowledge or skills deficits that practitioners from high-income settings are there to address. Instead, it is the case that local practitioners have spent years refining their skills around the infrastructure in their setting and have a contextualized understanding of delivering healthcare services and optimizing health outcomes for their population. Consequently, visiting practitioners should strive to learn and understand this, prior to trying to guide others in implementing strategies from their home country, which may be inappropriate in a different context.

An additional effect of the antiquated mindset of global health practice is the predisposition to create inappropriate power dynamics between global health collaborators, whereby the visiting practitioner is viewed as the expert, and the host practitioner is viewed as the learner. For example, a visiting student may perceive themselves to be more knowledgeable on treatment than a local clinician with more contextualized training and experience on managing the diseases in their setting. This mindset, and the subsequent inappropriate power dynamic, impedes true collaboration as it creates a one-way learning channel—north to south. However, given the importance of context discussed above, similar problems may have drastically different root causes and varying solutions.

KEY CONCEPT Making the mindset shift from expert to learner involves striving first to understand, before trying to be understood, much as one would do when undertaking any clinical rotation in different practice sites in your country of origin. It compels prioritization of local needs and local knowledge, setting up the conditions for true **bilateral learning** and collaborative development of solutions to global health challenges.[72]

Focus on Sustainable Solutions

Sustainability in the global health context refers to continuity of care beyond the engagement period. Solutions—both for individual patient care and at the health system level—should be able to outline an individual's or program's period of engagement. This is necessary so that health gains made are not eroded immediately when engagement ends.[73] An example of this is a hypertension care program that includes free supply of medicines where, without donor support for the program, patients will be expected to pay for their own medicines. Instead, at the outset, the program should align itself with what the payer system is like in the setting in which it is being implemented. If cost is a significant barrier to adherence, a sustainable solution for this needs to be included and planned for, for example, increasing insurance uptake.

Professional Ethics and Ethical Dilemmas

Professional ethics refers to the principles that govern right and wrong behavior in a given profession. Ethics should be distinguished from rules and regulations of practice, which may differ from setting to setting. Professional ethics for clinicians, however, are universal. Patient confidentiality, accountability, trustworthiness, respect for others, etc. should be upheld regardless of the context. Common examples of breaches include not protecting patient confidentiality through taking and sharing of clinical pictures without patient consent and inappropriate power dynamics in interprofessional work.

Ethical dilemmas arise when decisions have to be made where the only available options are not wholly appropriate from an ethical perspective. For example, a commonly reported ethical dilemma in global health is when professional ethics clash with cultural values and norms, such as when balancing patient autonomy and transparency with cultural expectations on how much to share with a patient or their family regarding a potentially poor prognosis.[74] In some settings, for example, informing the patient and/or family of a poor prognosis may be misconstrued as not doing all that is possible to help the patient, or as an attempt to control an outcome which is not up to you as a provider. In general, professional ethics should always be upheld when the alternative is unambiguous such as in the example of taking and sharing clinical pictures without patient consent. Other ethical dilemmas require individualized and contextualized solutions that should almost always be deferred to local practitioners.

Lastly, practitioners traveling to provide healthcare services in foreign settings must also make sure their own health is protected. With the growing frequency of communicable infectious diseases outbreaks, such as the Ebola virus and COVID-19, it is important that the healthcare workforce is adequately protected to ensure they can continue to treat those in need rather than exacerbating the well-described limitations in the supply of the healthcare workforce in LMICs.[75,76]

TRAVEL MEDICINE

People travel for many reasons, including tourism, study, business, visiting family, or altruistic work. The practice of travel medicine focuses on preventing illnesses and managing the health needs of international travelers. International travel has expanded substantially over the last few years. In the roughly 50 years between 1970 and 2020, the world population increased from approximately 2.5 billion to approximately 7.5 billion people, a threefold increase.[77] Concurrently, air travel increased during the same time from 310 million to 4.2 billion passengers—a 13-fold increase, and passenger-kilometer traveled increased 16-fold from 500 billion to 8 trillion.

The practice of travel medicine expanded to care for the increasing number of people traveling internationally and over greater distances than ever before. These travelers may also have preexisting medical illnesses that can be exacerbated by travel. Clinicians caring for travelers can provide valuable service to reduce their risks, and also fill a valuable public health need of reducing the risk of importing disease across borders. Many resources are available to assist clinicians to make appropriate decisions for international travelers, both prior to an international trip or following their return.

Pretravel Assessment

The medical risks of travel have a significant range. Depending on the itinerary, the risk of traveler's diarrhea is often around 50%, while the risk of acquiring Japanese encephalitis can have an incidence rate of 0.0001% per month.[78] Appropriate counseling and interventions can reduce these risks. A structured approach to the pretravel consultation, such as using the HUMID mnemonic described below, can help a clinician cover the most important topics.[79]

Patient Encounter 2, Part 1

The Ndubisi family is planning a trip to Nigeria. Mr. Ndubisi is a 32-year-old graduate student in psychology. He was born in Nigeria but attended high school in the United States. Mrs. Ndubisi is a 28-year-old pharmacy student. She was born in America and has traveled previously to Europe but has never traveled to Africa. They have two children, ages 1 and 4, and they plan to visit his extended family both in Lagos, Nigeria and the more rural areas for 6 weeks this coming summer after graduation.

What are some of the travel-related illnesses this family should consider as they prepare for their trip?

Does the fact that Mr. Ndubisi has family in Nigeria increase or decrease their risk of illness?

What medical history should be obtained before making recommendations prior to travel?

Human (individual risk assessment)

- List of chronic medical conditions and allergies
- List of medications and doses, with an adequate supply available for duration of travel
- Review drug interactions with new prescriptions
- Name and contact information of primary physician

Unique locations and hazards

- Review travel itinerary and potential threats
- Evaluate extreme environmental threats (heat, cold, altitude)
- Consider unique pathogens such as parasites, arthropods, and marine life
- Consider inaccessible or remote location without medical care
- Review safe sex, sunscreens, hygiene, etc.

Malaria prophylaxis

- Review appropriate prophylaxis for location and patients
- Issue prescriptions (may require weeks to obtain in some areas)
- Reinforce continuation of prescription after return and immediate evaluation for unexplained fevers for 1 year after travel

Immunizations

- Review current immunization status and update as needed
- Review immunization requirements for destination
- Give immunizations (yellow fever might require advance planning)

Diarrhea

- Review food safety, water safety, and hygiene
- Issue prescriptions for empiric treatment based on location of travel, age, and health status of patient
- Instruct to seek medical care if diarrhea does not resolve after treatment

▶ *Human*

KEY CONCEPT Providing a pretravel evaluation requires understanding the traveler's plans and reviewing their health needs. Patients may have chronic health conditions that will affect their travel plans.[80] Patients need to be certain they have an adequate supply of medications for their entire trip—and preferably enough additional doses to last in case their trip is unexpectedly delayed or prolonged. Medications should be brought in their original bottles with their name and prescriber's name printed on them to reduce problems going through customs.

Chronic health conditions can be affected by travel. Patients with diabetes may find that eating local cuisine while traveling can have a significant impact on their blood glucose levels, and their activity level as tourists may be different than their usual activities at home. Patients with asthma may be exposed to a different set of allergens; those who are sensitive to tobacco smoke may find variations in local laws and practices change their exposure to second-hand smoke.

Also, it is reasonable to anticipate some potential emergency situations that could be managed with self-directed care.[81] Navigating a health emergency in a foreign country and a different healthcare system with potential language barriers can be difficult. Self-directed care may be preferable to attempting to access a foreign health system for conditions that can be anticipated. Conditions like a chronic obstructive pulmonary disease exacerbation or dysuria with typical urinary tract infection symptoms could potentially be managed empirically in certain situations. Coronary artery disease is the leading cause of deaths globally, including among travelers.[82] Patients with known cardiac disease should bring a copy of their electrocardiography (ECG) or any implanted cardiac device cards in case problems develop while abroad. Allergies are also a common problem, which can be exacerbated by a language barrier.[83] People with food allergies, such as peanuts, may wish to bring a photograph of allergenic foods to better communicate to others which ingredients they must avoid. These patients should also anticipate possible emergencies and bring doses of emergency epinephrine, diphenhydramine, and potentially corticosteroids.

Even with the best preparations, travel emergencies can happen. Travelers from the United States can access the Department of State website for information on local hospitals and physicians from local embassies.[84] The International Association of Medical Assistance to Travelers is a nonprofit organization that maintains a list of clinicians in many countries that will evaluate English-speaking travelers.[85] Serious problems that require medical evacuation can be very expensive as well as frightening and are often not covered by a traveler's usual health financing plan. Evacuation insurance can fill this gap. For US travelers, the CDC provides some guidance on features to consider.[86]

▶ *Unique Risks*

Each traveler has an expected itinerary of where they will be going and some anticipated plans of what they will be doing. Evaluating this itinerary starts with which countries they will be visiting, but one should also consider some of the details. Risks will be different if they will be staying in largely urban or rural areas, if their time will be spent in forests or jungle, if they will be swimming at salt-water beaches or fresh-water lakes, or if they will be traveling to areas with significant elevation. While it is nearly impossible to have a comprehensive knowledge about every risk in every corner of the globe, there are many continually updated resources available to learn about geographically specific risks that are either free or require a subscription.

One interesting group that deserves special attention is patients who are visiting friends or relatives, or "VFRs." [86] Typically, they are patients who have ethnic origins from a low-income country, but now live in a high-income country. When such patients plan to visit their family or friends in the low-income country of origin, they often perceive their personal risk of illness to be quite low. They may assume they are immune to endemic diseases such as malaria and typhoid, but their actual risk of acquiring these illnesses is approximately eight times that of an expatriate tourist. VFR patients often have longer visits, stay in local homes, eat more authentic food, and have a higher risk of acquiring sexually transmitted diseases.[86]

Travelers planning to spend time at significant altitude may consider prophylaxis against altitude sickness. This can be a spectrum of diseases ranging from mild dyspnea, to headaches and nausea, to more severe forms of cerebral or pulmonary edema. Roughly 25% of people will be affected at 2500 m, although the severe manifestations are uncommon below 3500 m. The best prevention is to take a slow ascent over several days. For travelers going by car or airplane, acetazolamide at a dose of 125 mg twice daily can help prevent some of the symptoms.[88]

▶ *Malaria*

Malaria is the most common life-threatening travel-related illness, with roughly 2000 cases per year in US travelers. In a pretravel consultation, there are several issues of importance to discuss for malaria prevention, including prevention of mosquito bites, need for evaluation and treatment if symptoms develop, and prophylactic medications.

Malaria risk in travelers depends on the countries on the itinerary but can also vary significantly depending on regions within the country, lodging arrangements, and planned activities. While some countries have malaria endemic throughout their borders, some have the disease restricted to certain areas. Good resources are available and updated regularly by groups like the World Health Organization and Centers for Disease Control and Prevention.[89]

Preventing mosquito bites is the first step against preventing all mosquito-borne diseases, including malaria. Other insect-borne diseases like **Zika and West Nile encephalitis** are carried by mosquitoes and do not have vaccines available currently. People who are sleeping in rooms should ensure that they are air conditioned and have screens over the windows. If not, they should sleep under a bed net. A room fan at the end of the bed can also keep mosquitoes from flying.

The most common insect repellent in the United States is N,N-diethyl-meta-toluamide, also called DEET. Lotions and sprays are available in strengths from 10% to 100% DEET. Little additional benefit is provided in strengths beyond 50%, which will last approximately 6 hours. CDC and AAP recommend DEET may be used in infants as young as 2 months. Picaridin is a newer preventive lotion that is available in 15% to 30% strengths and has a similar spectrum of activity. Some patients may prefer to treat their clothes with permethrin—this strategy will typically last about 6 weeks through several washes. Other agents like citronella provide some activity, although only for about 20 minutes. Soybean oil can provide some protection for about 90 minutes. Other information can be found at the National Pesticide Information Center.[90]

In addition to precautions to avoid mosquito bites, travelers should use a recommended antimalarial prophylactic medication to areas where malaria is endemic, as described in Tables 5–5 and 5–6. Four agents are most commonly used.[86] Chloroquine is a highly effective preventive medication that is dosed once weekly. However, widespread resistance limits its use to few areas of the globe, including the Caribbean, Central America west of the Panama Canal, and parts of the Middle East. Mefloquine is also dosed once weekly and overcomes this resistance in nearly every part of the world except for parts of Southeast Asia. However, it comes with a significantly greater risk of toxicity. Doxycycline is taken daily when used for malaria prevention. It is effective, although its relatively short half-life means that missed doses pose a significant risk to the effectiveness of the regimen. Atovaquone/proguanil is one of the newer agents available for prophylaxis. It also is taken daily and has little known resistance. It has become the most widely prescribed antimalarial drug in the United States.[88] Less frequently used as prophylaxis are the agents primaquine and tafenoquine. These medications are especially effective against *Plasmodium vivax* but are contraindicated in patients with glucose-6-phosphatase dehydrogenase (G6PD) deficiency. Any patient wishing to take these medications must be tested for G6PD before starting them.

▸ *Immunizations*

A pretravel consultation is an opportunity to review the patient's immunization status and ensure they are up to date on routinely recommended vaccinations based on their age and risk factors as described in Table 5–7.[91] Additional vaccines that are unique to travel can then be considered based on local epidemiology and risks. Since these risks vary significantly from location to location and change over time, consulting one of the continually updated resources can help a clinician make appropriate decisions.

▸ *Diarrhea*

Traveler's diarrhea is the most common medical complaint of travelers—reaching nearly 50% for some itineraries. This clinical syndrome typically consists of 3 to 5 days of watery diarrhea, often with nausea and cramping. Fever is a red flag that would suggest a more invasive disease. Bacterial agents are considered as the cause the majority of the time, with the most common infectious agent being enterotoxigenic *Escherichia coli*, although *Campylobacter* species are also common in Southeast Asia. Traveler efforts to prevent this by simple dietary avoidance of raw fruits and vegetables, and contaminated water sources are often imperfect, and even conscientious travelers can still develop symptoms (Table 5–8).[92]

Bismuth subsalicylate can be taken as a prophylactic agent and can reduce the risk of traveler's diarrhea by about 50% in short-term exposures. Longer-term use has not been studied and is limited by the need to take a large number of tablets. Certain antibiotics such as fluoroquinolones, rifaximin, and azithromycin can also prevent traveler's diarrhea, but concern about antimicrobial resistance from widespread use limits these recommendations. Patients with significant comorbidities or immunosuppression may find the benefits of prophylaxis can outweigh the risks.

Self-directed therapy is another option that may be more appropriate for a wider range of travelers. Every patient with diarrhea should maintain an adequate fluid intake to replenish losses. Loperamide is also effective at reducing symptoms temporarily and is generally considered safe when diarrhea is not associated with fever or blood in the stool. Antibiotics can also be used for self-directed treatment for moderate to severe symptoms, and generally reduce symptoms to 24 hours or less (Table 5–9).[86]

Evaluation of the Returned Traveler

Travelers who develop illness while traveling internationally or shortly after returning have some unique challenges. Their additional activities and itineraries often add a wider range of diagnostic possibilities to their clinical symptoms. These additional possibilities may include conditions that are unfamiliar to the evaluating clinicians, some of which may be mild while some are life threatening. Ill returned travelers therefore should be promptly evaluated by clinicians who are able to manage these possibilities.

Gastrointestinal complaints are the most common problem seen after travel as seen in Table 5–10. While traveler's diarrhea is most commonly due to gram-negative enteric bacteria, this condition usually has an onset within 1 to 3 days after ingesting the infectious agent, and symptoms generally abate after 3 to 7 days. Patients with gastrointestinal symptoms who have a longer incubation period or have symptoms persisting beyond this period are more likely to have more specific travel-related illnesses such as *Giardia* or strongyloidiasis.

Patient Encounter 2, Part 2

After further discussion, the Ndubisi family indicates that Mr. Ndubisi has previously had an episode of clinical depression but has been taking sertraline with remission of symptoms for the last 2 years. Mrs. Ndubisi received routine prenatal care for her two pregnancies, and just finished breast-feeding her youngest child. She is now using combined estrogen/progesterone pills for contraception. The two children make all of their routine pediatric well visits and are currently on age-appropriate immunizations as recommended by the US Center for Disease Control and Prevention.

What human aspects of the Ndubisi family merit additional attention?

What unique aspects of their travel itinerary would pose a risk of travel-related illness?

What antimalarial precautions would be recommended? Would you recommend a prescription medication? If so, which one?

What immunizations would be recommended prior to the family's trip to Nigeria?

Would prophylactic treatment for traveler's diarrhea be recommended? What about prescribing antibiotics for self-directed therapy?

Table 5–5

Considerations When Choosing a Drug for Malaria Prophylaxis[86]

Drug	Reasons to Consider Use of This Drug	Reasons to Consider Avoiding Use of This Drug
Atovaquone-proguanil	• Good for last-minute travelers because the drug is started 1–2 days before travel • Some people prefer to take a daily medicine • Good choice for shorter trips because the traveler takes the medicine for only 7 days after traveling rather than 4 weeks • Well tolerated—side effects uncommon • Pediatric tablets are available and may be more convenient	• Cannot be used by women who are pregnant or breast-feeding a child that weighs < 5 kg • Cannot be taken by people with severe renal impairment • Tends to be more expensive than some of the other options (especially for long trips) • Some people (including children) would rather not take a medicine every day
Chloroquine	• Some people would rather take medicine weekly • Good choice for long trips because it is taken only weekly • Some people are already taking hydroxychloroquine chronically for rheumatologic conditions; in those instances, they may not have to take an additional medicine • Can be used in all trimesters of pregnancy	• Cannot be used in areas with chloroquine or mefloquine resistance • May exacerbate psoriasis • Some people would rather not take a weekly medication • For short trips, some people would rather not take medication for 4 weeks after travel • Not a good choice for last-minute travelers, because drug needs to be started 1–2 weeks before travel
Doxycycline	• Some people prefer to take a daily medicine • Good for last-minute travelers because the drug is started 1–2 days before travel • Tends to be the least expensive antimalarial • People who are already taking doxycycline chronically to prevent acne do not have to take an additional medicine • Doxycycline can also prevent some additional infections (eg, rickettsial infections, leptospirosis), so it may be preferred by people planning to hike, camp, and swim in fresh water	• Cannot be used by pregnant women and children aged < 8 years • Some people would rather not take a medicine every day • For short trips, some people would rather not take medication for 4 weeks after travel • Women prone to getting vaginal yeast infections when taking antibiotics may prefer taking a different medicine • People may want to avoid the increased risk of sun sensitivity • Some people are concerned about the potential of getting an upset stomach from doxycycline
Mefloquine	• Some people would rather take medicine weekly • Good choice for long trips because it is taken only weekly • Can be used in all trimesters of pregnancy	• Cannot be used in areas with mefloquine resistance • Cannot be used in patients with certain psychiatric conditions • Cannot be used in patients with seizure disorders • Not recommended for people with cardiac conduction abnormalities • Not a good choice for last-minute travelers because drug needs to be started ≥ 2 weeks before travel • Some people would rather not take a weekly medication • For short trips, some people would rather not take medication for 4 weeks after travel
Primaquine	• It is the most effective medicine for preventing *P. vivax*, so it is a good choice for travel to places with > 90% ***P. vivax*** • Good choice for shorter trips because the traveler takes the medicine for only 7 days after traveling rather than 4 weeks • Good for last-minute travelers because the drug is started 1–2 days before travel • Some people prefer to take a daily medicine	• Cannot be used in patients with G6PD deficiency • Cannot be used in patients who have not been tested for G6PD deficiency • There are costs and delays associated with getting a G6PD test; however, it only has to be done once. Once a normal G6PD level is verified and documented, the test does not have to be repeated the next time primaquine is considered • Cannot be used by pregnant women • Cannot be used by women who are breast-feeding, unless the infant has also been tested for G6PD deficiency • Some people would rather not take a medicine every day • Some people are concerned about the potential of getting an upset stomach from primaquine
Tafenoquine	• One of the most effective drugs for prevention of *P. vivax* malaria, though also prevents *P. falciparum* • Good choice for shorter trips because the traveler takes the medicine once, 1 week after traveling rather than 4 weeks • Good for last-minute travelers because the drug is started 3 days before travel	• Cannot be used in people with G6PD deficiency • Cannot be used in patients who have not been tested for G6PD deficiency • There are costs and delays associated with getting a G6PD test; however, it only has to be done once. Once a normal G6PD level is verified and documented, the test does not have to be repeated the next time tafenoquine or primaquine is considered • Cannot be used by children • Cannot be used by pregnant women • Cannot be used by women who are breast-feeding • Not recommended in those with psychotic disorders

G6PD, glucose-6-phosphatase dehydrogenase. From CDC Yellow Book 2020: Health Information for International Travel. 2020.

Table 5–6

Drugs Used in the Prophylaxis of Malaria[86]

Drug	Usage	Adult Dose	Pediatric Dose	Comments
Atovaquone-proguanil	Prophylaxis in all areas	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride 1 adult tablet daily	Pediatric tablets contain 62.5 mg atovaquone and 25 mg proguanil hydrochloride 5–8 kg: 1/2 pediatric tablet daily > 8–10 kg: 3/4 pediatric tablet daily > 10–20 kg: 1 pediatric tablet daily > 20–30 kg: 2 pediatric tablets daily > 30–40 kg: 3 pediatric tablets daily > 40 kg: 1 adult tablet daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Contraindicated in people with severe renal impairment (creatinine clearance < 30 mL/min). Atovaquone-proguanil should be taken with food or a milky drink. Not recommended for prophylaxis for children weighing < 5 kg, pregnant women, and women breast-feeding infants weighing < 5 kg. Partial tablet doses may need to be prepared by a pharmacist and dispensed in individual capsules, as described in the text.
Chloroquine	Prophylaxis only in areas with chloroquine-sensitive malaria	300 mg base (500 mg salt) orally, once/week	5 mg/kg base (8.3 mg/kg salt) orally, once/week, up to maximum adult dose of 300 mg base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas. May exacerbate psoriasis.
Doxycycline	Prophylaxis in all areas	100 mg orally, daily	≥ 8 years of age: 2.2 mg/kg up to adult dose of 100 mg/day	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 4 weeks after leaving such areas. Contraindicated in children < 8 years of age and pregnant women.
Hydroxychloroquine	An alternative to chloroquine for prophylaxis only in areas with chloroquine-sensitive malaria	310 mg base (400 mg salt) orally, once/week	5 mg/kg base (6.5 mg/kg salt) orally, once/week, up to a maximum adult dose of 310 mg base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas.
Mefloquine	Prophylaxis in areas with mefloquine-sensitive malaria	228 mg base (250 mg salt) orally, once/week	≤ 9 kg: 4.6 mg/kg base (5 mg/kg salt) orally, once/week > 9–19 kg: 1/4 tablet once/week > 19–30 kg: 1/2 tablet once/week > 30–45 kg: 3/4 tablet once/week > 45 kg: 1 tablet once/week	Begin ≥ 2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas. Contraindicated in people allergic to mefloquine or related compounds (quinine, quinidine) and in people with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in people with psychiatric disturbances or a previous history of depression. Not recommended for people with cardiac conduction abnormalities.
Primaquine	Prophylaxis for short-duration travel to areas with principally *P. vivax*	30 mg base (52.6 mg salt) orally, daily	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas.
	Presumptive antirelapse therapy (PART or terminal prophylaxis) to decrease the risk for relapses of *P. vivax* and *P. ovale*	30 mg base (52.6 mg salt) orally, daily	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, daily	PART indicated for people with prolonged exposure to *P. vivax*, *P. ovale*, or both: daily for 14 days after departure from the malarious area. Contraindicated in people with G6PD deficiency. Also contraindicated during pregnancy and lactation, unless the infant being breast-fed has a documented normal G6PD level.
Tafenoquine	Prophylaxis in all areas	200 mg orally	Not indicated in children < 16 years old	Begin taking daily for 3 days prior to travel to malarious areas. Then, take weekly while at the malarious area, and for 1 week after leaving the malarious area.
	Presumptive antirelapse therapy (PART or terminal prophylaxis) to decrease the risk for relapses of *P. vivax* and *P. ovale*	300 mg orally	300 mg orally	PART indicated for people who had prolonged exposure to *P. vivax, P. ovale*, or both: administered as a single dose. Contraindicated in people with G6PD deficiency. Also contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level.

G6PD, glucose-6-phosphatase dehydrogenase. From CDC Yellow Book 2020: Health Information for International Travel. 2020.

Table 5–7

Vaccines Which Should Be Available During Pretravel Consultation[88]

Disease and Vaccine Type	Adult Dose	Route of Administration	Standard Schedule	Accelerated Schedule for Series	Estimated Duration of Protection	References
Available in the United States						
Cholera: live attenuated bacteria	1 sachet	Oral	Single dose	NA	3-6 mo	Jackson and Chen[19]
Hepatitis A: inactivated virus	1 mL	Intramuscular	2 doses: day 0 and at 6-12 mo[†]	Available in combined hepatitis A and B formulation: days 0, 7, and 21 and at 12 mo[‡]	>20 yr (seropositivity); >40 yr (antibody modeling)	ACIP,[20] Theeten et al.[21]
Hepatitis B: recombinant hepatitis B surface antigen	1 mL	Intramuscular	3 doses: day 0 and at 1 mo and 6 mo	Available in combined hepatitis A and B formulation: days 0, 7, and 21 and at 12 mo[‡]	30 yr	Mast et al.,[22] FitzSimons et al.[23]
Combined hepatitis A and B: inactivated virus and recombinant viral antigen	1 mL	Intramuscular	3 doses: day 0 and at 1 mo and 6 mo	4 doses: days 0, 7, and 21 and at 12 mo[‡]	>15 yr (data on monovalent vaccines support long-term protection from anamnestic response)	Van Damme et al.[24]
Influenza						Grohskopf et al.[25]
Inactivated virus or recombinant, trivalent or quadrivalent	0.5 mL (0.1 mL for intradermal administration)	Intramuscular (intradermal formulation for age 18-64 yr)	1 dose	NA	1 yr	
Live attenuated virus, quadrivalent	0.1 mL in each nostril	Intranasal spray	1 dose	NA	1 yr	
Japanese encephalitis: inactivated virus, derived from cell culture	0.5 mL	Intramuscular	2 doses: days 0 and 28	2 doses: days 0 and 7	1-2 yr after initial dose; >6 yr if boosted at 1-2 yr	Fischer et al.,[26] CDC,[27] Jelinek et al.,[28] EMA,[29] Paulke-Korinek et al.,[30] Rabe et al.[31]
Measles-mumps-rubella: live attenuated virus	0.5 mL	Subcutaneous	2 doses: day 0 and at 4 wk		Lifelong, after 2 doses total at any time in life	McLean et al.[32]
Meningococcal disease — quadrivalent ACYW-135: bacterial polysaccharide, conjugated[§]	0.5 mL	Intramuscular	1 dose (off-label for those >55 yr old)	NA	3-5 yr	Cohn et al.,[33] Baxter et al.[34]
Poliomyelitis: inactivated virus	0.5 mL	Subcutaneous	Single dose in those who received primary childhood series	NA	Lifelong, after primary series plus a booster in adulthood (age ≥18 yr)	Wallace et al.[35]
Rabies: inactivated virus, derived from cell culture	1 mL	Intramuscular (0.1 mL intradermally may be considered for use off-label)	3 doses before exposure: days 0,7, and 21-28	NA	Patient should be informed that 2 additional doses are required on days 0 and 3 after each possible rabies exposure; no boosters are otherwise indicated	Manning et al,[36] Wieten et al,[37]

(Continued)

Table 5–7

Vaccines Which Should Be Available During Pretravel Consultation[88] (*Continued*)

Disease and Vaccine Type	Adult Dose	Route of Administration	Standard Schedule	Accelerated Schedule for Series	Estimated Duration of Protection	References
Tetanus-diphtheria-acellular pertussis (Tdap) or tetanus-diphtheria (Td): toxoid, protein antigen	0.5 mL	Intramuscular	1 dose in those who received primary childhood series	NA	10 yr; 5 yr for travelers at high risk for wounds (eg, adventure travelers, those engaging in activities that may result in injuries, and travelers to places where medical care is substandard)	CDC[38]
Typhoid						Jackson et al.[39]
Bacterial cell-wall polysaccharide	0.5 mL	Intramuscular	1 dose	NA	2-3 yr	
Live attenuated bacteria	4 capsules	Oral	4-capsule series, one every other day		5 yr	
Yellow fever: live attenuated virus	0.5 mL	Subcutaneous	1 dose	NA	10 yr for high-risk patients (in some countries, protection is considered to be long-term)	Gershman and Staples,[40] WHO,[41] Staples et al.[42]
Not currently available in the United States						
Cholera: inactivated whole-cell bacteria combined with recombinant B subunit of cholera toxin	1 sachet	Oral	2 doses, 1 wk apart	NA	2 yr	WHO[43]
Tickborne encephalitis: inactivated virus derived from cell culture	0.5 mL	Intramuscular	3 doses: day 0, at 1-3 mo, and at 5-12 mo	3 doses: days 0, 7, and 21 (protective 7 days after dose 3)	3 yr	WHO[44]

*Consideration may be given to stocking human papillomavirus and herpes zoster vaccines, as well as other vaccines (eg, pneurnococcal vaccines) for travelers with chronic illnesses, since the travel consultation is an excellent opportunity to update routine immunizations. CDC denotes Centers for Disease Control and Prevention, EMA, European Medicines Agency, FDA, Food and Drug Administration, NA not applicable, and WHO World Health Organization.

†The Advisory Committee on Immunization Practices (ACIP) recommends that the first dose of hepatitis A vaccine and IgG be administered in travelers older than 40 years of age who are departing in less than 14 days for a destination where hepatitis A is endemic; however, this is rarely done in practice and is not included in any non-U.S. national guideline.

‡The initial accelerated schedule, with doses on days 0, 7, and 21, provides protection for up to 1 year; the additional dose at 12 months provides long-term protection similar to that with the standard schedule.

§The ACIP recommends use of the conjugate vaccine in persons 55 years of age or older who need repeated meningococcal vaccination, including travelers who may need another dose in 5 years or more. From Freedman DO, Chen LH, Kozarsky PE. Medical Considerations before International Travel. N Engl J Med. 2016 Jul 21;375(3):247–60.

Table 5–8

Traveler's Diarrhea Treatment Recommendations[86]

Therapy of mild travelers' diarrhea
- Antibiotic treatment is not recommended in patients with mild travelers' diarrhea.
- Loperarnide or BSS may be considered in the treatment of mild travelers' diarrhea.

Therapy of moderate travelers' diarrhea
- Antibiotics may be used to treat cases of moderate travelers' diarrhea.
- Fluoroquinolones may be used to treat moderate travelers' diarrhea.
- Azithromycin may be used to treat moderate travelers' diarrhea.
- Rifaximin may be used to treat moderate, noninvasive travelers' diarrhea.
- Loperarnide may be used as adjunctive therapy for moderate to severe travelers' diarrhea. Antimotility agents alone are not recommended for patients with bloody diarrhea or those who have diarrhea and fever.
- Loperarnide may be considered for use as monotherapy in moderate travelers' diarrhea.

Therapy of severe travelers' diarrhea
- Antibiotics should be used to treat severe travelers' diarrhea.
- Azithromycin is preferred to treat severe travelers' diarrhea.
- Fluoroquinolones may be used to treat severe, nondysenteric travelers' diarrhea.
- Rifaximin may be used to treat severe, nondysenteric travelers' diarrhea.[1]
- Single-dose antibiotic regimens may be used to treat travelers' diarrhea.

[1] These treatment recommendations were developed prior to the approval of rifamycin SV in the United States. Because it is in the same category of antimicrobial drug as rifaximin and because they have the same mechanism of action, rifamycin SV can he considered as an alternative to rifaximin. From CDC Yellow Book 2020: Health Information for International Travel. 2020.

A traveler returning from a tropical country with a new onset of a fever should be evaluated urgently, if not emergently. Malaria due to *Plasmodium falciparum* can be a life-threatening condition, especially in travelers who have never developed any immunity from prior or ongoing exposures. Fever in a traveler returning from a malaria-endemic region therefore must prompt a through and expedited evaluation. Other febrile diseases such as dengue or chikungunya also should be evaluated quickly and appropriately treated. Some diseases like viral hemorrhagic fevers are rarely seen but are of such substantial public health concern that they must be ruled out (Figure 5–18).

Table 5–9

Acute Diarrhea Antibiotic Treatment Recommendations[86]

Antibiotic[1]	Dose	Duration
Azithromycin[2,3]	1,000 mg	Single or divided dose[4]
	500 mg daily	3 days
Levofloxacin	500 mg daily	1-3 days[4]
Ciprofloxacin	750 mg	Single dose[4]
	500 mg bid	3 days
Ofloxacin	400 mg bid	1-3 days[4]
Rifamycin SV[5]	388 mg bid	3 days
Rifaximin[5]	200 mg tid	3 days

[1] Antibiotic regimens may be combined with loperamide 4 mg initially followed by 2 mg after each loose stool, not to exceed 16 mg in a 24-hour period.

[2] Use empirically as first-line in Southeast Asia or other areas if fluoroquinolone-resistant bacteria are suspected.

[3] Preferred regimen for dysentery or febrile diarrhea.

[4] If symptoms are nor resolved after 24 hours, continue daily dosing for up to 3 days.

[5] Do not use if clinical suspicion for *Compylobacter, Salmonella, Shigella,* or other causes of invasive diarrhea. Use may he reserved for patients unable to receive fluoroquinolones or azithromycin. From CDC Yellow Book 2020: Health Information for International Travel. 2020.

SUMMARY

This chapter provides an overview of the key considerations for promoting health equity around the world. It considers ways of protecting travelers while also protecting the involved healthcare workforce. Conscientious international partnerships can be formed to tackle the global burden of disease. The role of social determinants of health in driving health outcomes must be considered when establishing such collaborations. Furthermore, it is essential that responses to these social determinants of health be integrated into the more traditional role of the healthcare system, which focuses on direct clinical care.[19] Future generations of practitioners should strive to build upon the early progress made in developing more comprehensive, ethical, socially accountable, and population-centered initiatives.

Table 5–10

Chief Complaints in Returned Travelers Presenting to Travel Clinics[87]

Complaint	Percentage (n: 42,178)
Gastrointestinal	34%
Febrile illness	23%
Dermatologic	19%
Respiratory/pharyngeal	11%
Neurologic	1.7%
GU/STI	2.9%

GU, genitourinary; STI, sexually transmitted infection. Data from Leder K, Tong S, Weld L, Kain KC, Wilder-Smith A, von Sonnenburg F, et al. Illness in travelers visiting friends and relatives: a review of the GeoSentinel Surveillance Network. Clinical infectious diseases : an official publication of the Infectious Diseases Society of America. 2006;43(9):1185–93.

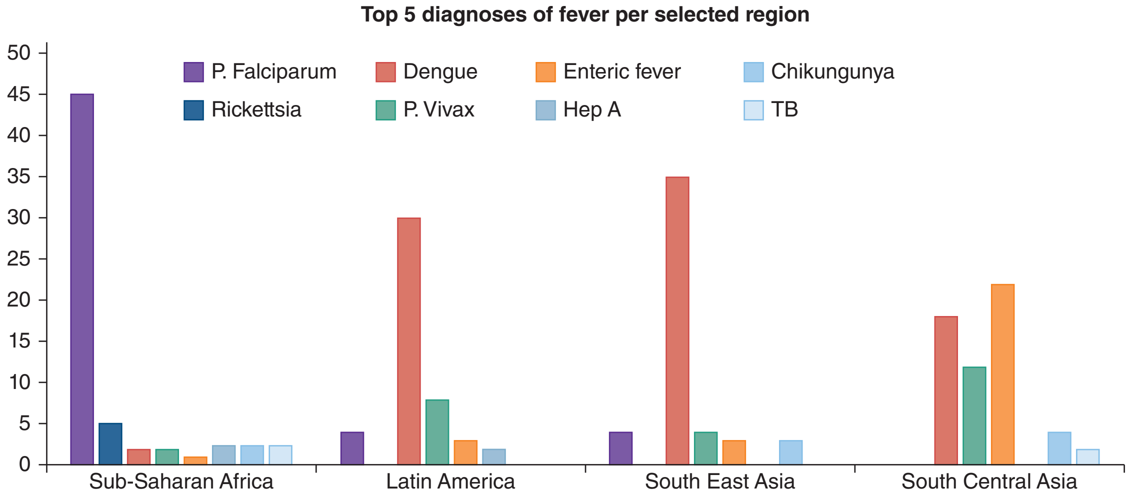

FIGURE 5–18. Top five diagnoses made in febrile patients returning from the selected region and presenting to specialty travel clinics. Reproduced with permission from From Leder K, Torresi J, Libman MD, et al. GeoSentinel Surveillance of Illness in Returned Travelers, 2007–2011. Ann Intern Med. 2013;158:456–468.

Patient Care Process

Collect Information:

- Obtain a thorough medical and medication history.
- Review prior immunization history, including both routine and prior travel immunizations.
- Obtain a detailed travel itinerary including locations and planned activities.

Assess the Information:

- Use an updated resource to determine risk of malaria and other geographically specific risks.
- Assess risks of other vaccine-preventable diseases based on travel, medical, and immunization history.
- Identify any noninfectious risks based on travel, medical, and immunization histories.
- Determine the risks and benefits of self-directed treatment for traveler's diarrhea.

Develop a Care Plan:

- Select an appropriate antimalarial medication for prophylaxis. Consider drug interactions, duration of travel, and potential toxicities.
- Develop an immunization regimen appropriate for the proposed itinerary.
- Counsel on food and water precautions and develop a strategy for treating the potential of traveler's diarrhea.

Implement the Care Plan:

- Review drugs, duration, dose, frequency, and side effects of selected medications.
- Educate the patient about the importance of compliance with the regimen and the risks of noncompliance.
- Ensure appropriate documentation of immunization administration for medical and legal purposes.

Follow up: Monitor and Evaluate: Glucose-6-Phosphatase Dehydrogenase Deficiency

- Follow up on subsequent immunizations for those that require multiple doses at precise intervals.
- Educate that patients who develop fever after returning from travel should be promptly evaluated with itinerary-specific diseases such as malaria considered among possible diagnoses.

Abbreviations Introduced in This Chapter

AIDS	Acquired immunodeficiency syndrome
COVID-19	Coronavirus disease-2019
DOAC	Direct oral anticoagulant
PEPFAR	President's Emergency Plan for AIDS Relief
WHO	World Health Organization
HALE	Healthy life expectancy
DALY	Disability-adjusted life year
EML	Essential medicines list
LMIC	Low- and middle-income country
MDA	Mass drug administration
MDG	Millennium Development Goal
NCD	Noncommunicable disease
NTD	Neglected tropical disease
R&D	Research and development
SDG	Sustainable Development Goal
SF	Substandard or falsified
STH	Soil-transmitted helminth
UNFPA	United Nations Fund for Population Activities
IHD	Ischemic heart disease
MMR	Maternal mortality ratio
TFR	Total fertility rate

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify guideline-based treatment goals for patients with hypertension.
2. Recognize underlying causes and contributing factors in the development of hypertension.
3. Describe the appropriate measurement of blood pressure (BP).
4. Classify BP levels after measurement.
5. Recommend lifestyle modifications.
6. Determine patient-centered pharmacotherapy for individuals with hypertension.
7. Identify specific conditions and populations requiring special consideration when designing a treatment plan for hypertension.
8. Construct an appropriate monitoring plan to assess hypertension treatment.

INTRODUCTION

It is well established that reducing elevated blood pressure (BP) in patients at sufficient cardiovascular event risk provides significant benefit. However, despite efforts to promote awareness and widespread use of antihypertensive medications, BP control remains suboptimal.[1]

Various algorithms recommend nonpharmacologic and pharmacologic management, with the underlying premise that lowering elevated BP reduces target organ damage leading to reductions in stroke, myocardial infarction (MI), end-stage renal disease, and heart failure (HF).[2,3] BP-related definitions, targets, and treatment recommendations for a particular patient may vary based on different guidelines and/or position statements, depending on their interpretation of the clinical evidence available at the time of development and the translatability of clinical data to their local practice. This chapter primarily focuses on the most recent comprehensive, evidence-based 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults, put forth by the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Clinical Practice Guidelines and hereafter referred to as the 2017 ACC/AHA guidelines.[2] This is not to minimize or discount other guidelines but to improve consistency for the learner.

KEY CONCEPT The 2017 ACC/AHA guidelines classify BP and provide guidance on accurate assessment of BP as well as the nonpharmacologic and pharmacologic approaches to managing hypertension. Various guidelines recognize that the lowest risk of adverse cardiovascular or renal outcomes is at a BP around 115/75 mm Hg, with risk rising as BP increases. For each increase of 20 mm Hg in systolic BP (SBP), or approximately 10 mm Hg increase in diastolic BP (DBP), the risk of death from ischemic heart disease, stroke, and other vascular diseases increases by twofold in individuals aged 40 to 69 years. The risk is even greater in older individuals.

KEY CONCEPT The 2017 ACC/AHA guidelines classify elevations in BP beyond specific thresholds as elevated BP, stage 1 hypertension, and stage 2 hypertension (Table 6–1) to imply different levels of risk and the need for varying intensities of intervention with drug therapy.[2] Specific BP thresholds for treatment and BP goals of therapy are established based on cardiovascular risk assessment or the presence of specific comorbid conditions (Figure 6–1 and Table 6–2).[2] Recommendations for BP-lowering medications typically begin with one or two (in the case of stage 2 hypertension and average BP of 20/10 mm Hg above the BP target) antihypertensive drugs. In addition, recommendations for specific medications are provided by race and/or the presence of compelling indications (Table 6–3) for which explicit evidence in the literature exists to document the utility of a particular agent or class of agents.[2] Selection of subsequent drug therapy involves an iterative process of adding antihypertensive drugs with different mechanisms of action as needed to achieve target BP. Although calls for greater personalization in selecting drug therapy have been advocated, including plasma renin activity (PRA) testing or noninvasive hemodynamic monitoring, these approaches are

Table 6–1

Classification of Hypertension in Adults[a,2]

BP Classification	Systolic BP (mm Hg)		Diastolic BP (mm Hg)
< Normal	< 120	AND	< 80
Elevated	120–129	AND	< 80
Stage 1 hypertension	130–139	OR	80–89
Stage 2 hypertension	≥ 140	OR	≥ 90

[a]Adults with systolic BP and diastolic BP in two categories should be assigned to the higher BP classification.

BP, blood pressure.

Table 6–2

Blood Pressure Thresholds and Goals of Pharmacologic Therapy in Patients With Hypertension According to Clinical Conditions[2]

Clinical Condition(s)	BP Threshold for Antihypertensive Therapy Initiation (mm Hg)	BP Goal (mm Hg)
General		
Clinical CVD or 10-year ASCVD risk ≥ 10%	≥ 130/80	< 130/80
No clinical CVD and 10-year ASCVD risk < 10%	≥ 140/90	< 130/80
Older persons (≥ 65 years of age; noninstitutionalized ambulatory, community-living adults)	≥ 130 (SBP)	< 130 (SBP)
Specific Conditions		
Diabetes mellitus	≥ 130/80	< 130/80
Chronic kidney disease	≥ 130/80	< 130/80
Chronic kidney disease postrenal transplantation	≥ 130/80	< 130/80
Heart failure	≥ 130/80	< 130/80
Stable ischemic heart disease	≥ 130/80	< 130/80
Secondary stroke prevention	≥ 140/90	< 130/80
Secondary stroke prevention (lacunar)	≥ 130/80	< 130/80
Peripheral arterial disease	≥ 130/80	< 130/80

ASCVD, atherosclerotic cardiovascular disease (calculator available online at http://tools.acc.org/ascvd-risk-estimator/); BP, blood pressure; CVD, cardiovascular disease; SBP, systolic blood pressure.

Adapted from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults. Hypertension. 2017, with permission.

not widely used.[4,5] In contrast, the importance of using 24-hour ambulatory BP monitoring (ABPM), home BP (HBP) monitoring, and ambulatory office-based BP (AOBP) monitoring has been recognized by the Centers for Medicare & Medicaid Services (CMS) and other organizations.[2,3,6] Regardless of the guideline and strategy implemented in practice, it is imperative that clinicians consider patient-specific characteristics and preferences among other considerations when establishing BP targets and drug selection.

EPIDEMIOLOGY

KEY CONCEPT Hypertension is widely prevalent and significantly contributes to cardiovascular-related morbidity, mortality, and associated health care costs. Globally, the estimated age-standardized prevalence of hypertension in adults (defined as SBP ≥ 140 mm Hg, diastolic DBP ≥ 90 mm Hg, and/or current use of antihypertensive medication) was 31.1% in 2010 with a modest decline in high-income countries and significant increase in low- and middle-income countries since 1975.[7] In the United States, nearly half (46%, 116.4 million) of adults greater than or equal to 20 years of age were estimated to be hypertensive when applying the definition of hypertension from the 2017 ACC/AHA guidelines.[1] The prevalence of hypertension differs based on age, sex, and ethnicity. As individuals age, risk of systolic hypertension increases. Eventually, more than 80% of the US population will have hypertension when aged 75 or older. Prior to age 64, women have a lower prevalence of hypertension than men but have a higher prevalence after age 65. Age-adjusted prevalence of hypertension is highest in non-Hispanic black individuals (56%–58.6%) when compared with non-Hispanic white individuals (41.3%–48.2%) and Mexican Americans (37.9%–44.4%).[1]

ETIOLOGY

KEY CONCEPT The cause of hypertension is usually unknown and referred to as primary hypertension in more than 90% of patients. However, in some patients there is an identifiable cause of hypertension, referred to as secondary hypertension. Causes of secondary hypertension include[2,8]:

More common (> 1%):

- Chronic kidney disease (CKD) (renal parenchymal disease)
- Drug-induced/related (Table 6–4)
- Obstructive sleep apnea
- Primary aldosteronism
- Renovascular hypertension or fibromuscular dysplasia

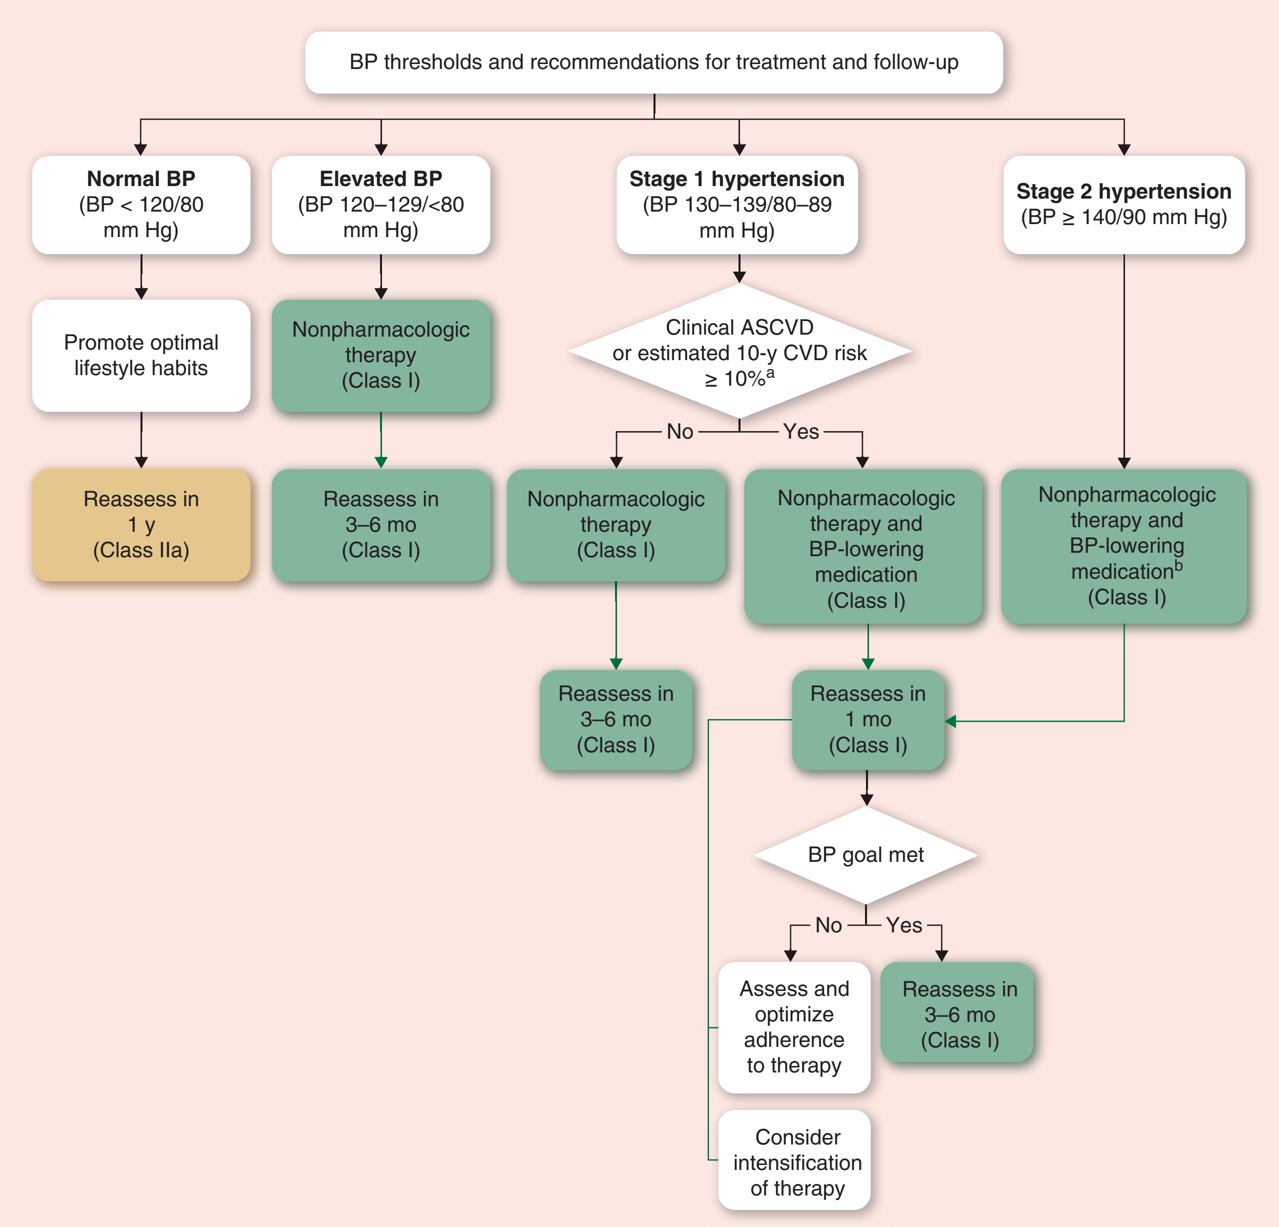
Less common (≤ 1%):

- Coarctation of the aorta
- Cushing syndrome and other glucocorticoid excess states
- Mineralocorticoid excess syndromes other than primary aldosteronism
- Genetic disorders (such as Liddle syndrome, Gordon syndrome, or Geller syndrome)
- Pheochromocytoma/paraganglioma
- Thyroid or parathyroid disease

The 2017 ACC/AHA guidelines recommend screening for secondary causes of hypertension in uncontrolled drug-resistant hypertension (three or more drugs), abrupt onset, age less than 30 years, excessive target organ damage, onset of diastolic hypertension in older adults, or in the presence of unprovoked or excessive hypokalemia.[2] In addition to primary and secondary hypertension, the clinician may encounter what is referred to as resistant hypertension. **KEY CONCEPT** Patients failing to achieve goal BP despite adherence to optimal doses of three antihypertensive agents of different classes (ideally, one being a diuretic) or those achieving goal BP on four or more antihypertensive medications have resistant hypertension and should be evaluated for secondary causes of hypertension.[9] Several causes of resistant hypertension are listed in Table 6–4 and should be carefully considered in such patients.[10] Additional consideration should be given to the clinical scenario of pseudohypertension, or elevated BP resulting from a myriad of potentiating factors including therapy nonadherence, white coat hypertension, or poor BP measurement technique.[9]

PATHOPHYSIOLOGY

KEY CONCEPT The pathophysiology of primary hypertension is heterogeneous but ultimately exerts its effects through two primary determinants of BP: cardiac output (CO) and peripheral vascular resistance (PVR). The processes influencing these two determinants are numerous and complex, and although the underlying cause of primary hypertension remains unknown, it is most likely multifactorial. As a review of these mechanisms is beyond the scope of this text, readers are referred to other sources.[8]



BP thresholds and recommendations for treatment and follow-up
Normal BP (BP < 120/80 mm Hg)
Elevated BP (BP 120–129/<80 mm Hg)
Stage 1 hypertension (BP 130–139/80–89 mm Hg)
Stage 2 hypertension (BP ≥ 140/90 mm Hg)
Promote optimal lifestyle habits
Nonpharmacologic therapy (Class I)
Clinical ASCVD or estimated 10-y CVD risk ≥ 10%a
No
Yes
Reassess in 1 y (Class IIa)
Reassess in 3–6 mo (Class I)
Nonpharmacologic therapy (Class I)
Nonpharmacologic therapy and BP-lowering medication (Class I)
Nonpharmacologic therapy and BP-lowering medicationb (Class I)
Reassess in 3–6 mo (Class I)
Reassess in 1 mo (Class I)
BP goal met
No
Yes
Assess and optimize adherence to therapy
Reassess in 3–6 mo (Class I)
Consider intensification of therapy

FIGURE 6–1. General recommendations for blood pressure (BP) threshold and recommendations for treatment and follow-up. Patients with elevated BPs should incorporate nonpharmacologic therapies to promote BP lowering. As BP reaches stage 1 hypertension, thresholds for therapy are guided based on a patient's level of risk as determined by baseline presence of cardiovascular disease (CVD), chronic kidney disease (CKD), or diabetes mellitus (DM) (all placing patient at higher risk) and CVD risk as calculated with the American College of Cardiology/American Heart Association (ACC/AHA) Pooled Cohort Equations (values greater than or equal to 10% defining higher risk). Lower-risk patients are reasonable for an initial trial of nonpharmacologic therapies while those with higher risk or stage 2 hypertension are initially begun on BP-lowering medications. Consideration may be given in patients with stage 2 to the initiation of combination therapy at treatment onset. "Class" indicates the strength of the recommendation, with Class I considered the strongest. [a]Using the ACC/AHA Pooled Cohort Equations. Note that patients with DM or CKD are automatically placed in the high-risk category. For initiation of renin–angiotensin system (RAS) inhibitor or diuretic therapy, assess blood tests for electrolytes and renal function 2 to 4 weeks after initiating therapy. [b]Consider initiation of pharmacologic therapy for stage 2 hypertension with two antihypertensive agents of different classes. Patients with stage 2 hypertension and BP greater than or equal to 160/100 mm Hg should be promptly treated, carefully monitored, and subject to upward medication dose adjustment as necessary to control BP. Reassessment includes BP measurement, detection of orthostatic hypotension in selected patients (eg, older or with postural symptoms), identification of white coat hypertension or a white coat effect, documentation of adherence, monitoring of the response to therapy, reinforcement of the importance of adherence, reinforcement of the importance of treatment, and assistance with treatment to achieve BP target. (ASCVD, atherosclerotic cardiovascular disease; mo, month; y, year.) Hypertension. 2017. https://doi.org/10.1161/HYP.0000000000000065.)

Table 6–3

Compelling Indications for Individual Drug Classes[2]

	Recommended Drug Class						
Compelling Indication	**Diuretic**	**Ald Ant**	**BB**	**CCB**	**ACE-I**	**ARB**	**Dir Vaso**
Heart failure with reduced ejection fraction	X	X	X		X	X	X
Heart failure with preserved ejection fraction	X		X		X	X	
Stable ischemic heart disease[a]	X	X	X	X	X	X	
Chronic kidney disease[b]					X	X	
Postrenal transplantation				X	X[c]		
Diabetes mellitus	X			X	X[d]	X[d]	
Secondary stroke prevention	X				X	X	
Atrial fibrillation						X	
Peripheral arterial disease	X			X	X	X	
Thoracic aortic disease			X				
Black race[e]	X			X			

[a] Recommended β-blockers for blood pressure (BP) control or angina relief include carvedilol, metoprolol tartrate, metoprolol succinate, nadolol, bisoprolol, propranolol, and timolol. Avoid β-blockers with intrinsic sympathomimetic activity. Atenolol should not be used as it is less effective than placebo for reducing cardiovascular events. CCBs recommended (class I) if blood pressure goal not met with BB, ACE-I or ARBs, and angina pectoris present.

[b] Recommendations stronger (class IIa) for patients with chronic kidney disease (CKD) and albuminuria (≥ 300 mg/day or ≥ 300 mg/g creatinine [34 mg/mmol creatinine]) and weaker (class IIb) for CKD stage 3 or higher without albuminuria or stage 1 or 2 with albuminuria (≥ 300 mg/day or ≥ 300 mg/g creatinine [34 mg/mmol creatinine]).

[c] ACE-I may be reserved in the development of albuminuria or heart failure after transplantation.

[d] ACE-I or ARB may be considered in the presence of albuminuria.

[e] Black adults with or without diabetes mellitus but without heart failure or CKD.

ACE-I, angiotensin-converting enzyme inhibitor; Ald Ant, aldosterone antagonist; ARB, angiotensin receptor blocker; BB, β-blocker; CCB, calcium channel blocker; Dir Vaso, direct vasodilator.

Data from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults. J Am Coll Cardiol. 2017. https://doi.org/10.1161/HYP.0000000000000065.

Patient Encounter 1

A 49-year-old man comes into your clinic with complaints of upper respiratory symptoms. Seated BP measured in the left arm is 148/96 mm Hg and 150/94 mm Hg in the right arm. The patient's physical examination was unremarkable. His past medical history is significant for dyslipidemia. He does not smoke tobacco or drink alcohol, and he walks daily for 30 minutes; however, he struggles with a heart healthy diet. He takes no medication on a chronic basis, but he reports taking an antihistamine/decongestant and ibuprofen for his current symptoms over the past several days. His cholesterol panel revealed a high-density lipoprotein (HDL) cholesterol level of 40 mg/dL (1.03 mmol/L), triglyceride level of 140 mg/dL (1.58 mmol/L), and total cholesterol of 198 mg/dL (5.12 mmol/L). Calculated low-density lipoprotein (LDL) cholesterol level is 130 mg/dL (3.36 mmol/L). All other laboratory values were within normal limits.

What steps are involved in assuring the patient's BP measurements are accurate?

Based on the information above, what stage of hypertension does this patient have?

What is the patient's BP target and threshold for antihypertensive therapy?

The development of primary hypertension involves interplay between genetic and environmental factors interacting with multiple physiological systems including neural, renal, hormonal, and vascular. Further complicating this is that an individual's phenotype of primary (or essential) hypertension (eg, systolic hypertension in teenagers and young adults, diastolic hypertension in middle-aged individuals, and isolated systolic hypertension in the elderly) may have different contributing mechanisms.[8] Because of these complexities, no final common pathway has been identified, and a single target for the treatment of primary hypertension remains elusive. Therefore, guidelines for the selection of specific therapeutic agents allow the clinician some flexibility in choices based on patient-specific factors.

Genetic Factors

Despite the identification of more than 1000 genetic loci associated with BP regulation, these loci together only explain about 5.7% of the variability of SBP, DBP, and pulse pressure.[11] However, rare monogenetic disorders can cause secondary hypertension in children, adolescents, or young adults, who typically have a suppressed PRA or plasma renin concentration (PRC). Environmental factors and gene-environment interactions, on the other hand, confer a larger effect on the pathophysiology of hypotension. Consequently, with very few exceptions, the information available to date is far from sufficient to provide any practical guidance for clinicians.[12] Nevertheless, these genetic associations reveal novel mechanisms and pathways regulating BP and may accelerate development of new drug therapies.

Table 6–4

Causes of Resistant Hypertension[10]

Apparent Resistance
- Improper blood pressure measurement
- Failure to receive or take antihypertensive medication appropriately (nonadherence)
- Inadequate doses (subtherapeutic)
- Improper antihypertensive selection or combination
- White coat hypertension

True Resistance
- Secondary hypertension
- Drug effects and interactions
  - Adrenal steroid hormones
  - Amphotericin B
  - Cocaine, amphetamines, and other illicit drugs
  - Cyclosporine and tacrolimus
  - Erythropoietin
  - Fluid retention from kidney disease or potent vasodilators (eg, minoxidil)
  - Herbal products (ma huang, guarana, bitter orange, blue cohosh)
  - Highly active antiretroviral therapy (HAART)
  - Inadequate diuretic therapy
  - Natural licorice (including some chewing tobacco)
  - Neurologic and psychiatric agents (eg, venlafaxine, lithium, thioridazine hydrochloride)
  - Nonsteroidal anti-inflammatory medications
  - Oral contraceptive hormones
  - Recent caffeine or nicotine intake
  - Sympathomimetics (decongestants, anorectics, and stimulants)
  - Vascular endothelial growth factor inhibitors (bevacizumab, sorafenib, sunitinib)
- Volume overload
- Excess sodium intake
- Comorbidities
  - Obesity
  - Excess alcohol intake
  - Chronic pain syndromes
  - Intense vasoconstriction (arteritis)
  - Anxiety-induced hyperventilation/panic attacks
- Genetic variation
  - Genetic differences in drug efficacy or metabolism

Environmental Factors

Environmental factors contributing to hypertension are well-characterized. Nicotine use (including cigars and smokeless tobacco) and caffeine cause transient increases in BP via norepinephrine release and, in the case of caffeine, by its antagonism of vasodilatory adenosine receptors.[2] Daily use of electronic cigarettes adds additional cardiovascular risks especially in the younger population in part because of the association with increased BP, higher sympathetic nerve activity, and increased myocardial infarction.[13] Acute alcohol ingestion may have a transient variable effect (increased due to sympathetic nerve activity or lowering due to vasodilation), whereas chronic heavy consumption of alcohol and binge drinking raises the risk of hypertension.[8] Many other environmental factors have been implicated in the development of hypertension. These include obesity, physical inactivity, adverse fetal environment, postnatal weight gain, premature birth and low birth weight, potassium and magnesium depletion, vitamin D deficiency, and environmental toxins (eg, lead).[8]

Neural Mechanisms

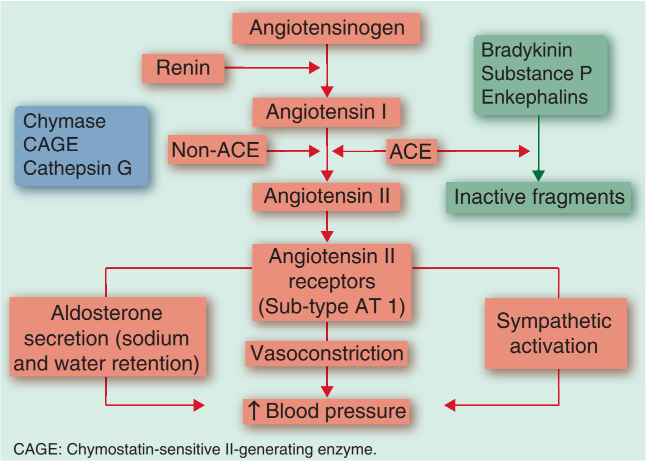
Overactivity of the sympathetic nervous system (SNS) in the early stages of primary hypertension manifests as increased heart rate, CO, and peripheral vasoconstriction. Despite this, outcome trials of agents targeting the SNS (α- and β-adrenergic blockers) have not performed as well as other drug classes. Nevertheless, strategies aimed at targeting the SNS continue with specific interest in invasive strategies aimed at resistant hypertension.[9]

Renal Mechanisms

The contribution of sodium to the development of primary hypertension is related to excess sodium intake and/or abnormal sodium excretion by the kidneys.[8] It is generally accepted that reducing dietary sodium intake while increasing dietary potassium intake reduces BP and cardiovascular disease (CVD).[14,15]

Hormonal Mechanisms

Renin is produced and stored in the juxtaglomerular cells of the kidney, and its release is stimulated by impaired renal perfusion, salt depletion, and β_1-adrenergic stimulation. The release of renin is the rate-limiting step in the eventual formation of angiotensin II, which is a potent vasoconstrictor (Figure 6–2).[8] The role of the renin-angiotensin-aldosterone system (RAAS) in primary hypertension is supported by the presence of high levels of renin, suggesting the system is inappropriately activated. Proposed mechanisms include increased sympathetic drive, defective regulation of the RAAS (nonmodulation), and the existence of a subpopulation of ischemic nephrons that release excess renin.[8] However, there are also patients with primary hypertension, and low levels of renin, which suggests alternative mechanisms, unrelated to renin levels or activity, may be in play. Thus, although



CAGE: Chymostatin-sensitive II-generating enzyme.

FIGURE 6–2. Diagram of the renin-angiotensin-aldosterone system (RAAS), a key system involved in the modulation of blood pressure. The diagram depicts the pathways involved in the action of various antihypertensive agents including angiotensin-converting enzyme (ACE) inhibitors, ARBs, diuretics, and aldosterone antagonists. By inhibiting the action of ACE, ACE inhibitors reduce both the formation of the vasoconstrictors angiotensin II and the degradation of vasodilating substances including bradykinin. ARBs primarily act through inhibition of the action of angiotensin II on the angiotensin-I receptors that modulate vasoconstriction. Aldosterone antagonists directly inhibit the action of aldosterone; diuretics affect sodium and water retention at a renal level. (ARB, angiotensin receptor blockers; AT1, angiotensin-1.) (From Victor RG, Kaplan NM. Kaplan's Clinical Hypertension, 10th ed. Philadelphia, PA: Wolters Kluwer Lippincott Williams & Wilkins Health; 2010, with permission.)

uncommon in general practice, PRA measurements may be utilized to guide antihypertensive therapy selection particularly in younger patients with genetic disorders. In fact, it has been demonstrated that patients with low PRA (< 0.65 ng/mL/hour [0.18 ng/L/s]) respond preferentially to diuretics, aldosterone antagonists, and calcium channel blockers (CCBs), whereas those with higher PRA levels respond preferentially to renin-mediated therapies such as β-blockers, angiotensin-converting enzyme inhibitors (ACE-Is), angiotensin receptor blockers (ARBs), and direct renin inhibitors.[16] However, use of PRA measurements to guide therapy is not without controversy, and the reader is referred to other sources for more information.[12]

Vascular Mechanisms

Elevated PVR is the hemodynamic hallmark of primary hypertension. The increase in PVR typically observed may be due to a reduction in arterial lumen size as a result of vascular remodeling. This remodeling, or change in vascular tone, may be modulated by various endothelium-derived vasoactive substances, growth factors, and cytokines. This increase in arterial stiffness or reduced compliance results in an incremental rise in systolic BP.[8]

Contributing Comorbidities

Several comorbidities have a high concurrence with the presence of hypertension leading to a higher risk of target organ damage, cardiovascular morbidity and mortality, and overall healthcare costs. Specifically, these include diabetes mellitus (DM), dyslipidemia, obesity, and CKD. As such, assessment of atherosclerotic cardiovascular disease (ASCVD) risk in all patients with hypertension should be part of the management plan while pursuing target BPs through nonpharmacologic and pharmacologic means.[2]

MEASUREMENT OF BLOOD PRESSURE

KEY CONCEPT Appropriate technique in measuring BP is a vital component to the diagnosis and management of hypertension. Accurate measurement of a patient's BP requires control of factors that may influence variability in the measure. Failure to consider these factors, including body position, cuff size, device selection, auscultatory technique, and dietary intake prior to the visit, may lead to misclassification and thus inaccurate assessments of risk. Clinicians should instruct patients to avoid exercise, alcohol, caffeine, or nicotine 30 minutes before BP measurement. Patients should be sitting comfortably with their back supported and arm free of constrictive clothing with legs uncrossed and feet flat on the floor for a minimum of 5 minutes before the first reading. Systolic and diastolic BP tend to increase when the cuff size is too small. Ideally, the cuff bladder should encircle at least 80% of the arm's circumference to ensure a more accurate measurement of BP.[2]

To reduce deviations in BP measurement in the clinic, the patient and clinician should not talk during measurement. The measurement arm should be supported and positioned at heart level. If a mercury or aneroid device is used, then the palpatory method (inflate the cuff to approximately 80 mm Hg rapidly while palpating the radial pulse, then increase pressure slowly by 10 mm Hg increment every two to three seconds until the radial pulse is no longer felt [estimated SBP]; the cuff is then inflated further until the pressure is about 30 mm Hg higher) must be used first to estimate the SBP.[2] If an automated device is used, this is not necessary. After the patient's cuff is inflated above the systolic pressure, the pressure indicator should drop at a rate of 2 to 3 mm Hg/s. A stethoscope placed over the brachial artery in the antecubital fossa identifies the first and disappearance of audible Korotkoff sounds, which should be taken as systolic and diastolic pressure, respectively. A minimum of two readings at least one minute apart are then averaged. If measurements vary by more than 5 mm Hg between the two readings, then one or two additional BP measurements are collected (at least one minute apart from each measurement) and the multiple readings averaged. BP classification is based on the average of two or more properly measured BP readings on each of two or more office visits. Details and further recommendations for accurate measurement of BP in special populations can be found elsewhere.[2,3] Finally, measurement of clinic or office BPs is often poorly correlated with assessments of BP in other settings. Consequently, under select circumstances, clinicians are increasingly using 24-hour ABPM, AOBP monitoring, and HBP monitoring. Corresponding values of systolic and diastolic BP for clinic, 24-hour ABPM, AOBP, and HBP measurements are provided in Table 6–5.[2] These methods of BP measurement are useful in identifying patients with white coat hypertension or in the case of 24-hour ABPM, elevations of BP during the night and masked hypertension, or hypertension not identified through traditional office measurement. They may also aid in the management of patients with refractory hypertension with minor target organ damage, suspected autonomic neuropathy, hypotensive symptoms, and patients with large differences between home and office BP measurements. Benefits derived from these additional methods of BP monitoring may be of greater prognostic significance than traditional office-based measurements.[7,16] Consequently, the 2017 ACC/AHA guidelines recommend utilizing out-of-office self-monitoring of BP to confirm hypertension diagnosis and for titration of BP-lowering medications in conjunction with clinic and telehealth counseling.[2]

Table 6–5

Corresponding Values (mm Hg) of Systolic BP/Diastolic BP for Various Methods of BP Measurement[2]

Clinic	HBPM[a]	Daytime ABPM[a]	Nighttime ABPM[a]	24-Hour (Overall) ABPM[a]
120/80	120/80	120/80	100/65	115/75
130/80	130/80	130/80	110/65	125/75
140/90	135/85	135/85	120/70	130/80
160/100	145/90	145/90	140/85	145/90

[a] Average of recorded values.

ABPM, ambulatory BP measurement; BP, blood pressure; HBPM, home BP measurement.

TREATMENT

Desired Outcomes

The goal of BP management is to reduce the risk of CVD-related morbidity and mortality manifested as target organ damage such as coronary artery disease (CAD), stroke, and kidney disease.

General Approach to Treatment

KEY CONCEPT Drug therapy for the management of patients with hypertension should be considered as adjunctive to

Clinical Presentation and Diagnosis of Primary Hypertension

General

Prevalence of hypertension is likely to be highest with middle-aged or older patients.

Gender: In the United States, hypertension is slightly more prevalent in men than women before the age of 35 years, similar between the ages of 35 and 64 years, and higher in women than men thereafter.

Symptoms

The patient with primary hypertension may be asymptomatic yet still have major CVD risk factors.

Signs

BP should be assessed as an average of two or more BP readings (SBP and DBP) on two or more occasions.

Classification of an individual's hypertension (Table 6–1) can be made based on the higher classification from either the SBP or DBP readings; for example, an individual whose readings are consistently 136/94 mm Hg would be classified as having stage 2 hypertension.

Basic Testing (facilitates CVD risk factor profiling, establishes a baseline for monitoring medication use, and facilitates screening for select secondary causes of hypertension):

- Fasting lipid panel (to determine ASCVD risk and those who may benefit from statin therapy as described in Chapter 13, "Dyslipidemias")
- Hemoglobin A_{1C} or fasting plasma glucose (to identify patients with impaired fasting glucose or diabetes as described in Chapter 44, "Diabetes Mellitus")
- Complete blood count
- Serum sodium, potassium, calcium, creatinine with estimated glomerular filtration rate (GFR; may all be included as part of a comprehensive metabolic panel)
- Thyroid-stimulating hormone (simple test and hypo- or hyperthyroidism are secondary causes of hypertension)
- Urinalysis
- Electrocardiogram (ECG)

Optional Testing (may provide information on target organ damage):

- Echocardiogram
- Uric acid
- Urinary albumin to creatinine ratio

The following abnormal tests may indicate hypertension-related damage:

- Serum creatinine elevated (> 1.2 mg/dL [106 μmol/L])
- Microalbuminuria, which is diagnosed either from a 24-hour urine collection (20–200 mcg/min) or from elevated concentrations (30–300 mg/L) on at least two occasions. Use of the albumin-to-creatinine ratio (ACR) in a spot urine sample is becoming more common, and **microalbuminuria** is defined by this measure as 30 to 300 mg/g creatinine (3.4–34 mg/mmol creatinine)

Common Comorbidities and Factors Contributing to Cardiovascular Risk

- DM
- Metabolic syndrome
- Insulin resistance
- Dyslipidemia
- Microalbuminuria/CKD
- Family history
- Central obesity
- Physical inactivity
- Tobacco use

Cardiovascular Risk Assessment

Calculate with risk assessment tools, such as the ACC/AHA ASCVD Risk Estimator (http://tools.acc.org/ascvd-risk-estimator/)

Target Organ Damage

- Cerebrovascular disease (eg, stroke or transient ischemic attack)
- Ocular (hypertensive retinopathy)
- Cardiac (left ventricular hypertrophy, left ventricular dysfunction, CAD, HF)
- CKD (eg, albuminuria, nephrosclerosis)
- Peripheral arterial disease

nonpharmacologic approaches for BP lowering. Ultimately, the attainment of target BP in many cases may be more important than the antihypertensive agent selected. Previous research has established the value of using individual antihypertensive drugs versus placebo to achieve reduction in morbidity and mortality by lowering BP. According to the 2017 ACC/AHA guidelines, the recommended BP target for the vast majority of patients is less than 130/80 mm Hg.[2] The BP threshold for treatment varies according to the patient's baseline cardiovascular risk. BP-lowering medications are recommended in patients with clinical CVD (defined as coronary heart disease (CHD), HF, or stroke) and an average SBP of 130 mm Hg or higher or an average DPB of 80 mm Hg or higher. In addition, BP-lowering medications are recommended for primary prevention in adults with an estimated 10-year ASCVD risk of 10% or higher and whose SBP/DBP exceeds 130/80 mm Hg. The recommended tool for calculating ASCVD risk is the ACC/AHA ASCVD Risk Estimator (http://tools.acc.org/ascvd-risk-estimator/). BP thresholds and goals for pharmacologic therapy in these patients and those with other clinical conditions are summarized in Table 6–2. Although these guidelines clearly recommend treatment thresholds for most individuals with or without CVD or select comorbidities, the benefits of aggressive BP control using pharmacotherapy remain debatable for certain patients. Examples where conflicting data require reconciliation include controlled studies, such as the SPRINT (Systolic Blood Pressure Intervention Trial),[17] ACCORD (Action to Control Cardiovascular Risk in Diabetes),[18] and SPS3 (Secondary Prevention of Small Subcortical Strokes; blood-pressure targets in patients with recent lacunar stroke)[19] trials, where improved outcomes across all major endpoints for patients achieving a more intensive

BP-lowering goal were not consistently observed. Although these inconsistencies underscore the need for additional high-quality research with the aim of determining the most appropriate BP targets for specific patient groups, the 2017 ACC/AHA guidelines were generated by inclusion of many associations and groups representing a wide array of specialty populations.[2]

Evidence supports the position that the main benefits of pharmacologic therapy are related to achievement of BP lowering and are generally independent of the selection of an individual drug regimen. Inherent in this position is the realization that lifestyle changes or nonpharmacologic approaches alone are rarely successful in attaining target BPs, and multidrug therapy (sometimes as many as three or more agents) is necessary for most patients.[20] Given the need for multiple medications to control hypertension, clinicians should work to minimize pill burden, frequency of administration, and cost. When possible and appropriate, selecting fixed-combination drug therapies, longer-acting formulations, and generic or formulary-based medications may optimize adherence. The 2017 ACC/AHA guidelines state that it is reasonable to initiate pharmacologic therapy with a single agent in patients with stage 1 hypertension.[2] In those with stage 2 hypertension and an average BP more than 20/10 mm Hg above their BP target, it is recommended to start therapy simultaneously with two agents from different classes.[2] Furthermore, this guideline identifies black adults as a cohort who may be considered for two or more drugs to control hypertension. Both circumstances acknowledge the urgency to control hypertension with a high likelihood of needing multiple medications.

Another general consideration for antihypertensive therapy planning includes incorporation of chronotherapeutic principles. The timing of administration of antihypertensive medications may have relevance to the manifestations of adverse effects and/or optimizing therapeutic outcomes. A study of patients with CKD and diabetes demonstrated that moving the administration time of one antihypertensive agent to bedtime dosing significantly reduced composite cardiovascular events compared to administering all antihypertensive agents at one time in the morning.[21]

Nonpharmacologic Treatment

Therapeutic lifestyle modifications consisting of nonpharmacologic approaches to BP reduction should be part of all treatment plans. The most widely studied interventions demonstrating effectiveness include:

- Dietary sodium restriction
- Increasing dietary potassium intake
- Low-fat diet, high in vegetables and fruits
- Weight reduction in overweight or obese individuals
- Regular physical activity
- Moderation of alcohol consumption

KEY CONCEPT Implementation of these lifestyle modifications successfully lowers BP, often with results similar to those of therapy with a single antihypertensive agent.[2] Combining multiple lifestyle modifications can have even greater BP-lowering effects. Sodium restriction to 2.4 g (100 mmol) of elemental sodium (6 g of sodium chloride or one teaspoon of table salt) per day lowers BP and has been recommended for the general population, especially individuals with hypertension.[2] Although controversy surrounds the optimal level of sodium intake and its cardiovascular benefits and risks, adoption of an optimal dietary pattern that includes consuming fewer processed foods is expected to afford overall cardiovascular benefits.[22]

Compared to the general population, BP lowering through sodium restriction is more pronounced in salt-sensitive individuals (low PRA), persons with diabetes, metabolic syndrome, or CKD, as well as older individuals and black people.[5] Simple dietary advice and instructions on reading nutrition labels should be introduced to patients initially and assessed and reinforced at subsequent visits. A diet high in fruits, vegetables, and low-fat dairy products, along with a reduced intake of total and saturated fat, can significantly reduce BP in as little as 8 weeks.[23] See Table 6–6.[2]

Smoking cessation should be encouraged for overall cardiovascular health despite its lack of chronic effects on BP.[2] Although BP-lowering lifestyle modifications have never been documented to reduce cardiovascular morbidity and mortality in patients with hypertension, they do effectively lower BP in most hypertensive patients and exhibit a favorable effect on other risk factors including dyslipidemia and insulin resistance. This may eliminate the need for drug therapy in those with mild elevations in BP or minimize the doses or number of antihypertensive agents required in those on therapy.[2]

Table 6–6

Lifestyle Modifications to Manage Hypertension[a,2]

Modification	Recommendation	Approximate Systolic BP Reduction (Range)
Weight reduction	Maintain normal body weight (body mass index: 18.5–24.9 kg/m^2)	1 mm Hg/1 kg
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	11 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to no more than 2.4 g sodium or 6 g sodium chloride (100 mmol/day). If these targets cannot be achieved, an absolute reduction in 1 g sodium/day is recommended	5–6 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 min/day, most days of the week)	5–8 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than two standard drinks per day in most men and to no more than one standard drink per day in women and lighter weight persons[b]	4 mm Hg

[a] For overall cardiovascular risk reduction, stop smoking. The effects of implementing these modifications are dose and time dependent and could be greater for some individuals.

[b] One standard drink is defined as 12 oz (355 mL) beer, 5 oz (148 mL) wine, or 1.5 oz (44 mL) 80-proof whiskey.

BP, blood pressure; DASH, dietary approaches to stop hypertension.

Pharmacologic Treatment

KEY CONCEPT An approach to selection of drugs for the treatment of patients with hypertension should be evidence-based with considerations regarding the individual's comorbidities, co-prescribed medications, and practical patient-specific issues including tolerability and cost. The evidence-based 2017 ACC/AHA guidelines recommend drug therapy that is largely grounded in the best available evidence for superiority in outcomes—specifically morbidity and mortality.[2] The approach is often tempered with practical considerations related to competing options for specific comorbidities and issues regarding a patient's experience or tolerance for side effects and, in some cases, the cost of medications.

Landmark trials such as the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) have provided some objective basis for comparisons between initiating antihypertensive drug therapy with one class of antihypertensives versus another; however, there is room for criticism of these studies.[20,24,25] Consequently, practical interpretations of their conclusions must leave room for individualization based on clinical judgment. Overall, current clinical guidelines provide a reasonable basis for guiding the selection of drug classes for individuals based on their stage of hypertension, comorbidities, and special circumstances. The following sections summarize key features of specific drug classes and guideline-based recommendations. An overview of specific oral antihypertensive drug classes in common use is summarized in Table 6–7.[2,26,27]

Diuretics

Diuretics are a heterogenous group of medications with different recommendations for use among each group. The four subtypes include thiazides/thiazide-like diuretics, loop diuretics, potassium-sparing agents, and aldosterone antagonists. Each diuretic subtype has properties that distinguish their role in select patient populations. Thiazide diuretics are by far the most commonly prescribed with the greatest number of outcome-based studies supporting their use. This type of diuretic inhibits the sodium-chloride symporter in the renal distal convoluted tubule, thus increasing sodium and chloride excretion. In the United States, hydrochlorothiazide and chlorthalidone represent the most commonly prescribed thiazide-type diuretics and have been the subject of large outcome-based studies. For example, in the ALLHAT trial, patients randomized to chlorthalidone, a thiazide-type diuretic, as initial antihypertensive therapy had similar CHD outcomes to those randomized to receive initial therapy with either amlodipine or lisinopril.[20] However, differences in outcomes for select secondary endpoints or special populations demonstrated superiority of chlorthalidone-based therapy over either ACE-I or CCB-based regimens. Criticisms of the different BPs achieved in the various treatment groups, the artificial construct guiding the use of add-on drugs to base therapy, and the overrepresentation of African Americans exhibiting select endpoints have weakened the interpretability of this trial.[20] Furthermore, other studies have challenged the status of diuretics as an ideal baseline choice for initial antihypertensive drug therapy for all patients[25,26] and even the choice of diuretic used,[28] supporting the debate over whether the means by which BP is lowered (specific drug selected) is more or less important than the extent and/or time taken to lower BP. Nonetheless, thiazide-type diuretics, specifically chlorthalidone, remain supported by many as acceptable baseline initial therapy for hypertensive patients without compelling indications for other agents.[2]

Key differences in the features of various thiazide diuretics may also play a role in selection. Practical differences among thiazides include their relative diuretic potency, with chlorthalidone being considered approximately 1.5 to 2 times more potent than hydrochlorothiazide for BP reduction.[28] Recent analyses have demonstrated superiority of chlorthalidone over hydrochlorothiazide,[28] leading the 2017 ACC/AHA guidelines to specifically recommend chlorthalidone over other diuretics.[2] Because the relationship between antihypertensive efficacy and metabolic (hyperlipidemia and hyperglycemia) and electrolyte-related (hypokalemia, hypomagnesemia, hyperuricemia, and hypercalcemia) side effects of thiazide diuretics are dose-related, attention to the differential in potency may be important. These effects may complicate the management of higher-risk patients with common comorbidities such as dyslipidemia or diabetes, or even those likely to be sensitive to complications from hyperuricemia and the potassium- or magnesium-wasting effects of diuretics such as patients with dysrhythmias or those taking digoxin. Thiazide diuretic-induced development of new-onset diabetes remains debatable since the ALLHAT and Systolic Hypertension in the Elderly Program (SHEP) demonstrated no significant adverse cardiovascular events from new diuretic-associated diabetes versus other trials contradicting this observation.[29] Nonetheless, clinicians should generally not exceed 25 to 50 mg/day of hydrochlorothiazide or 25 mg/day of chlorthalidone.[2] In addition, regardless of the dose used, careful assessment of the potential for metabolic- or electrolyte-based effects is essential.

Additionally, it is important to recognize that when estimated creatinine clearance approaches or is less than 30 mL/min (0.50 mL/s), thiazide diuretics have limited efficacy, rendering loop diuretics to be preferred. Clinicians are advised to reevaluate the use of thiazide diuretics prescribed to individuals whose renal function has been declining with age and whose risk for the consequences of metabolic effects may be more significant.[30]

Loop diuretics, such as furosemide, bumetanide, torsemide, and ethacrynic acid, have a common site of action in the thick ascending limb of the loop of Henle. As this region reabsorbs over 35% to 45% of filtered sodium, their diuretic efficacy is superior to that of thiazides, potassium-sparing diuretics, and aldosterone antagonists. With the exception of torsemide, which has a longer half-life, the loop diuretics should be administered twice daily (BID) when utilized primarily for their antihypertensive (vs diuretic) effect. Ethacrynic acid, unlike other loop diuretics, does not contain a sulfonamide moiety and as such may carry preference in patients with sulfonamide sensitivity. The most significant adverse effect of loop diuretic use is excessive diuresis leading to hyponatremia or hypotension. Additionally, hypokalemia, hypomagnesemia, and hypocalcemia may develop over time and contribute to the potential for cardiac arrhythmias. Overall, relevance of drug–drug interactions and potential for aggravating select conditions (hyperglycemia, dyslipidemias, and hyperuricemia) should be routinely monitored.[8]

Potassium-sparing diuretics that do not act through mineralocorticoid receptors include triamterene and amiloride. These agents are often prescribed in combination with potassium-wasting diuretics to mitigate potassium loss. When administered alone or as a combination product, these agents result in modest diuresis given their site of action on the distal tubule and collecting ducts has minimal impact on blocking sodium reabsorption. Their most significant risk is the potential for hyperkalemia. This is especially relevant in the context of those patients with moderate to severe renal impairment or those receiving nonsteroidal anti-inflammatory drugs (NSAIDs), potassium supplements, or

Table 6–7

Commonly Used Oral Antihypertensive Drugs by Pharmacologic Class[2,26,27]

Class	Brand	Usual Dose, Range (mg/day)	Frequency	Select Adverse Events	Comments[a]
Diuretics					
Thiazides and thiazide-like	Chlorthalidone (Hygroton)	12.5–25	QDay	Hypokalemia and other electrolyte imbalances Negative effect on glucose and lipids	Thiazide diuretics are generally more effective antihypertensive agents than loop diuretics Ineffective in patients with estimated CrCl < 30 mL/min (0.5 mL/s), except metolazone Not first-line agents in pregnancy, but may be used with close monitoring for hypokalemia Monitor electrolytes (ie, decreased serum potassium) and metabolic abnormalities (ie, dyslipidemia, hyperglycemia) Use caution in patients with gout and severe renal impairment Contraindications include hypersensitivity and anuria
	Hydrochlorothiazide (Esidrix, HydroDiuril, Microzide, Oretic)	12.5–50	QDay		
	Indapamide (Lozol)	1.25–2.5	QDay		
	Metolazone (Zaroxolyn)	2.5–10	QDay		
Loops	Bumetanide (Bumex)	0.5–2	QDay or BID	Hypokalemia and other electrolyte imbalances	Preferred diuretic class in patients with estimated CrCl < 30 mL/min (0.5 mL/s) Monitor electrolytes (ie, decreased potassium) and metabolic abnormalities (ie, dyslipidemia, hyperglycemia) Use with caution in patients with gout Contraindications include hypersensitivity, anuria, acute renal insufficiency
	Furosemide (Lasix)	20–80	BID		
	Torsemide (Demadex)	5–10	QDay		
Potassium-sparing	Amiloride (Midamor)	5–10	QDay or BID	Potassium-sparing diuretics may enhance hyperkalemic effects of drug therapies (eg, ACE inhibitor, aldosterone antagonist)	Reserved for patients with diuretic-induced hypokalemia Monitor electrolytes (ie, potassium) Contraindications include hypersensitivity, acute renal insufficiency, hyperkalemia Avoid in patients with estimated CrCl < 30 mL/min (0.5 mL/s)
	Triamterene (Dyrenium)	50–100	QDay or BID		
Aldosterone antagonists	Eplerenone (Inspra)	50–100	QDay or BID	Hyperkalemia Gynecomastia (spironolactone)	Eplerenone contraindicated as an antihypertensive in patients with estimated CrCl < 50 mL/min (0.83 mL/s) or serum creatinine > 1.8 mg/dL (159 µmol/L) for women or 2 mg/dL (177 µmol/L) in men as well as type 2 diabetes mellitus with microalbuminuria. Also contraindicated in patients concomitantly receiving strong CYP3A4 inhibitors or a serum potassium > 5.0 mEq/L (mmol/L) at initiation
	Spironolactone (Aldactone)	25–100	QDay		
β-Blocker					
Cardioselective	Atenolol (Tenormin)	25–100	QDay or BID	Bradycardia Heart block Heart failure Dyspnea, bronchospasm Fatigue, dizziness, lethargy, depression	Caution with heart rate < 60 and respiratory disease Selectivity of β_1 agents is diminished at higher doses Abrupt discontinuation may cause rebound hypertension May mask signs/symptoms of hypoglycemia in diabetic patients
	Bisoprolol (Zebeta)	2.5–10	QDay		
	Metoprolol tartrate (Lopressor)	100–200	BID		
	Metoprolol succinate (Toprol XL)	50–200	QDay		
Nonselective	Nadolol (Corgard)	40–120	QDay	Hyper-/hypoglycemia, hyperkalemia, hyperlipidemia	Contraindicated in hypersensitivity, sinus node dysfunction or severe sinus bradycardia (in the absence of a pacemaker), heart block (greater than first degree), cardiogenic shock, acute decompensated heart failure
	Nebivolol (Bystolic)	5–20	QDay		
	Propranolol (Inderal)	80–160	BID		
	Propranolol long-acting (Inderal LA, InnoPran XL)	80–160	QDay		
	Timolol (Blocadren)	10–40	QDay		
Mixed α- and β-blocker	Carvedilol (Coreg)	12.5–50	BID		
	Carvedilol CR (Coreg CR)	20–80	QDay		
	Labetalol (Trandate)	200–800	BID		

CCB					
Nondihydropyridines	Diltiazem long-acting (Cardizem SR, Cardizem CD, others)	120–360	QDay	Bradycardia, heart block (nondihydropyridines) Constipation (nondihydropyridines) Peripheral edema, headache, flushing	Caution with heart rate < 60 (verapamil, diltiazem) Use caution in concomitant use with β-blocker; may potentiate heart block Extended-release formulations are preferred for once- or twice-daily medication administration
	Verapamil sustained-release (Calan SR, Isoptin SR, Verelan)	120–360	QDay		
Dihydropyridines	Amlodipine (Norvasc)	2.5–10	QDay	Gingival hyperplasia (dihydropyridines) Reflex tachycardia (dihydropyridines)	Contraindicated in hypersensitivity, sinus node dysfunction, or severe sinus bradycardia (in the absence of a pacemaker) (nondihydropyridines), heart block (greater than first degree) in the absence of a pacemaker (nondihydropyridines), atrial fibrillation/flutter associated with accessory bypass tract (nondihydropyridines), reduced ejection fraction (most CCBs except amlodipine)
	Felodipine (Plendil)	2.5–10	QDay		
	Isradipine SR (DynaCirc SR)	5–10	BID		
	Nicardipine SR (Cardene SR)	60–120	BID		
	Nifedipine long-acting (Adalat CC, Procardia XL)	30–90	QDay		
	Nisoldipine (Sular)	17–34	QDay		
ACE inhibitors	Benazepril (Lotensin)	10–40	QDay or BID	Cough Hyperkalemia Renal insufficiency Angioedema	Monitor electrolytes (ie, serum potassium) Monitor renal function Initial dose may be reduced in renal impairment, the elderly, patients who are volume depleted or maintained on diuretic therapy Use with caution in patients with baseline hyperkalemia Contraindicated in pregnancy and hypersensitivity
	Captopril (Capoten)	25-150	BID or TID		
	Enalapril (Vasotec)	10–40	QDay or BID		
	Fosinopril (Monopril)	10–40	QDay		
	Lisinopril (Prinivil, Zestril)	10–40	QDay		
	Moexipril (Univasc)	7.5–30	QDay or BID		
	Perindopril (Aceon)	4–16	QDay		
	Quinapril (Accupril)	10–80	QDay or BID		
	Ramipril (Altace)	2.5–10	QDay or BID		
	Trandolapril (Mavik)	1–4	QDay		
ARBs	Azilsartan (Edarbi)	40–80	QDay	Hyperkalemia Renal function deterioration Angioedema Hypotension/syncope	Above comments to ACE inhibitors also apply to ARBs
	Candesartan (Atacand)	8–32	QDay or BID		
	Eprosartan (Teveten)	600–800	QDay or BID		
	Irbesartan (Avapro)	150–300	QDay		
	Losartan (Cozaar)	50–100	QDay or BID		
	Olmesartan (Benicar)	20–40	QDay		
	Telmisartan (Micardis)	20–80	QDay		
	Valsartan (Diovan)	80–320	QDay		
Direct renin inhibitors	Aliskiren (Tekturna)	150–300	QDay	Hyperkalemia Hypotension	Use caution in patients with severe renal impairment and in patients with deteriorating renal function or renal artery stenosis, both bi- and unilateral Contraindicated in combination with ACE-Is or ARBs in patients with diabetes
Central α_2-agonists	Methyldopa (Aldomet)	250–500	BID	Transient sedation initially Hepatotoxicity, hemolytic anemia, peripheral edema (methyldopa) Orthostatic hypotension (methyldopa, clonidine) Dry mouth, muscle weakness (clonidine)	First-line agent in pregnancy (methyldopa) Tolerance may occur 2–3 months after initiation of methyldopa; increase dose or add thiazide Contraindications include hypersensitivity, concurrent use of MAO inhibitor (methyldopa), hepatic disease (methyldopa), pheochromocytoma (methyldopa)
	Clonidine oral (Catapres)	0.1–0.8	BID		
	Clonidine patch (Catapres TTS)	0.1–0.3	Once weekly		
	Guanfacine (Intuniv)	0.5–2	QDay		

(Continued)

Table 6–7

Commonly Used Oral Antihypertensive Drugs by Pharmacologic Class[2,26,27] (*Continued*)

Class	Brand	Usual Dose, Range (mg/day)	Frequency	Select Adverse Events	Comments[a]
α_1-Blockers	Doxazosin (Cardura) Prazosin (Minipress) Terazosin (Hytrin)	1–16 2–20 1–20	QDay BID or TID QDay or BID	Syncope, dizziness, palpitations, orthostatic hypotension	Contraindicated in hypersensitivity
Direct vasodilator	Isosorbide dinitrate 20 mg and hydralazine 37.5 (BiDil)	20–120/37.5–225	TID	Edema, hypertrichosis (minoxidil) Tachycardia	Give minoxidil with diuretic and β-blocker to mitigate side effects Contraindicated in hypersensitivity, pheochromocytoma (minoxidil), increased intracranial pressure (isosorbide dinitrate + hydralazine)
	Hydralazine (Apresoline)	100–200	BID	Lupus-like syndrome (hydralazine)	
	Minoxidil (Loniten)	5–100	QDay or BID		
Peripheral sympathetic inhibitors	Reserpine (generic only)	0.05–0.25	QDay	Depression Orthostatic hypotension Nasal congestion, fluid retention, peripheral edema Diarrhea, increased gastric secretion	Contraindications include hypersensitivity, peptic ulcer disease or ulcerative colitis, history of mental depression or electroconvulsive therapy

[a] Comments listed are not intended to be inclusive of all adverse effects, monitoring parameters, cautions, or contraindications and may vary by source.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BID, twice daily; CCB, calcium channel blocker; CrCl, creatinine clearance; CYP, cytochrome P450; MAO, monoamine oxidase; QDay, once daily; TID, three times daily.

Modified from Weber MA, Schiffrin EL, White WB, et al. Clinical practice guidelines for the management of hypertension in the community. J Clin Hypertens. 2014;16(1):14–26; and Saseen JJ, Maclaughlin EJ. Hypertension. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York: McGraw-Hill; 2017:57–58.

other agents with potassium-sparing properties, such as ACE-Is or ARBs.[8]

Aldosterone Antagonists

Aldosterone antagonists such as spironolactone and eplerenone modulate vascular tone through a variety of mechanisms besides diuresis (Figure 6–2). Their potassium-sparing effects mediated through aldosterone antagonism counteract the potassium-wasting effects of other diuretics such as thiazide or loop diuretics. Patients with resistant hypertension (with or without primary aldosteronism) experience significant BP reductions with the addition of low-dose spironolactone (12.5–50 mg/day) to diuretics, ACE-Is, and ARBs.[31] Although a positive attribute, it is important to recognize the risk for hyperkalemia in patients with impaired or fluctuating renal function, or those who are receiving ACE-Is, ARBs, direct renin inhibitors, potassium supplements, potassium-containing salt substitutes, or NSAIDs. In addition, spironolactone is associated with gynecomastia, whereas eplerenone rarely causes this complication, presumably because of its greater aldosterone blocking specificity than spironolactone and minimal effects on androgens and progesterone.[8]

β-Blockers

Contemporary guidelines refrain from supporting the use of β-blockers as first-line antihypertensive agents.[2] The basis of this position varies but often cites studies indicating inferior outcomes and a lack of positive outcomes in elderly patients when compared to other antihypertensives.[32] These analyses were conducted with a limited number of β-blockers (usually atenolol), and thus their findings may or may not apply to newer formulations of existing agents (eg, metoprolol succinate) or agents with unique properties such as carvedilol or nebivolol.[32] However, the role of β-blockers in patients with specific select comorbidities is well-established (Table 6–3).[2] Specific studies conducted in patients with comorbidities such as CAD, HF with reduced ejection fraction (HFrEF), or recent MI have clearly demonstrated morbidity and mortality benefits from β-blocker use.[2] Their hemodynamic effects and antiarrhythmic properties make them desirable for hypertensive patients who suffer from ischemic conditions including acute coronary syndromes (ACS). The mechanisms through which β-blockers affect BP are complex but most certainly include their modulation of renin, which appears to result in a reduction in CO and/or reduction in PVR along with their negative inotropic/chronotropic actions (Figure 6–2).

The specific pharmacologic properties of β-blockers are varied and diverse. An understanding of these properties may assist in the selection of one agent over others given a patient's specific condition(s) or comorbidities. One of these properties is cardioselectivity: the property of some β-blockers that preferentially block the β_1-receptor versus β_2-receptor. Some β-blockers exhibit membrane stabilization activity, which relates to the β-blocker's capacity to exhibit certain antiarrhythmic properties. Some β-blockers, as shown in Figure 6–3, possess properties referred to as intrinsic sympathomimetic activity (ISA). β-Blockers possessing this property effectively block the β-receptor at higher circulating catecholamine levels, such as during exercise, while having modest β-blocking activity at times of lower catecholamine levels, such as at rest, but β-blockers with ISA are not recommended for use in the post-ACS patient.[33]

Cardioselectivity represents the most clinically relevant property of β-blockers. With regard to cardioselectivity, it is important to consider patients with asthma and/or chronic obstructive pulmonary disease. A β-blocker with relative cardioselectivity to block β_1-receptors may be more desirable in such a patient, whereas a nonselective β-blocker may be potentially disadvantageous. In such a patient, low doses of cardioselective β-blockers may achieve adequate blockade of β_1-receptors in the heart and kidneys while minimizing the undesirable effects of β_2-receptor blockade on the smooth muscle lining the bronchioles. In doing so, hypertension may be managed while avoiding complications of the coexisting reactive airway disease, which is mediated by β_2-receptor stimulation. Similarly, either because of a reduction in the β_2-mediated vascular blood flow or by enhanced unopposed α-agonist–mediated vasoconstriction, a patient with peripheral vascular disease and intermittent claudication may experience a worsening of symptoms with use of a nonselective β-blocker (Figure 6–3). It is important to remember that cardioselectivity depends on dose, with diminished selectivity exhibited with higher doses.

A limited number of β-blockers also possess vasodilatory properties that are either mediated through α_1-receptor blockade

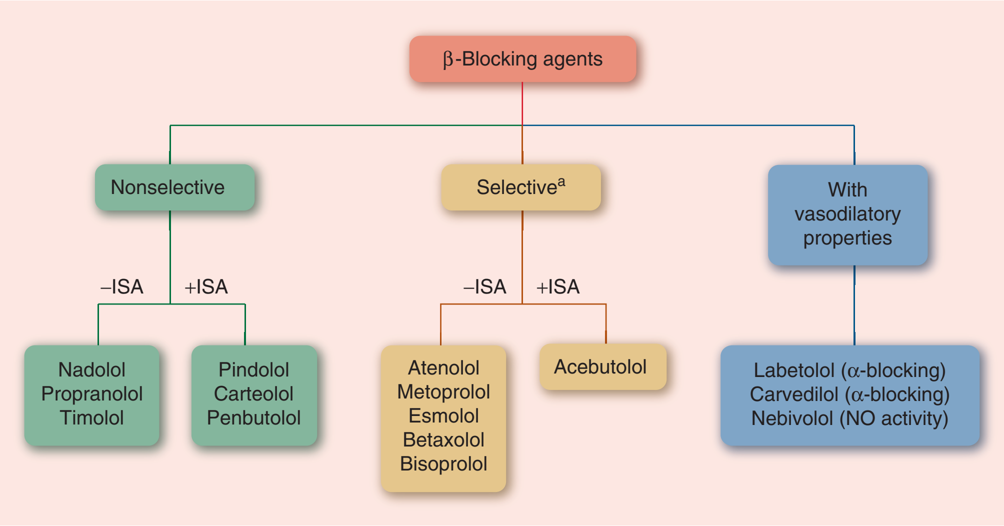

FIGURE 6–3. Flowchart listing various β-blocking agents separated by β-receptor activity and intrinsic sympathomimetic activity. [a]β-1 Cardioselective. (ISA, intrinsic sympathomimetic activity; NO, nitric oxide.)

(carvedilol, labetalol) or via L-arginine/nitric oxide–induced release from endothelial cells, with subsequent increased nitric oxide bioavailability in the endothelium (nebivolol). Although theoretically of benefit, there has been no proven evidence of superior outcomes from use of β-blockers with these vasodilatory properties.

The adverse effects of β-blockers follow their pharmacology. Their potential to precipitate bradycardia, various degrees of heart block, or signs and symptoms of HF may be of concern to those with a subclinical diagnosis of HF, the elderly, or those with reduced left ventricular ejection fraction (LVEF). Conversely, abrupt discontinuation of β-blockers has been cited as a precipitating factor in the development of ischemic syndromes, especially for those patients in whom β-blockers were used for extended periods of time, at higher doses, or who had underlying ischemic heart disease. In such cases, tapering the dose over a period of several days to one or even 2 week(s) is recommended. β-Blocker use in diabetics is usually a complex decision requiring consideration of their consequential effects on insulin, glucose availability, and blocking the signs and symptoms of hypoglycemia against their potential for morbidity/mortality benefits for select candidates with comorbidities such as HFrEF. Lastly, β-blockers, particularly first-generation agents (ie, those other than carvedilol and nebivolol), have a greater effect on glucose metabolism as well as other metabolic effects, and they should be used cautiously, if at all, with diuretics unless compelling indications exist for both.

The Food and Drug Administration (FDA)-approved drug labeling for metoprolol, carvedilol, nebivolol, and propranolol states that when coadministered with drugs that affect cytochrome P450 (CYP) 2D6 metabolic pathways, their efficacy and/or toxicity may be altered. However, specific recommendations vary by agent. For example, recommendations for metoprolol state that dose titration or an alternative agent should be considered for individuals classified as CYP2D6 poor, intermediate, and ultrarapid metabolizers. However, similar recommendations are not explicitly suggested for carvedilol, nebivolol, or propranolol.

Calcium Channel Blockers

Exhibiting considerable interclass diversity, CCBs are recognized as effective antihypertensives, particularly in the elderly.[2,30] The variety of pharmacologic properties among the subclasses of CCBs is significant and categorizes their expected effects on the cardiovascular system and potential risk of toxicities. Dihydropyridine CCBs such as nifedipine and amlodipine are recommended as potential first-line antihypertensive agents but are commonly associated with edema, especially when used at higher doses.[2] As previously reviewed, CCBs were found to be similar to chlorthalidone and lisinopril with regard to CHD events.[20] Nondihydropyridine CCBs such as verapamil and diltiazem are recognized for their electrophysiological effects and negative chronotropic and inotropic effects. These pharmacologic properties may be exploited for their specific clinical utility. Verapamil and diltiazem effectively block cardiac conduction through the atrioventricular node, exhibiting value in the management of patients with atrial fibrillation in addition to hypertension. However, their negative inotropic effects can be detrimental to patients with reduced LVEF and should be avoided. In contrast, the dihydropyridine subclass of agents has no utility for managing patients with atrial dysrhythmias but may be used safely (exception being nifedipine) in patients with reduced ejection fraction. Similarly, all CCBs possess some coronary vasodilating properties and, therefore, may be used in select patients for the management of patients with angina, in addition to their antihypertensive benefits.[8]

ACE Inhibitors

ACE-Is have been extensively studied for the treatment of hypertension, and outcome-based trials generally support their use for a wide array of patients, especially with select comorbidities. These compelling indications include their qualified role in managing patients with hypertension who have a history of type 1 or 2 DM, HF, MI, CKD, or stroke.[2] Comparative trials using either ACE-Is, diuretics, or CCBs as initial drug therapy have demonstrated similar primary outcomes.[20] It is therefore reasonable to conclude that diuretics, CCBs, and ACE-Is represent appropriate choices as first- or second-line antihypertensive therapies that effectively achieve a target BP goal for most patients with or without comorbidities.

Although generally well-tolerated, ACE-Is are associated with two hallmark side effects: hyperkalemia and a persistent dry cough. Modest elevations in serum potassium should be anticipated when starting or increasing the dose of an ACE-I, particularly in patients with compromised renal function and those receiving any concurrent NSAIDs, potassium supplements, or potassium-containing salt substitutes. Hyperkalemia is rarely a reason for discontinuation of therapy. Nonetheless, periodic monitoring of serum potassium is prudent for patients receiving ACE-Is. The dry cough associated with ACE-Is is thought to be caused by accumulation of bradykinin resulting from a direct effect of inhibiting ACE. If a cough jeopardizes compliance with the agent, ARBs should be considered as possible alternative agents because there is less incidence of cough.

Less common adverse effects of ACE-Is include acute kidney injury, particularly in patients with hemodynamically significant bilateral renal artery stenosis (or unilateral if one functioning kidney), preexisting kidney dysfunction, blood dyscrasias, or angioedema, the latter particularly in black African or African Caribbean origin.

In general, effects of ACE-Is on renal function and potassium can be predicted given an understanding of their pharmacologic actions (Figure 6–2). Inhibition of angiotensin II synthesis through ACE inhibition (or direct blockage of the angiotensin II receptor by ARBs) reduces the efferent renal artery tone, thereby changing the intraglomerular pressure. Although changes in the afferent renal artery tone also occur, the overall effects usually produce a reduction in GFR of up to 30%.[2,8] Such reductions in GFR are not usually indications to discontinue use of the ACE-I; however, continued monitoring for further decreases in GFR and consideration of dose reduction remain prudent. Alternatively, should declines in GFR exceed 30%, dose reduction or discontinuation is warranted until further evaluation can be made.

Angiotensin Receptor Blockers

ARBs are inhibitors of the angiotensin-1 (AT1) receptors (Figure 6–2). AT1 receptor stimulation evokes a pressor response via a host of accompanying effects on catecholamines, aldosterone, and thirst.[8] Consequently, inhibition of AT1 receptors directly prevents this pressor response and results in upregulation of the RAAS. Upregulation of the RAAS results in elevated levels of angiotensin II, which have the added effect of stimulating the angiotensin-2 (AT2) receptors. AT2-receptor stimulation is generally associated with antihypertensive activity; however, long-term effects of AT2-receptor stimulation on cellular growth and repair mechanisms are relatively unknown. While the pharmacologic differences between ARBs and ACE-Is are clear, the therapeutic relevance resulting from these differences remains ambiguous. Previously, the clinical benefits of ARBs were considered less robust as compared to ACE-Is, but the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) has demonstrated that in high-risk patients, telmisartan is noninferior to ramipril for the reduction of death from cardiovascular causes, MI, stroke, or hospitalization for HF.[34] This study also demonstrated that an ACE-I in combination with an ARB reduces proteinuria to a greater extent than either agent alone but increases the composite of dialysis, doubling of serum creatinine, and death.[35] Although better tolerated than ACE-Is, ARBs have not been shown to demonstrate superiority of outcomes relative to ACE-Is.

At this point, ARBs have emerged as an effective class of antihypertensives whose low incidence of side effects and demonstrated clinical role in patients with specific comorbidities have afforded them an attractive position in the antihypertensive armamentarium. However, as with ACE-Is, patients may develop angioedema. Although estimates of cross-reactivity are reportedly low,[36] one should always exercise caution when considering the use of an ARB in a patient with a known history of angioedema to an ACE-I. Like ACE-Is, the antihypertensive effectiveness of ARBs is greatly enhanced by combining them with diuretics. Combining an ACE-I with an ARB for treating hypertension should almost always be avoided. Overall, ARBs have proven their value as reasonable first-line agents for uncomplicated patients with hypertension, well-tolerated alternatives to ACE-Is for patients with select comorbidities (CKD, DM, and prior MI [Table 6–3]), and alternatives when ACE-Is are not well-tolerated.

Patient Encounter 2

A 65-year-old man returns to your clinic for a follow-up visit. During his previous visit 1 month ago, his BP measurements were 168/98 and 176/98 mm Hg. His seated BP measurements today are 170/92 and 178/94 mm Hg. His heart rate is 100 beats/min. He was prescribed amlodipine-benazepril 5–20 mg once daily and atorvastatin 10 mg once daily about 6 weeks ago. He states that he has been taking the medications only intermittently and not for the past 2 weeks due to complaints of a dry cough when he took the medications and that resolved when not taking. He has a previous history of heavy alcohol consumption and cigarette smoking (three packs per day), but states that he no longer smokes tobacco or consumes alcohol. The patient confirms smoking marijuana occasionally. He is fit-appearing, is able to tolerate exercise well, and states that he tries to maintain a well-balanced diet. The patient's past medical history is significant for a minor gastrointestinal (GI) bleed within the past month that has since resolved and has no past surgical history. Physical examination is unremarkable. Pertinent laboratory values include serum creatinine of 1.3 mg/dL (115 μmol/L), potassium of 4.1 mEq/L (mmol/L), sodium of 141 mEq/L (mmol/L), fasting glucose of 99 mg/dL (5.5 mmol/L), cholesterol of 157 mg/dL (4.06 mmol/L), HDL of 38 mg/dL (0.98 mmol/L), LDL of 89 mg/dL (2.3 mmol/L), and triglycerides of 148 mg/dL (1.67 mmol/L).

Based on the information provided, what is the best approach for managing hypertension in this patient? Create a care plan that includes (a) goals of therapy, (b) a patient-specific therapeutic plan, and (c) a plan for appropriate monitoring to achieve goals and avoid adverse effects.

Renin Inhibitors

Aliskiren is the only currently available agent in this class of antihypertensive agents. Although similar to ACE-Is and ARBs in that it acts within the RAAS, it is unique in that it directly blocks renin, thereby reducing PRA and subsequently AT1 and AT2 with a resultant reduction in BP. This disruption of the negative feedback loop results in a compensatory increase in prorenin and renin levels, the significance of which is not well-established. Aliskiren has been shown to be well-tolerated and effective in reducing BP when used as monotherapy and in combination with other antihypertensive agents, including thiazide diuretics, ARBs, and CCBs.[3] However, long-term clinical trials evaluating efficacy and safety have not been completed, and thus the effects of aliskiren on morbidity and mortality are unknown as yet. Additionally, the Aliskiren Trial In Type 2 Diabetes Using Cardio-renal End points (ALTITUDE) comparing ACE-I or ARB monotherapy to that in combination with aliskiren was stopped prematurely as the combination therapy did not reduce cardiovascular endpoints.[37] Therefore, combining two or more RAAS blocking agents (ACE-Is, ARBs, or renin inhibitors) for the treatment of hypertension is not recommended.[35,37] Because of aliskiren's role in the RAAS, recommendations and precautions for monitoring serum potassium and kidney function should be similar to those of ACE-Is and ARBs.

α_1-Blockers

Generally, α_1-blockers should not be used as monotherapy. Further, doxazosin is associated with an increase in cardiovascular and cerebrovascular events.[20] However, α_1-blockers may be considered as add-on therapy to other agents (eg, fourth or fifth line) when hypertension is not adequately controlled. In addition, they may have a specific role in the antihypertensive regimen for elderly men with **prostatism**; however, their use is often curtailed by complaints of transient dizziness, palpitations, or syncope following the first dose and **orthostatic hypotension** with chronic use. Due to their ability to cross blood–brain barrier, α_1-blockers can also cause asthenia, vivid dreams, and depression. In addition, **priapism** may occur. When selected, however, combination therapy with a thiazide is recommended to minimize potential edema resulting from the α_1-blocker's tendency to cause sodium and water retention. The roles of doxazosin, terazosin, and prazosin in management of patients with hypertension are limited due to the paucity of outcome data and absence of a unique role for special populations or compelling indications.[2,3]

Central α_2-Agonists

Limited by their tendency to cause **orthostasis**, sedation, dry mouth, and vision disturbances, clonidine, methyldopa, guanfacine, and guanabenz represent rare choices in contemporary treatment of patients with hypertension. However, adding clonidine to other antihypertensive agents may be used for individuals with resistant hypertension, and methyldopa is a viable option for pregnancy. Their central α_2-adrenergic stimulation is thought to reduce sympathetic outflow and enhance parasympathetic activity, thereby reducing heart rate, CO, and total PVR. Occasionally used for cases of resistant hypertension, these agents may have a role when other more conventional therapies appear ineffective. The availability of a transdermal clonidine patch applied once-weekly may offer an alternative to hypertensive patients with adherence problems. Of particular importance is the potential for severe rebound hypertension when clonidine is abruptly discontinued. Rather, clonidine's dose should be gradually reduced when being discontinued. In patients concurrently taking a β-blocker, the β-blocker should be tapered to discontinuation first, ideally several days before initiating the clonidine taper. Because clonidine withdrawal results in an increase in SNS activity, patients withdrawing from clonidine while on a β-blocker could experience unbalanced α-mediated vasoconstriction.[8]

Other Agents

Direct vasodilators such as hydralazine and minoxidil represent alternative agents used for patients with resistant hypertension. They primarily act to relax smooth muscles in arterioles and activate baroreceptors. Because of the reflex tachycardia and fluid retention they cause, their use in the absence of concurrently administered β-blockers and diuretics such as furosemide is uncommon. Other side effects associated with minoxidil include pericardial effusion, nonspecific T-wave change on the ECG, and hypertrichosis (excessive body hair), particularly in women. Rarely, hydralazine-induced lupus-like syndrome can occur in some patients. Although uncommon, females, those receiving doses in excess of 200 mg/day, individuals with slow hepatic acetylation capacity, or having certain immunogenic factors appear to be at greater risk.[38] Because slow acetylation can increase the bioavailability of hydralazine leading to adverse effects, in 2013 the FDA listed N-acetyltransferase-1 (*NAT1*) and *NAT2* genes as biomarkers for the effectiveness and/or toxicity of hydralazine. References describing the appropriate use and monitoring of these infrequently utilized agents should be consulted before use.[8] Finally, reserpine, although slow to act, reduces sympathetic tone and thus PVR by depleting norepinephrine from sympathetic nerve endings. Although included in the SHEP and ALLHAT trials,[20] reserpine's numerous side effects including gastric ulceration, depression, and sexual side effects have limited its utility. Two additional agents, guanethidine and guanadrel, act as postganglionic sympathetic inhibitors inhibiting the release of norepinephrine as well as depleting norepinephrine from these nerve terminals. However, these agents have little role in the management of hypertension because of significant adverse effects.[8]

Antihypertensive Toxicity and Management

Common adverse reactions and monitoring parameters with each class of antihypertensive agents are discussed in the earlier sections. Overdoses occurring from antihypertensive agents are relatively uncommon, but their consequences, especially those involving β-blockers, CCBs, and vasodilators, can be profound.[39] This contrasts with the toxicities observed from diuretics, ACE-Is, ARBs, and direct renin inhibitors, which are generally more limited. Early gastrointestinal decontamination followed by routine supportive care, including intravenous (IV) crystalloid boluses, airway protection, and/or vasopressor administration should be initiated in patients manifesting significant bradycardia, hypotension, and/or seizures. If unresponsive to standard supportive care, glucagon and/or high-dose insulin with glucose (if no response to glucagon) may be used when β-blocker toxicity is suspected or confirmed. The early use of high-dose insulin and IV calcium can be effective for CCB poisonings. While administering calcium, one should monitor the ECG, avoid rapid infusions, and never infuse calcium in the same line as phosphate-containing solutions to prevent precipitation. Patients who ingest sustained-release formulations may experience delayed responses and prolonged toxicity and require 24-hour observation, even if asymptomatic upon presentation.

Patient Encounter 3

A 61-year-old man with history of hypertension, gout, and HFrEF presents to clinic for his annual examination. Upon reviewing his medication history, you see the patient has been taking chlorthalidone 12.5 mg daily, lisinopril 40 mg daily, carvedilol 25 mg twice daily, potassium chloride 20 mEq daily, and allopurinol 200 mg daily. Physical examination is unremarkable and no edema is present, but he continues with class II HF symptoms (dyspnea with normal activity). Laboratory values are remarkable for potassium 3.8 mEq/L (mmol/L), serum creatinine 1.5 mg/dL (133 μmol/L), and serum uric acid 9.4 mg/dL (559 μmol/L). Patient's average seated BP is 132/81 mm Hg with heart rate of 76 beats/min.

Based on the 2017 ACC/AHA guidelines, is this patient achieving his BP goal?

Would you consider changes to current antihypertensive therapy given the patient's BP, laboratory values, and medical history?

How would you assess the effectiveness of your therapeutic recommendations for this patient?

SPECIAL PATIENT POPULATIONS

Compelling Indications and Special Considerations

KEY CONCEPT Specific comorbidities, patient factors, and clinical scenarios may direct therapeutic goals and approach to therapy. These additional factors to consider include:

Comorbidities:

- Stable ischemic heart disease (SIHD)
- HF
- Diabetes
- CKD
- Valvular heart disease
- Atrial fibrillation
- Cerebrovascular disease

Special populations:

- Advanced age
- Pediatrics
- Race and ethnicity

Clinical scenarios:

- Hypertensive crisis
- Isolated systolic hypertension
- Pregnancy

The treatment of hypertension requires the clinician to consider acute and chronic factors that may alter the general approach to setting goals and initiating therapy. Blood pressure treatment thresholds and goals are listed in Table 6–2, and compelling indications for specific drug therapies are summarized in Table 6–3.[2]

In patients with an ACS or stable angina and hypertension, β-blockers and possibly long-acting CCBs are indicated because of their antihypertensive and antianginal effects.[2] Nitrate therapy should also be considered in patients with persistent angina or in the setting of ACS for symptom control. In post-MI patients, especially those with reduced LVEF, β-blockers and ACE-Is or ARBs are indicated due to their proven reduction of cardiovascular morbidity/mortality in this population. Aldosterone antagonists are also indicated for the post-MI patient with reduced LVEF and either diabetes or symptoms of HF.[36] Patients with CAD were included in the SPRINT trial, which showed a reduction in major adverse cardiovascular events, including mortality, with intensive SBP reduction (< 120 mm Hg) versus standard treatment (< 140 mm Hg) as measured via AOBP.[17] It should be noted that serious adverse events of hypotension, syncope, electrolyte abnormalities, and acute kidney injury or acute renal failure were more frequent in the intensive therapy arm and must weigh into decisions regarding application of the SPRINT findings. These data were considered by the 2017 ACC/AHA guidelines committee as part of the evidence and rationale to support a BP target of less than 130/80 mm Hg in this patient population.[2]

Patients with HF represent a heterogeneous cohort with specific recommendations for antihypertensive therapy depending on their classification. Current ACC/AHA guidelines recommend a BP target of less than 130/80 mm Hg for patients with HFrEF and HF with preserved ejection fraction (HFpEF).[2] Similarly, patients at risk for HF (stage A HF) are given a BP target recommendation of less than 130/80 mm Hg.[2] Patients with HFrEF and hypertension should be treated with evidence-based β-blockers (bisoprolol, carvedilol, or metoprolol succinate), ACE-Is or ARBs, and aldosterone antagonists as each has evidence supporting their morbidity/mortality benefits for such patients. In contrast, diuretics are recommended in HF patients with evidence of volume overload for symptom relief. African Americans with symptomatic HFrEF are ideal candidates for combination therapy with isosorbide dinitrate and hydralazine based on morbidity and mortality benefits and potential beneficial effects on lowering BP.[36] The dihydropyridine CCBs, amlodipine or felodipine, may be used in patients with HFrEF for uncontrolled BP; however, they offer no beneficial effect on morbidity and mortality and may increase the risk of edema.[36] For patients with HFpEF, use of non-dihydropiridine CCBs (diltiazem and verapamil) is not discouraged, in contrast to patients with HFrEF with whom they should not be used.[36] Updated HFpEF recommendations highlight the potential role for aldosterone antagonists in decreasing HF hospitalization in this cohort in addition to benefit as an antihypertensive if indicated.[40]

Initial drug therapy recommendations for patients with diabetes and hypertension without CKD (regardless of age) are dependent on if the patient is Black or non-Black.[2] Black patients with diabetes and no CKD should be treated initially with thiazide-type diuretics or CCBs alone or in combination. Alternatively, ACE-Is or ARBs, if ACE-I intolerant, should be considered for these patients when albuminuria (≥ 300 mg/day or ≥ 300 mg/g creatinine [34 mg/mmol creatinine]) is present. Non-Black patients with hypertension, diabetes, and no CKD are candidates for ACE-Is or ARBs as well as thiazide-type diuretics and CCBs for initial therapy.[2] In patients with CKD (stage 3 or higher or stage 1 or 2 with albuminuria (≥ 300 mg/day or ≥ 300 mg/g creatinine [34 mg/mmol creatinine])) and hypertension, ACE-Is, or ARBs if ACE-I intolerant, are recommended to slow progression of renal disease.[2] ACE-Is in combination with a thiazide diuretic are preferred in patients with a history of prior stroke or transient ischemic attack based on a reduced risk of recurrent stroke with the combination.

Hypertension in patients with asymptomatic aortic stenosis can be treated with standard pharmacologic therapy, but initiation of low doses and cautious titration should be observed. In patients with chronic aortic dissection, β-blockers were associated with improved survival, whereas ACE-Is were not.[2]

In patients with atrial fibrillation, ARB therapy is suggested for reduction in recurrence of atrial fibrillation.[2] This is based on comparisons of ARB versus CCB or β-blocker therapy where ARB therapy had clinical superiority with regard to atrial fibrillation recurrence.[2] Of note, no data on the role of ACE-Is in this situation are currently available.

Hypertensive crisis includes both hypertensive emergencies and hypertensive urgencies. A hypertensive emergency occurs when severe elevations in BP are accompanied by acute or life-threatening target organ damage such as ACS, unstable angina with dynamic ST changes, encephalopathy, intracerebral hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, rapidly progressive renal failure, accelerated malignant hypertension with papilledema, and eclampsia, among others. BP is generally greater than 180/120 mm Hg, although a hypertensive emergency can occur at lower levels, particularly in individuals without previous hypertension. The goal in most hypertensive emergency cases is to reduce SBP by up to 25% in the first hour; if stable, then lower to 160/100–110 mm Hg over the next 2 to 6 hours; and then carefully lower to normal over the following 24 to 48 hours. For individuals with compelling conditions, including aortic dissection, severe preeclampsia or eclampsia, or pheochromocytoma crisis, a more aggressive BP-lowering approach (reduce SBP to < 140 mm Hg in the first hour and < 120 mm Hg in aortic dissection) should be taken.[2] IV therapy is generally required and may consist of the agents listed in Table 6–8. In the setting of spontaneous intracranial hemorrhage occurring within the previous 6 hours and SBP between 150 and 220 mm Hg, immediate lowering of SBP to less than 140 mm Hg failed to reduce rates of death and severe disability, and there have been suggestions of risks, such as renal adverse events, associated with such a strategy.[2] Alternatively, hypertensive urgency is manifested as a severe elevation in SBP greater than 180 mm Hg and/or DBP greater than 110 mm Hg without evidence of acute or life-threatening target organ damage.[2] In these individuals, BP can usually be managed by restarting or intensifying oral therapy and treating anxiety as needed with close follow-up in the ambulatory setting. Emergency department referral is not typically indicated for these patients.[2]

The target for BP in patients 65 years and older remains uncertain and in part depends on whether the patient is ambulatory, community dwelling, institutionalized, and able to tolerate therapy.[2] A target systolic BP of less than 130 mm Hg is recommended in noninstitutionalized ambulatory community dwelling patients. However, if the patient has a high burden of comorbidity and limited life expectancy, a patient-centered, team-based approach evaluating potential risks and benefits of therapy is warranted.[2] The treatment of patients 65 years of age and older with hypertension should follow the same approach as other populations, with the exception that lower starting doses may be warranted to avoid adverse effects. Special attention should be paid to postural hypotension. This includes careful assessment of orthostatic symptoms measuring BP in the upright seated position and upon standing for 1 and 3 minutes. Additionally, caution should be taken to avoid volume depletion and rapid titration of antihypertensive therapy. It should also be noted that in the Hypertension in the Very Elderly Trial (HYVET), which supports BP lowering in the elderly, patients were excluded if standing

Table 6–8

Parenteral Antihypertensive Agents for Hypertensive Emergency and Special Conditions [2,27]

Drug	Dose Range[a]	Onset	Duration	Adverse Effects[b]	Special Indications
Adrenergic inhibitors					
Esmolol hydrochloride	500–1000 mcg/kg/min IV over 1 minute, then 50 mcg/kg/min by infusion; may repeat bolus after 5 minutes at 50 mcg/kg/min increment; maximum 200 mcg/kg/min	1–2 minutes	10–20 minutes	Nausea, asthma, first-degree heart block, HF	Preferred agent for acute aortic dissection, ACS and perioperative hypertension. Avoid use in combination with other β-blocker therapy, bradycardia or decompensated HF.
Labetalol hydrochloride	0.3–1 mg/kg (maximum 20 mg) slow IV injection or 0.4–1 mg/kg/hour IV infusion up to 3 mg/kg/hour; may repeat every 4–6 hours; maximum total cumulative dose 300 mg	5–10 minutes	3–6 hours	Vomiting, scalp tingling, dizziness, asthma, COPD, nausea, heart block, orthostatic hypotension, HF	Most hypertensive emergencies, including eclampsia and preeclampsia. Avoid use in reactive airway disease, second- or third-degree heart block or bradycardia.
Phentolamine	5 mg IV bolus, may repeat every 10 minutes	1–2 minutes	10–30 minutes	Tachycardia, flushing, headache, nausea, vomiting	Catecholamine excess such as adrenergic crisis secondary to pheochromocytoma or cocaine or amphetamine overdose or clonidine withdrawal.
Angiotensin-converting enzyme inhibitors					
Enalaprilat	1.25 mg IV over 5 minutes, may increase to 5 mg and repeat every 6 hours	15–30 minutes	6–12 hours	Precipitous fall in pressure in high-renin states; variable response	High plasma renin activity; avoid in acute MI, bilateral renal stenosis, and pregnancy.
Dihydropyridine calcium channel blockers					
Clevidipine	Initial 1–2 mg/hour IV, doubling every 90 seconds until BP at target, then increasing by less than doubling every 5–10 minutes; maximum 32 mg/hour	2–4 minutes	5–15 minutes; maximum 72 hours	Atrial fibrillation, fever, insomnia, nausea, headache, vomiting, postprocedural hemorrhage, acute renal failure, respiratory failure	Most hypertensive emergencies. Avoid use if hypersensitivity to soy or egg products, pathological hyperlipidemia, lipoid nephrosis, or acute pancreatitis. Use low-end dose range for elderly.
Nicardipine hydrochloride	Initial 5 mg/hour IV, increasing by 2.5 mg/hour every 5 minutes; maximum 15 mg/hour	5–10 minutes	15–30 minutes, may exceed 4 hours	Tachycardia, headache, flushing, local phlebitis	Preferred agent for most hypertensive emergencies, pregnancy, except acute pulmonary edema. Avoid use in acute aortic dissection. No dose adjustment needed for elderly.
Dopamine$_1$-receptor agonist					
Fenoldopam mesylate	0.1–0.3 mcg/kg/min as IV infusion[c]	< 5 minutes	30 minutes	Tachycardia, headache, nausea, flushing	Preferred agent in acute renal failure. Avoid use in glaucoma, elevated intracranial pressure, and sulfite allergy.
Vasodilators					
Hydralazine hydrochloride	Initial 10 mg as slow IV push; maximum initial dose 20 mg; repeat every 4–6 hours as needed	10–20 minutes 20–30 minutes	1–4 hours IV	Tachycardia, flushing, headache, vomiting, aggravation of angina	Preferred agent in pregnancy. Not first line in most patients due to unpredictability of response and prolonged duration of action.

(Continued)

Table 6–8

Parenteral Antihypertensive Agents for Hypertensive Emergency and Special Conditions [2,27] (*Continued*)

Drug	Dose Range[a]	Onset	Duration	Adverse Effects[b]	Special Indications
Nitroglycerin	Initial 5 mcg/min as IV infusion; increase in increments of 5 mcg/min to achieve BP target; maximum dose 20 mcg/min	2–5 minutes	5–10 minutes	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Preferred agent in ACS, acute pulmonary edema, and perioperative hypertension. Use caution if use of phosphodiesterase type-5 inhibitors (see package inserts for formal recommendations)
Sodium nitroprusside	Initial 0.3–0.5 mcg/kg/min as IV infusion[d]; increase in increments of 0.5 mcg/kg/min to achieve BP target; maximum dose 10 mcg/kg/min	Immediate	1–2 minutes	Nausea, vomiting, muscle twitching, sweating, thiocyanate, and cyanide intoxication	Use low-dose range for elderly.

[a]These doses may vary from those in the *Physicians' Desk Reference.*

[b]Hypotension may occur with all agents.

[c]Requires special delivery system.

[d]Requires special delivery system. For infusion rates over or equal to 4–10 mcg/kg/min or duration more than 30 minutes, coadminister thiosulfate to prevent cyanide toxicity.

ACS, acute coronary syndrome; BP, blood pressure; COPD, chronic obstructive pulmonary disease; HF, heart failure; IV, intravenous; MI, myocardial infarction.

Data from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults. J Am Coll Cardiol. 2017; and Saseen JJ, Maclaughlin EJ. Hypertension. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:74.

SBP at baseline was less than 140 mm Hg.[41] Newer data from SPRINT suggest that patients 75 years of age and older benefit in a similar fashion from intensive SBP reduction (< 120 vs < 140 mm Hg as measured by AOBP) as did patients less than 75 years of age with regard to cardiovascular morbidity and mortality risk reduction.[17] While some patients may benefit from pursuing intensive BP-lowering targets, tolerability must not be overlooked, and aspects of patient selection and safety considerations are paramount when considering any BP-lowering strategy in the elderly.

In individuals with isolated systolic hypertension (defined as elevated SBP [≥ 140 mm Hg] and low DBP [< 90 mm Hg]), the optimal level of diastolic pressure is not known, and although treated patients who achieve diastolic pressures less than 60 to 70 mm Hg had poorer outcomes in a landmark trial, their cardiovascular event rate was still lower than those receiving placebo.[30]

While the treatment approach of hypertension in minority populations is similar to other populations, special consideration should be paid to socioeconomic and lifestyle factors that may be important barriers to BP control. In addition, in patients of African origin, diminished BP responses have been seen with ACE-Is and ARBs compared with diuretics or CCBs.[2] A consensus document has also highlighted that long-acting CCBs and RAAS inhibitors with or without a diuretic should be used to improve outcomes in Asian patients.[42]

Hypertension in pregnancy is a major cause of maternal, fetal, and neonatal morbidity and mortality. There are four different categories of hypertension in pregnancy: preexisting chronic hypertension, gestational hypertension, preeclampsia–eclampsia, and preeclampsia superimposed on chronic hypertension. Each category is treated slightly differently. General recommendations for antihypertensive therapy in pregnancy favor methyldopa, nifedipine, and/or labetalol use versus other antihypertensives. Despite recommendations for use, these agents carry statements that “fetal risk cannot be ruled out” based on current FDA labelling recommendations and, as such, discussions regarding therapy should be had with all patients who are, or who may be planning to become, pregnant. Due to the known presence of fetal risk, ACE-Is, ARBs, or aliskiren should not be used in women who are pregnant. Readers are also referred to the American College of Obstetricians and Gynecologists task force on hypertension in pregnancy for detailed therapeutic options for guidelines on the diagnosis and management of gestational hypertension and preeclampsia.[43]

In children and adolescents, three or more BP readings are compared with tables listing the 90th, 95th, and 95th percentile + 12 mm Hg for BPs based on age, height, and gender that classify BP as normal, elevated, and stage 1 and stage 2 hypertension.[44] Prevalence of hypertension in adolescent populations is increasing. This, along with increases in obesity, sedentary lifestyle, or a positive family history, increases the risk of CVD. Clinicians should be aware that secondary causes are common in adolescents with hypertension, and identification and aggressive modification of risk factors with nonpharmacologic and pharmacologic interventions is paramount for risk reduction of target organ damage. The 2017 Clinical Practice Guideline for Screening and Management of High Blood Pressure in Children and Adolescents published by the American Academy of Pediatrics provides specific recommendations to modify and treat risk factors in this population of patients.[44]

OUTCOME EVALUATION

Short-term goals are to achieve reduction in BP safely through the iterative process of using pharmacologic therapy, along with nonpharmacologic therapy and lifestyle changes. Key to achieving target BP goals is a comprehensive monitoring plan, which considers the following:

- In patients in whom healthy lifestyle changes alone are recommended (ie, elevated BP or stage 1 hypertension without clinical ASCVD, CKD, DM, and estimated 10-year CVD risk < 10%), BP should be reassessed every 3 to 6 months.
- In patients starting pharmacologic therapy, BP and HR should be measured at monthly intervals, or more frequently in patients with marked elevations or significant comorbidities (eg, HF, CKD) until BP goal is achieved.
- Monitor renal function and electrolytes within 2 to 4 weeks of initiating or increasing doses of antihypertensive therapy that may affect these parameters (eg, diuretics, aldosterone antagonists, ACE-Is, and ARBs). Earlier monitoring should be considered in those with CKD, baseline electrolyte abnormalities, or HF.

Patient Care Process

Collect Information:

- Perform a medication history including prescription and nonprescription medications, herbal products, and dietary supplements as well as history of allergies to medications or other substances.
- Obtain health data including personal and family medical history, past surgeries/procedures, immunization status, fall risk, health and wellness information, laboratory and physical assessment findings.
- Speak with patient and review records to obtain lifestyle habits (eg, sodium intake, cooking practices, physical activity, use of alcohol/tobacco/recreational drugs), preferences and beliefs, health literacy, cultural factors, health and functional goals, and socioeconomic factors that affect access to medications and other aspects of care.
- Document current BP and heart rate (office, HBP, or 24-hour ABPM or AOBP results if available).

Assess the Information:

- Identify any substances or lifestyle habits that could adversely affect BP control or negatively interact with current medications.
- Based on medical history, physical examination, laboratory results, and review of systems determine whether patient has any target organ damage or comorbidities related to or associated with high BP or if experiencing any signs or symptoms of high BP.
- Calculate patient's 10-year risk of a cardiovascular event to establish BP threshold for initiation of pharmacologic therapy if stage 1 hypertension and no clinical ASCVD, DM, or CKD, and candidacy for other cardioprotective therapies (eg, statin therapy, antiplatelet therapy).
- Establish an appropriate BP goal.
- Determine patient's awareness and knowledge (eg, health literacy) of health effects of high BP and benefits and risks of treatment.
- Identify compelling indications for specific antihypertensives (Table 6–3) or specific considerations (eg, pregnancy).
- Evaluate appropriateness, effectiveness, safety (adverse events, drug interactions), and patient adherence to current pharmacotherapy.
- Review immunization status and need for preventive care and other healthcare services, where appropriate.

Develop a Care Plan:

- Collaborate with patient to identify feasible lifestyle modifications (Table 6–6).
- If patient is not at BP goal, determine whether antihypertensive pharmacotherapy is indicated, and select appropriate therapy based on compelling indications (Tables 6–2 and 6–3), specific patient characteristics (eg, pregnancy), and patient preferences.
- Utilize medications with complementary mechanisms of action and at doses that are optimal for patient (Table 6–7).
- Determine affordability of medications (eg, insurance coverage) and availability on health care formulary, if applicable.
- Engage and empower the patient through education and self-management.

Implement the Care Plan:

- Educate and provide resources about implementing lifestyle modifications and changes in drug therapy including medication administration, storage, adherence, and potential adverse effects and their management.
- Help patient select a self-monitoring device and seek commitment on a mutually agreed upon frequency of measurements.
- Advise patient on how to monitor, document, and report BP measurements as well as when to seek medical advice or care.
- Address any patient concerns about management of hypertension.
- Arrange for preventive care (eg, immunizations) and other healthcare services that were previously identified as warranted.

Follow-up: Monitor and Evaluate:

- Follow at monthly intervals or more frequently in patients with marked elevations or significant comorbidities (eg, HF, CKD), until BP goal is achieved.
- Review medication and lifestyle adherence, BP measurements, adequacy of BP control, and laboratory and other diagnostic tests to assess changes in clinical status and target organ damage.
- Determine whether patient is experiencing any adverse reactions or drug interactions.
- Once BP is controlled, monitor patient every 3 to 6 months to assess BP control, electrolytes and renal function as appropriate, clinical status, and target organ damage.

- Increase the dose of initial drug (replace with an alternative if adverse event or no significant reduction in BP) or add an additional drug to current regimen if BP goal is not reached.
- Once BP target is achieved, monitor patient every 3 to 6 months to assess BP control, electrolytes and renal function as appropriate, clinical status and target organ damage.
- Implement lifestyle changes that address risk factors for CVD such as obesity, physical inactivity, insulin resistance, dyslipidemia, smoking cessation, need for low-dose aspirin, or statin therapy.
- Monitor for efficacy, adverse events, drug interactions, and adherence to therapy as keys to achieving the long-term goals of reducing risk of morbidity and mortality associated with CVD.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Drs. Robert Straka and David Parra, authors of this chapter in previous editions of this book.

Abbreviations Introduced in This Chapter

ABPM	Ambulatory blood pressure monitoring
ACCORD	Action to Control Cardiovascular Risk in Diabetes
ACE-I	Angiotensin-converting enzyme inhibitor
ACC	American College of Cardiology
ACR	Albumin-to-creatinine ratio
ACS	Acute coronary syndromes
AHA	American Heart Association
ALLHAT	Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial
ALTITUDE	Aliskiren Trial in Type 2 Diabetes Using Cardiorenal End points
AOBP	Ambulatory office-based blood pressure
ARB	Angiotensin receptor blocker
ASCVD	Atherosclerotic cardiovascular disease
AT1	Angiotensin-1
AT2	Angiotensin-2
BID	Twice daily
BP	Blood pressure
CAD	Coronary artery disease
CCB	Calcium channel blocker
CHD	Coronary heart disease
CKD	Chronic kidney disease
CMS	Centers for Medicare & Medicaid Services
CO	Cardiac output
COPD	Chronic obstructive pulmonary disease
CrCl	Creatinine clearance
CVD	Cardiovascular disease
CYP	Cytochrome P450
DASH	Dietary Approaches to Stop Hypertension
DBP	Diastolic blood pressure
DM	Diabetes mellitus
ECG	Electrocardiogram
FDA	Food and Drug Administration
GFR	Glomerular filtration rate
GI	Gastrointestinal
HAART	Highly active antiretroviral therapy
HBP/HBPM	Home blood pressure/home blood pressure measurement
HDL	High-density lipoprotein
HF	Heart failure
HFpEF	Heart failure with preserved ejection fraction
HFrEF	Heart failure with reduced ejection fraction
HYVET	Hypertension in the Very Elderly Trial
ISA	Intrinsic sympathomimetic activity
IV	Intravenous
LDL	Low-density lipoprotein
LVEF	Left ventricular ejection fraction
MAO	Monoamine oxidase
MI	Myocardial infarction
NAT1	N-acetyltransferase-1
NSAID	Nonsteroidal anti-inflammatory drug
ONTARGET	Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial
PRA	Plasma renin activity
PRC	Plasma renin concentration
PVR	Peripheral vascular resistance
QDay	Once daily
RAAS	Renin-angiotensin-aldosterone system
SBP	Systolic blood pressure
SHEP	Systolic Hypertension in the Elderly Program
SIHD	Stable ischemic heart disease
SPRINT	Systolic Blood Pressure Intervention Trial
SPS3	Secondary Prevention of Small Subcortical Strokes
SNS	Sympathetic nervous system
TID	Three times daily

7 Heart Failure

Tien M. H. Ng and Samantha L. Yeung

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Classify heart failure (HF) syndrome types into HF with reduced ejection fraction (HFrEF), HF with preserved ejection fraction (HFpEF), HF with mid-range ejection fraction (HFmrEF), and HF with recovered ejection fraction (HFrecEF).
2. Differentiate between the common underlying etiologies of HF, including ischemic, nonischemic, and idiopathic causes.
3. Describe the pathophysiology of HF as it relates to neurohormonal activation of the renin-angiotensin-aldosterone system, sympathetic nervous system, and endogenous counterregulatory vasodilatory peptide systems.
4. Identify signs and symptoms of HF and classify a given patient by New York Heart Association Functional Classification and American College of Cardiology/American Heart Association Heart Failure Stage.
5. Discuss and modify the goals of therapy for a patient with acute and/or chronic HF.
6. Create a strategy for the nonpharmacologic management of a patient with HF that includes patient education.
7. Develop an evidence-based pharmacologic treatment and monitoring plan for a patient with chronic HFrEF.
8. Design a pharmacologic treatment and monitoring plan for a patient with acute HF.
9. Formulate a therapeutic management plan for a patient with HFpEF.

INTRODUCTION

Heart failure (HF) is a syndrome defined as the inadequate ability of the heart to pump enough blood to meet the blood flow and metabolic demands of the body.[1] HF is most commonly a result of low **cardiac output** (CO) secondary to impaired cardiac function. High-output HF is characterized by an inordinate increase in the body's metabolic demands that outpaces an increase in CO of a generally normally functioning heart. The term *heart failure* refers to low-output HF for the purposes of this chapter.

HF can result from any structural or functional cardiac disorder that impairs the ability of the ventricle to eject or fill with blood.[1] Apart from the clinical syndrome, it is commonly characterized by assessment of left ventricular (LV) function. Impairment in ventricular contraction (systolic dysfunction) and/or ventricular filling (diastolic dysfunction) can result in a similar decrease in CO. Ejection fraction (EF) is the fraction of the volume present at the end of diastole that is pushed into the aorta during systole. When the primary defect is LV systolic dysfunction, evidenced by a left ventricular ejection fraction (LVEF) of 40% (0.40) or less, and is accompanied by symptoms, it is referred to as HF with reduced ejection fraction (HFrEF). HFrEF can occur with or without a component of diastolic dysfunction, which coexists in up to two-thirds of patients. When the primary defect is LV diastolic dysfunction, evidenced by an LVEF of 50% (0.50) or greater along with other criteria to document impaired ventricular filling, and symptoms are present, it is referred to as HF with preserved ejection fraction (HFpEF). HFpEF occurs in approximately one-third to one-half of patients with HF, with long-standing hypertension being the leading cause. Patients with symptoms of HF and an LVEF between 41% and 49% (0.41 and 0.49) are termed to have HF with mid-range ejection fraction (HFmrEF). HF with recovered ejection fraction (HFrecEF) refers to patients who have an LVEF greater than 40% (0.40) but at one time had an LVEF less than or equal to 40% (0.40). Ventricular dysfunction can also reflect involvement of either the left or right ventricle (or both) and be referred to as left-sided or right-sided HF, respectively. This has implications for symptomatology because predominant right-sided failure manifests as systemic congestion, whereas predominant left-sided failure results in pulmonary symptoms.

In addition to derangement of cardiac function, HF is diagnosed by a history of specific signs and symptoms related to congestion and hypoperfusion. Because HF can occur in the presence or absence of fluid overload, the term *heart failure* is preferred over the former term *congestive heart failure*. The term *acute heart failure* (AHF) is used to signify either an acute decompensation of a patient with a history of chronic HF or to refer to a patient presenting with new-onset HF symptoms. Many disorders, such as those of the heart valves, pericardium, epicardium, endocardium, or great vessels, may lead to HF, but most patients develop symptoms due to impairment in LV function. Terms commonly associated with HF, such as *cardiomyopathy* and *LV dysfunction*, are not equivalent to HF but describe possible structural or functional reasons for the development of HF.

EPIDEMIOLOGY

HF is a major public health concern affecting approximately 6.2 million people in the United States. HF manifests most commonly in adults older than 60 years.[2] The growing prevalence of HF corresponds to advancements in evidence-based medical therapy in patients with risk factors for HF and increasing proportions of older adults. The relative incidence of HF is slightly higher in women compared to men; the prevalence of HF in women is also higher due to the greater incidence rate and longer life expectancy. Hospitalizations for HF have declined slightly in the past decade, to approximately 800,000 admissions annually in the United States.[2] According to national registries, patients presenting with HF are older and have numerous comorbidities such as coronary artery disease (CAD), renal insufficiency, diabetes, and obesity. Total estimated costs for managing both chronic and acute HF in the United States for 2012 was approximately $30.7 billion, of which more than two-thirds were attributable to direct medical costs. Globally, the cost of HF in that same year was estimated to be $108 billion.[3]

Prognosis remains poor, with the 5-year mortality rate for chronic HF greater than 50%.[2] Survival strongly correlates with severity of symptoms and functional capacity. For patients hospitalized for HF, the average hospital length of stay is estimated to be approximately 4 to 6 days, a number that has remained constant over the past decade.[4] In-hospital mortality rate has been estimated at approximately 4%, with ranges from 2% to 20%.[4] Readmissions are also high, with up to 30% to 60% of patients readmitted within 6 months of initial discharge date.[4]

ETIOLOGY

HF is the eventual outcome of numerous cardiac diseases or disorders (Table 7–1).[5] HF can be classified by the primary underlying etiology as ischemic or nonischemic, with the majority related to ischemia in the United States. KEY CONCEPT The most common causes of HF are CAD, hypertension, and *dilated cardiomyopathies*.

Table 7–1

Causes of Heart Failure

Heart failure with reduced ejection fraction (HFrEF)
- Coronary artery disease (eg, myocardial infarction or ischemia)
- Dilated cardiomyopathies (eg, drug-induced, viral infections, postpartum)
- Pressure overload (eg, systemic or pulmonary hypertension, aortic or pulmonic valve stenosis)
- Volume overload (eg, valvular regurgitation, shunts, high-output states)

Heart failure with preserved ejection fraction (HFpEF)
- Increased ventricular stiffness
  - Ventricular hypertrophy (eg, hypertrophic cardiomyopathy, hypertension)
  - Infiltrative myocardial diseases (eg, amyloidosis, sarcoidosis, endomyocardial fibrosis)
  - Myocardial infarction or ischemia
- Mitral or tricuspid valve stenosis
- Pericardial disease (eg, pericarditis, pericardial tamponade)

Reproduced with permission from Parker RB, Nappi JM, Cavallari LH. Chronic heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020.

PATHOPHYSIOLOGY

A basic grasp of normal cardiac function sets the stage for understanding pathophysiological processes contributing to HF development, progression, and management. CO is defined as the volume of blood ejected per unit of time (L/min) and is a major determinant of tissue perfusion. CO is the product of heart rate (HR) and stroke volume (SV): CO = HR × SV. The following sections describe how each parameter relates to CO.

HR is controlled by the autonomic nervous system, where sympathetic stimulation of β-adrenergic receptors results in an increase in HR and subsequent increase in CO in most instances. SV is the volume of blood ejected with each systole. SV is determined by factors regulating **preload**, **afterload**, and contractility. Preload is a measure of ventricular filling pressure at the end of diastole (also known as LV end-diastolic pressure) and is related to the volume of blood in the left ventricle just prior to systole (also known as LV end-diastolic volume). Preload is determined by venous return, ventricular relaxation, as well as atrial contraction. An increase in venous return to the left ventricle results in the stretch of cardiomyocyte sarcomeres (or contractile units) and a subsequent increase in the number of cross-bridges formed between actin and myosin myofilaments. In a healthy heart, this results in an increase in the force of contraction based on the **Frank-Starling mechanism**.[6] Afterload is the resistance to ventricular ejection and is regulated by ejection impedance, wall tension, and geometry. Thus, elevated aortic and systemic pressures result in an increase in afterload and reduced SV. Contractility, also known as the **inotropic** state of the heart, is an intrinsic property of cardiac muscle incorporating fiber shortening and tension development. Contractility is influenced to a large degree by adrenergic nerve activity and circulating catecholamines such as epinephrine and norepinephrine.

Compensatory Mechanisms

There are fundamental pathophysiological differences between HFrEF and HFpEF. This section will focus more on HFrEF, with specifics of HFpEF pathophysiology discussed later in this chapter. In the setting of a loss of myocardium (such as after an acute myocardial infarction [MI]), a number of adaptive and maladaptive mechanisms are activated in response to the reduced CO and increased hemodynamic burden. They include the Frank-Starling mechanism, tachycardia and increased afterload, and ventricular hypertrophy and cardiac remodeling (Table 7–2).[5,6]

▶ *Preload and the Frank-Starling Mechanism*

In the setting of a sudden decrease in CO, the body's natural response is to increase blood volume and prioritize perfusion of vital organs such as the heart and brain. Decreased renal perfusion activates the renin-angiotensin-aldosterone system (RAAS), triggering the production of angiotensin II and downstream synthesis and release of aldosterone. Aldosterone stimulates sodium and water retention, increasing intravascular volume and hence preload. In the absence of LV systolic dysfunction, increases in preload result in proportional increases in CO. However, in a failing heart, alterations in the contractile filaments reduce the ability of cardiomyocytes to adapt to increases in preload. Thus, an increase in preload can further impair contractile function and a further decline in CO. See Figure 7–1.

Table 7–2

Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure[5,6]

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through sodium and water retention)	Optimizes stroke volume via Frank-Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO_2
Vasoconstriction	Maintains BP and perfusion in the face of reduced cardiac output	Increased MVO_2 Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (due to SNS activation)	Increases cardiac output	Increased MVO_2 Shortened diastolic filling time β_1-Receptor downregulation, decreased receptor sensitivity Precipitation of ventricular arrhythmias Increased risk of myocardial cell death
Ventricular hypertrophy and remodeling	Maintains cardiac output Reduces myocardial wall stress Decreases MVO_2	Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk

BP, blood pressure; MVO_2, myocardial oxygen consumption; SNS, sympathetic nervous system.

▶ *Tachycardia and Increased Afterload*

An increase in HR is another mechanism to increase CO, especially when contractility is reduced. This is achieved through sympathetic nervous system (SNS) activation and the agonist effect of norepinephrine on cardiac β-adrenergic receptors. SV is relatively fixed in HF; thus, HR becomes a major determinant of CO. Although this mechanism increases CO acutely, the chronotropic and inotropic responses to sympathetic activation increase myocardial oxygen demand, worsen underlying ischemia, contribute to proarrhythmia, and further impair both systolic and diastolic function.

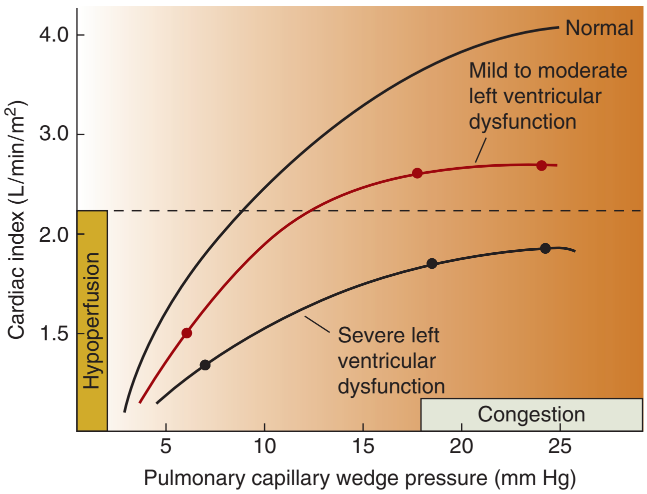

FIGURE 7–1. Relationship between cardiac output (shown as cardiac index) and preload (shown as pulmonary capillary wedge pressure). Cardiac index is expressed in conventional units of $L/min/m^2$ and can be converted to SI units of $L/s/m^2$ by multiplying by 0.0167. (Reproduced with permission from Parker RB, Nappi JM, Cavallari LH. Chronic heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:83.)

Activation of both the RAAS and SNS also contributes to vasoconstriction in an attempt to redistribute blood flow from peripheral organs to coronary and cerebral circulation.[6] However, arterial vasoconstriction and the resulting increase in afterload may further impair SV. Therefore, arterial vasoconstriction is maladaptive in the failing heart, contributing to a further decrease in CO, continued stimulation of compensatory responses, and a vicious cycle of neurohormonal activation.

▶ *Cardiac Remodeling and Ventricular Hypertrophy*

Cardiac remodeling is a compensatory adaptation to a change in wall stress and is largely regulated by neurohormonal activation, with angiotensin II and aldosterone being key stimuli.[6] The process entails changes in myocardial and extracellular matrix composition and function that result in both structural and functional alterations to the heart. In HF, the changes in cardiac size, shape, and composition are detrimental to heart function. In addition to myocyte size and extracellular matrix changes, heart geometry shifts from an elliptical to a less efficient spherical shape. These changes can occur acutely or manifest over time. After remodeling, the heart can maintain CO for many years. However, function generally continues to deteriorate until progression to clinical HF.

Ventricular hypertrophy, an adaptive increase in ventricular muscle mass due to the growth of existing myocytes, occurs in response to an increased hemodynamic burden such as volume or pressure overload.[5] Hypertrophy can be concentric or eccentric. Concentric hypertrophy occurs in response to pressure overload such as in long-standing hypertension or pulmonary hypertension, whereas eccentric hypertrophy occurs after an acute MI. Eccentric hypertrophy involves an increase in myocyte size in a segmental fashion, as opposed to the global hypertrophy occurring in concentric hypertrophy. Hypertrophy is commonly a component of cardiac remodeling. Although hypertrophy may reduce cardiac wall stress in the short term, continued hypertrophy accelerates myocyte cell death through an overall increase in myocardial oxygen demand. Maladaptive ventricular hypertrophy is also a major contributor to diastolic dysfunction.

Neurohormonal Model of Heart Failure

KEY CONCEPT Development and progression of HF is also intimately linked to neurohormonal pathways activated as a compensatory response to a decline in CO. Activated pathways include those with pathological consequences such as the RAAS, SNS, endothelin, and vasopressin, as well as counterregulatory pathways such as the natriuretic peptides and nitric oxide. This model is the basis for many of the current guideline-directed medical therapies (GDMT) for HFrEF.

▶ *Angiotensin II*

Angiotensin II is a key neurohormone in the pathophysiology of HF. Angiotensin II contributes to an increase in systemic vascular resistance (SVR) and blood pressure (BP) through vasoconstriction. The resulting increase in afterload increases myocardial oxygen demand and opposes the desired increase in SV. In the kidneys, angiotensin II acutely raises intraglomerular pressure through constriction of the efferent arterioles.[6] However, the increase in glomerular filtration pressure may be offset by a reduction in renal perfusion secondary to angiotensin II's influence over the release of other vasoactive neurohormones such as vasopressin and endothelin-1 (ET-1). Angiotensin II also potentiates the release of aldosterone from the adrenal glands and norepinephrine from adrenergic nerve terminals. Additionally, angiotensin II induces vascular hypertrophy and remodeling in both cardiac and renal cells.

▶ *Aldosterone*

Aldosterone's contribution to HF pathophysiology is multifaceted. Renally, aldosterone stimulates sodium and water retention to increase intravascular volume and preload. This mechanism is maladaptive as it exacerbates the already elevated ventricular filling pressures. Aldosterone also contributes to electrolyte abnormalities, especially hypokalemia and hypomagnesemia, which increase the risk for arrhythmias. Aldosterone is an etiological factor in cardiac remodeling through promotion of myocardial fibrosis by causing increased extracellular matrix collagen deposition and inflammation.[6] Aldosterone also potentiates SNS activation. The combination of these effects increases the risk of sudden cardiac death in HF. Elevated aldosterone concentrations are associated with a poorer prognosis in HF.

▶ *Norepinephrine*

Norepinephrine is a classic marker for SNS activation. It plays an adaptive role in the failing heart by increasing HR and myocardial contractility to augment CO and mediating vasoconstriction to maintain organ perfusion. However, excess levels are directly cardiotoxic. Sympathetic activation also increases the risk for arrhythmias and ischemia and accelerates myocyte cell death through increased myocardial workload and apoptosis. Ventricular hypertrophy and remodeling are also influenced by norepinephrine.[6]

Plasma norepinephrine concentrations are elevated proportionally to HF severity, with highest levels correlating to the poorest prognosis. HF is also characterized by diminished responsiveness to catecholamines.[6] Adrenergic receptor desensitization and downregulation (decreased receptor number and post-receptor responses and signaling) occur under sustained sympathetic stimulation. The desensitization is another driver for heightened norepinephrine release.

▶ *Endothelin*

Endothelin-1 is one of the most potent physiological vasoconstrictors.[6] ET-1 binds to two G-protein–coupled receptors, endothelin-A (ET-A) and endothelin-B (ET-B). ET-A receptors mediate vasoconstriction and are prevalent in vascular smooth muscle and cardiac cells. ET-B receptors are expressed on the endothelium and in vascular smooth muscle, and receptor stimulation mediates vasodilation and endothelin clearance. Levels of ET-1 correlate with HF functional class and mortality. However, endothelin receptor antagonists have failed to improve long-term outcomes of patients with HFrEF.

▶ *Arginine Vasopressin*

Vasopressin exerts its effects through vasopressin type 1a (V_{1a}) and vasopressin type 2 (V_2) receptors.[5,6] V_{1a} stimulation leads to vasoconstriction and trophic effects on the heart, whereas actions on the V_2 receptor cause free water retention through aquaporin channels in the renal collecting duct. Vasopressin increases preload, afterload, and myocardial oxygen demand in the failing heart. Higher vasopressin concentrations are linked to dilutional hyponatremia and a poorer prognosis in HF. Vasopressin receptor antagonists have not been shown to improve HFrEF prognosis when added to established therapies.

▶ *Counterregulatory Hormones (Natriuretic Peptides, Bradykinin, and Nitric Oxide)*

Atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) are endogenous neurohormones, synthesized mainly from the atria and ventricles, respectively, that regulate sodium and water balance. Natriuretic peptides decrease sodium reabsorption in the collecting duct of the kidney and cause vasodilation through the cyclic guanosine monophosphate (cGMP) pathway.[6] They are degraded by an enzyme called neprilysin, which has become an important therapeutic target in the management of HFrEF. Release of ANP and BNP is stimulated by increased cardiac chamber wall stretch usually indicative of volume load. Higher concentrations of natriuretic peptides correlate with a more severe HF functional class and prognosis. Plasma concentrations of BNP are used as a diagnostic biomarker in HF.[6]

Bradykinin is part of the kallikrein-kinin system, which shares a link to the RAAS through angiotensin-converting enzyme (ACE). Bradykinin is a vasodilatory peptide that is released in response to a variety of stimuli, including neurohormonal and inflammatory mediators known to be activated in HF.[6] As a consequence, bradykinin levels are elevated in HF patients and thought to partially antagonize the vasoconstrictive peptides.

Nitric oxide, a vasodilatory hormone released by the endothelium, is found in higher concentrations in patients with HF and provides two main benefits: vasodilation and neurohormonal antagonism of endothelin.[6] Nitric oxide's production is affected by the enzyme inducible nitric oxide synthase (iNOS), which is upregulated in the setting of HF likely in response to activation of angiotensin II, norepinephrine, and multiple cytokines. In HF, the physiological response to nitric oxide appears to be blunted, which contributes to the imbalance between vasoconstriction and vasodilation. Other vasodilatory peptides (eg, adrenomedullin, substance P) also have a putative role in the pathophysiology of HF and remain in investigation as potential targets for pharmacologic therapy development.

▶ *Proinflammatory Cytokines*

Inflammatory cytokines have been implicated in the pathophysiology of HF.[6] Several proinflammatory cytokines (eg, tumor necrosis factor [TNF]-α, interleukin [IL]-1, IL-6, and interferon-γ) and anti-inflammatory cytokines (eg, IL-10) are overexpressed in the failing heart. The most is known about

TNF-α, a pleiotropic cytokine that acts as a negative inotrope, stimulates cardiac cell apoptosis, uncouples β-adrenergic receptors from adenylyl cyclase, and is related to cardiac cachexia. The exact role of cytokines and inflammation in HF pathophysiology continues to be studied.

▸ *Other Prognostic Biomarkers*

Aside from natriuretic peptides having both diagnostic and prognostic implications, other novel biomarkers are linked to HF prognosis.[7] Soluble suppression of tumorigenicity-2 (sST2) is a biomarker for myocardial fibrosis and has prognostic value for both chronic and acute HF. Galectin-3 (Gal-3) is a member of the lectin family found to play a role in ventricular remodeling and fibrosis through stimulation of the transforming growth factor-β (TGF-β) signaling pathway. Myocardial Gal-3 levels are upregulated in patients with HF; however, the association between plasma and myocardial Gal-3 levels remains under investigation. Neutrophil gelatinase-associated lipocalin (NGAL) is a protein that is highly expressed in the kidneys and is being studied as a marker of acute kidney injury and prognosis in HF. Other prognostic biomarkers include high-sensitivity troponin (hsTn) and midregional proadrenomedullin (MR-proADM).[7] The guidelines suggest measurement of these biomarkers in chronic HF may provide value for added risk stratification.

Precipitating and Exacerbating Factors in Heart Failure

HF patients exist in one of two clinical states. When a patient's volume status and symptoms are stable, their HF condition is said to be "compensated." In situations of volume overload or other worsening symptoms, the patient is considered "decompensated." Acute decompensation can be precipitated by numerous etiologies (Table 7–3).[5]

KEY CONCEPT The clinician must identify potential reversible causes of HF exacerbations including prescription and nonprescription drug therapies, dietary indiscretions, and medication nonadherence. Nonadherence with dietary restrictions or chronic HF medications deserves special attention because it is the most common cause of acute decompensation and can be prevented. As such, an accurate history regarding diet, food choices, and the patient's knowledge regarding sodium and fluid intake (including alcohol) is valuable in assessing dietary indiscretion. Nonadherence with medical recommendations such as laboratory and other appointment follow-up can also be indicative of nonadherence with diet or medications.

Table 7–3

Exacerbating or Precipitating Factors in Heart Failure[5]

Cardiac	Metabolic	Patient-Related
Acute ischemia	Anemia	Dietary/fluid nonadherence
Arrhythmia	Hyperthyroidism/thyrotoxicosis	HF therapy nonadherence
Endocarditis	Infection	Use of cardiotoxins (cocaine, chronic alcohol, amphetamines, sympathomimetics)
Myocarditis	Pregnancy	Offending medications (NSAIDs, COX-2 inhibitors, steroids, lithium, β-blockers, calcium channel blockers, antiarrhythmics, alcohol, thiazolidinediones)
Pulmonary embolus	Worsening renal function	
Uncontrolled hypertension		
Valvular disorders		

COX-2, cyclooxygenase-2; HF, heart failure; NSAID, nonsteroidal anti-inflammatory drug.

CLINICAL PRESENTATION AND DIAGNOSIS OF HEART FAILURE

In low-output HF, symptoms are generally related to either congestion behind the failing ventricle(s) or hypoperfusion (decreased tissue blood supply), or both. Congestion is the most common finding in HF. Elevated filling pressure in the left ventricle (left-sided HF) causes fluid to back up in the lungs causing pulmonary symptoms, whereas elevated right ventricular filling pressure (right-sided HF) leads to systemic symptoms of congestion. Symptoms of left-sided HF include dyspnea, orthopnea, and paroxysmal nocturnal dyspnea (PND), whereas symptoms of right-sided HF include peripheral edema, gastrointestinal (GI) bloating, and fatigue. Although most patients initially have left ventricular failure (LVF), both ventricles will eventually be involved leading to pulmonary and systemic symptoms. Because of the complex nature of this syndrome, it has become more difficult to attribute a specific sign or symptom as caused by either right ventricular failure (RVF) or LVF. Symptoms related to hypoperfusion of peripheral tissues include decreased urine output, mental confusion, and cold extremities.

General Signs and Symptoms

Refer to the Clinical Presentation and Diagnosis of Chronic Heart Failure textbox for descriptions of signs and symptoms. Patients can experience a variety of symptoms related to buildup of fluid. The most recognized finding of systemic venous congestion is peripheral edema. It usually occurs in dependent areas of the body, such as the ankles (pedal edema) for ambulatory patients or sacral region for bedridden patients. Lower extremity edema should be quantified by how far it extends, that is, feet, ankles, calves, or thighs. Pitting edema is graded on a scale from 0 (no edema) to 4+ (severe edema) and is based on the depth and duration of the indentation that occurs upon releasing digital pressure over the site. Abdominal congestion may cause bloating, pain, early satiety, nausea, anorexia, and constipation. Intestinal edema may delay absorption of oral medications, including diuretics used to treat congestion. Often patients may have difficulty fitting into their shoes or pants due to edema. Weight gain often precedes signs of overt peripheral edema. Therefore, it is crucial for patients to weigh themselves daily even in the absence of symptoms to assess fluid status.

A clinically validated measure of venous congestion is assessment of the jugular venous pressure (JVP). This is performed by examining the right internal jugular vein for distention or elevation of the pulsation while reclining at a 45-degree angle (angle may be adjusted if the pulsation is not visible). A JVP more than 4 cm above the sternal angle is indicative of elevated right atrial pressure. JVP may be normal at rest, but if application of pressure to the abdomen can elicit a sustained elevation of JVP, this is defined as hepatojugular reflux (HJR). A positive finding of HJR indicates splanchnic congestion and results from displacement of volume from the abdomen into the jugular vein because the right atrium is unable to accept this additional blood. Hepatic congestion can cause abnormalities in liver function, which can be evident in liver function tests and/or clotting times. Development of hepatomegaly occurs infrequently and is caused by long-term systemic venous congestion.

Clinical Presentation and Diagnosis of Heart Failure

General

Patient presentation may range from asymptomatic to cardiogenic shock.

Symptoms

- Dyspnea, particularly on exertion
- Orthopnea
- Shortness of breath (SOB)
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Tachypnea
- Cough
- Fatigue
- Nocturia and/or polyuria
- Hemoptysis
- Abdominal pain
- Anorexia
- Nausea
- Bloating
- Ascites
- Mental status changes (confusion, hallucinations)
- Weakness
- Lethargy
- Insomnia

Signs

- Pulmonary rales or crackles
- Pulmonary edema
- S_3 gallop
- Pleural effusion
- Cheyne-Stokes respiration
- Tachycardia
- Cardiomegaly
- Peripheral edema (eg, pedal edema, which is swelling of feet and ankles)
- Jugular venous distension (JVD)
- Hepatojugular reflux (HJR)
- Hepatomegaly
- Cyanosis of the digits
- Pallor or cool extremities

Laboratory Tests

- BNP greater than 100 pg/mL (ng/L; 28.9 pmol/L) or N-terminal proBNP (NT-proBNP) greater than 300 pg/mL (ng/L; 35.4 pmol/L) in acute HF setting; BNP greater than 35 pg/mL (ng/L; 10.1 pmol/L) or NT-proBNP greater than 125 pg/mL (ng/L; 14.7 pmol/L) in nonacute HF setting
- Electrocardiogram (ECG): May be normal or could show numerous abnormalities including acute ST-T–wave changes from myocardial ischemia, atrial fibrillation, bradycardia, and LV hypertrophy.
- Serum creatinine: May be increased owing to hypoperfusion; preexisting renal dysfunction can contribute to volume overload.
- Complete blood count: Useful to determine if HF is due to reduced oxygen-carrying capacity. Anemia is common in patients with HF.
- Chest x-ray: Useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions.
- Echocardiogram: Used to assess LV size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction.

In chronic severe HF, unintentional weight loss can be an indicator of cardiac cachexia, defined as a nonedematous weight loss more than 6% of the previous normal weight over a period of at least 6 months. HF prognosis worsens considerably once cardiac cachexia has been diagnosed. This results from several factors including loss of appetite, malabsorption due to GI edema, elevated metabolic rate, and elevated levels of norepinephrine and proinflammatory cytokines. Absorption of fats is especially affected, leading to deficiencies of fat-soluble vitamins.

Dyspnea, or shortness of breath (SOB), can result from pulmonary congestion or systemic hypoperfusion due to LVF. Exertional dyspnea occurs when patients experience breathlessness induced by physical activity or a lower level of activity than previously. Patients often state that activities such as stair climbing, carrying groceries, or walking a particular distance cause SOB. In severe HF, dyspnea is present even at rest.

Orthopnea is dyspnea that is positional. Orthopnea is present if a patient is unable to breathe comfortably while lying flat (ie, in recumbent position). It manifests within minutes of a patient lying down and is relieved immediately when the patient sits upright. Patients can relieve orthopnea by elevating their head and shoulders with pillows. The practitioner should inquire as to the number of pillows needed to prevent dyspnea as a marker of worsening HF. PND occurs when patients awaken suddenly with a feeling of breathlessness and suffocation. PND is caused by increased venous return and mobilization of interstitial fluid from the extremities leading to alveolar edema, and usually occurs within 1 to 4 hours of sleep. In contrast to orthopnea, PND is not relieved immediately by sitting upright and often takes up to 30 minutes for symptoms to subside.

Pulmonary congestion may also cause a nonproductive cough that occurs at night or with exertion. Not all patients with LVF will exhibit signs of pulmonary congestion if lymphatic clearance is intact. In cases of pulmonary edema, the most severe form of pulmonary congestion, patients may produce pink frothy sputum and experience extreme breathlessness and anxiety due to feelings of suffocation and drowning. Severe pulmonary edema can progress to respiratory failure, necessitating mechanical ventilation.

Patient History

A thorough history is crucial to identify cardiac and noncardiac disorders or behaviors that may lead to or accelerate the development of HF. Past medical history, family history, and social history are important for identifying comorbid illnesses that are risk factors for development of HF or underlying etiological factors. A complete medication history (including prescription and nonprescription drugs, herbal therapy, and vitamin supplements) should be obtained each time a patient is seen to evaluate adherence, assess appropriateness of therapy, eliminate drugs that may be harmful in HF (Table 7–4), and determine additional monitoring requirements.[5] For newly diagnosed HF, previous exposure to radiation or chemotherapeutic agents as well as current or past use of alcohol and illicit drugs should be assessed. For patients with a known history of HF, questions related to symptomatology and exercise tolerance are essential for assessing any clinical status changes that may warrant further evaluation or adjustment of medications.

Heart Failure Classification

There are two common systems for categorizing patients with HF. The New York Heart Association (NYHA) Functional Classification (FC) system is based on the patient's activity and exercise tolerance. Patients in functional class I exhibit no symptoms or limitations of daily activities, while patients in functional class IV are symptomatic at rest (Table 7–5). The NYHA FC system reflects a subjective assessment by a healthcare provider and can

Table 7–4

Drugs That May Precipitate or Exacerbate Heart Failure

Negative Inotropic Effect
- Antiarrhythmics (eg, disopyramide, dronedarone, flecainide, propafenone, sotalol)
- β-Blockers (eg, propranolol, metoprolol, carvedilol)
- Calcium channel blockers (eg, verapamil, diltiazem)
- Itraconazole

Cardiotoxic
- Doxorubicin, daunorubicin, epirubicin, idarubicin
- Daunomycin
- Cyclophosphamide
- Pertuzumab
- Trastuzumab
- Bevacizumab
- Mitoxantrone
- Ifosfamide
- Mitomycin
- Lapatinib
- Sunitinib
- Sorafenib
- Imatinib
- Carbamazepine
- Ethanol
- Amphetamines (eg, cocaine, methamphetamine)

Sodium and Water Retention
- NSAIDs
- COX-2 inhibitors
- Rosiglitazone and pioglitazone
- Glucocorticoids
- Androgens and estrogens
- Salicylates (high dose)
- Sodium-containing drugs (eg, carbenicillin disodium, ticarcillin disodium)

Uncertain Mechanism
- TNF-α (adalimumab, infliximab, etanercept)
- Dipeptidyl peptidase-4 (DPP-4) inhibitors (eg, saxagliptin)

COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug; TNF, tumor necrosis factor.

Patient Encounter Part 1

A 65-year-old man with a history of hypertension, dyslipidemia, and coronary artery disease presents for follow-up. The patient noticed increasing shortness of breath when doing daily chores and quite a bit of swelling in his legs by midday. He complains of waking up at night intermittently because of difficulty breathing that takes a while to improve after sitting up. He has also needed to sleep on several pillows to get adequate rest. He used to be able to walk a few blocks and three flights of stairs comfortably before getting breathless, but now has to rest going up one flight of stairs. Additionally, his belly feels swollen and tight. He has been eating more take-out fast food lately because he always feels tired.

What information is suggestive of a diagnosis of HF?

What are potential etiologies or contributing factors for HF in this patient?

What additional information should be gathered during the interview of this patient that may relate to the development of HF symptoms?

Table 7–5

New York Heart Association (NYHA) Functional Classification and American College of Cardiology/American Heart Association (ACC/AHA) Staging

NYHA Functional Class	ACC/AHA Stage	Description
N/A	A	Patients at high risk for heart failure but without structural heart disease or symptoms of heart failure.
I	B, C	Patients with structural heart disease but without limitations of physical activity or symptoms of heart failure. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
II	C	Patients with structural heart disease that results in slight limitations of physical activity or symptoms of heart failure. Ordinary physical activity results in fatigue, palpitations, dyspnea, or angina.
III	C	Patients with structural heart disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.
IV	C, D	Patients with structural heart disease that results in an inability to carry on physical activity without discomfort. Symptoms of heart failure are present at rest. Stage D refers to end-stage heart failure patients.

change frequently (improve or worsen) over short periods of time. In general, anticipated survival declines in conjunction with a decline in functional ability.

The American College of Cardiology/American Heart Association (ACC/AHA) developed a staging system based on the development and progression of the HF syndrome. Patients are placed into stages A through D (Table 7–5).[1] The staging system proposes management strategies for each stage including risk factor modification to guide best practices for preventing further progression. The staging system complements the NYHA FC system; however, patients can move between NYHA functional classes as symptoms improve with treatment, whereas HF staging does not reverse (eg, stage C patients will never revert to stage B, even after treatment). Functional classification and staging allow for longitudinal assessment of a patient's risk and prognosis, disease progression, and requirements for and response to nonpharmacologic and pharmacologic therapies.

TREATMENT OF CHRONIC HEART FAILURE

Desired Therapeutic Outcomes

There is no cure for HF. **KEY CONCEPT** The general therapeutic management goals for chronic HF include preventing the onset of clinical symptoms or reducing symptoms, preventing or reducing hospitalizations, slowing progression of the disease, improving quality of life, and prolonging survival. The ACC/AHA staging system provides a guide for application of these goals based on clinical progression for a given patient. Goals are additive as one moves from stage A to stage D.[1] For stage A, risk factor management is the primary goal to reduce onset of structural heart disease. Stage B emphasizes pharmacologic therapies to reduce further myocardial damage and slow progression to the onset of clinical symptoms. Stage C involves additional therapies that control symptoms and decrease morbidity and mortality. Finally, in stage D, the focus shifts toward palliative care and other quality-of-life–related issues. Only with aggressive management throughout all the stages can the odds of survival be improved. Attainment of these goals is based on designing a therapeutic plan that encompasses strategies to treat contributing disorders (ie, comorbidities), nonpharmacologic interventions, and optimization of GDMT.[8]

Control and Treatment of Contributing Disorders

All patients presenting with HF must be assessed to determine the etiology of cardiac dysfunction. The most common etiology of HF in the United States is ischemic heart disease. An ischemic workup that includes echocardiography, stress testing with imaging, and/or coronary angiography is warranted in all patients presenting with reduced LVEF regardless of the presence of traditional CAD risk factors or CAD history. Revascularization of patients with obstructive CAD and reversible ischemic defects may help restore some cardiac function and improve survival. Aggressive control of hypertension (goal BP of < 130/80 mm Hg), diabetes, obesity, and sleep-disordered breathing (eg, obstructive sleep apnea) is also essential because each of these conditions can contribute to further cardiac damage. Surgical repair of valvular disease or congenital malformations may be warranted if detected. Clinical HF partly depends on metabolic processes, so correction of imbalances such as thyroid disease, anemia, and nutritional deficiencies is important. Identifying and discontinuing medications that can exacerbate HF is also mandated.

Nonpharmacologic Interventions

It is imperative that patients recognize the role of self-management in HF. **KEY CONCEPT** Nonpharmacologic treatment involves dietary modifications such as sodium and fluid restriction, as well as risk factor reduction, including smoking cessation, timely immunizations, and supervised regular physical activity. These interventions help slow disease progression and prevent AHF exacerbations.

Patients should be educated and encouraged to become involved in their own care, including self-monitoring. Fluid status should be monitored daily by assessing weight, peripheral edema, and exercise tolerance. Daily weights should be performed first thing in the morning upon arising and before any food intake to maintain consistency, recorded in a journal, and brought to each scheduled provider appointment. Changes in weight can indicate fluid retention prior to onset of peripheral or pulmonary congestive symptoms. Individuals who have an increase of 3 lb (1.4 kg) in a single day or 5 lb (2.3 kg) over a week should alert their HF provider. Some patients may be educated about self-adjusting diuretic doses based on daily weights. In addition to weight changes, a marked decline in exercise tolerance should also be reported to the HF provider.

Nonadherence is a leading cause for AHF exacerbations. Ensuring an understanding of the importance of each medication, proper administration, and potential adverse effects may improve adherence. Stressing the rationale for each medication is especially important for NYHA FC I or ACC/AHA stage B patients who are asymptomatic yet started on medications. A clinician's involvement in medication adherence and intensive follow-up care has been shown to reduce HF hospitalizations.

Dietary modifications in HF consist of initiation of an AHA step II diet as part of cardiac risk factor reduction, sodium restriction, and sometimes fluid restriction. Because sodium and water retention is a compensatory mechanism that contributes to volume overload in HF, restriction is often necessary to help minimize congestion. The normal American diet includes 3 to 6 g of sodium per day. Most patients with stage C or D HF should limit salt intake to a maximum of 3 g/day. Patients should minimize cooking with salt and limit intake of foods with high salt content, such as fried or processed food (lunch meats, soups, cheeses, salted snack foods, and canned food). Sodium restriction can be challenging, and drastic dietary changes may lead to nonadherence. Sodium restriction may be more effective if implemented slowly over time. Salt substitutes should be used judiciously because many contain significant amounts of potassium that may increase the risk of hyperkalemia. Fluid restriction may not be necessary in many patients. When applicable, fluid intake is generally limited from all sources to less than 2 L/day. A referral to a registered dietician may also be warranted.

Exercise is recommended in patients with compensated HF. Exercise improves peripheral muscle conditioning and efficiency in the setting of low CO, which contributes to better exercise tolerance. Regular low-intensity, aerobic exercise (eg, light house/yard work, walking, swimming, or riding a bike) is encouraged; heavy weight training is discouraged. The prescribed exercise regimen should be tailored to individual functional ability, and thus it is recommended patients initially participate in cardiac rehabilitation programs. It is important that patients do not overexert themselves to fatigue or exertional dyspnea.

Modification of classic risk factors, such as tobacco and alcohol consumption, is important to prevent further cardiac damage. All patients with HF who smoke should be counseled on tobacco

Patient Encounter Part 2

Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension × 20 years, dyslipidemia × 20 years, coronary artery disease (myocardial infarction 10 years ago), glucose intolerance, depression (untreated)

Allergies: No known drug allergies

Meds: Aspirin 81 mg once daily, atenolol 25 mg once daily, hydrochlorothiazide 25 mg once daily, simvastatin 20 mg once daily at bedtime, coenzyme Q10 100 mg twice daily, naproxen 250 mg twice daily as needed for pain

FH: Father had MI at 55 years of age

SH: He is married, has one child, and runs his own business; quit smoking 10 years ago, but drinks three beers daily

PE:

BP 146/88 mm Hg, pulse 89 beats/min and regular, respiratory rate 16 breaths/min, Ht 5 ft 8 in (173 cm), Wt 251 lb (114 kg), body mass index (BMI): 38.1 kg/m^2

Lungs: Bibasilar rales, decreased breath sounds at the bases, no wheezes

CV: JVP 15 cm above sternal angle. Regular rate and rhythm with normal S_1 and S_2; there is an S_3 and a soft S_4 present; there is a 2/6 systolic ejection murmur heard best toward the apex of the heart; point of maximal impulse displaced laterally

Abd: Tense and distended, and bowel sounds are present, (+) hepatomegaly

Ext: 2+ pitting edema extending to below the knees is observed

Chest x-ray: Cardiomegaly, pulmonary congestion

Echocardiogram: EF = 35% (0.35)

Laboratory Values:

Hct: 41.1% (0.411)

WBC: $7.3 \times 10^3/\mu L$ ($7.3 \times 10^9/L$)

Sodium: 137 mEq/L (mmol/L)

Potassium: 3.6 mEq/L (mmol/L)

Bicarbonate: 22 mEq/L (mmol/L)

Chloride: 98 mEq/L (mmol/L)

Magnesium: 1.5 mEq/L (0.75 mmol/L)

Fasting blood glucose: 120 mg/dL (6.7 mmol/L)

Uric acid: 6 mg/dL (357 μmol/L)

BUN: 40 mg/dL (14.3 mmol/L)

SCr: 1.6 mg/dL (141 μmol/L)

Alk Phos: 120 IU/L (2.0 μkat/L)

Aspartate aminotransferase: 100 IU/L (1.67 μkat/L)

Total bilirubin: 0.6 mg/dL (10.3 μmol/L)

What other laboratory or diagnostic tests are required for assessment of the patient's condition?

How would you classify his NYHA FC and ACC/AHA HF stage?

Classify the clinical presentation of the patient in terms of HF signs and symptoms.

What are your treatment goals for the patient?

cessation and offered a referral to a cessation program. Patients with alcoholic cardiomyopathy should abstain from alcohol. Whether patients with other etiologies of HF should abstain from any alcohol intake remains controversial. Proponents of moderation of alcohol base their rationale on the potential cardioprotective effects. However, opponents to any alcohol intake point out that alcohol is potentially cardiotoxic.

In general, it is suggested patients remain up-to-date on standard immunizations, including vaccinations for influenza and pneumococcal infections.

Pharmacologic Treatment

The ACC/AHA staging system delineates specific pharmacotherapy options based on disease progression.[1] For patients in stage A (risk factors for structural heart disease), every effort is made to minimize the impact of diseases that can damage the heart. Antihypertensive and lipid-lowering therapies should be utilized when appropriate to decrease the risk for stroke, MI, and HF. ACE inhibitors or angiotensin receptor blockers (ARBs) should be considered in patients at high risk for vascular disease. For patients in stage B (structural heart disease but asymptomatic), therapy targets preventing or slowing disease progression by interfering with neurohormonal pathways that lead to cardiac damage and mediate pathological remodeling. The goal is to prevent or delay the onset of HF symptoms. Therapies include ACE inhibitors or ARBs and β-adrenergic blockers (β-blockers). For patients in stage C (symptomatic LV systolic dysfunction, EF ≤ 40% [0.40]), goals focus on alleviating congestion, improving functional ability, slowing disease progression, and reducing risk for hospitalizations and death. Treatment entails a strategy that combines diuretics to control intravascular fluid balance with neurohormonal antagonists (including ACE inhibitors or ARBs or angiotensin receptor neprilysin inhibitor [ARNI], β-blockers, and aldosterone receptor antagonists) to minimize the detrimental effects of the RAAS and SNS. In patients of African American descent or patients with an intolerance to ACE inhibitor/ARB, combination hydralazine and isosorbide dinitrate is a reasonable alternative regimen. Both digoxin and ivabradine may be added to improve symptoms in patients receiving GDMT. Dosing and monitoring of pharmacologic agents for HF are described in Tables 7–6 and 7–7. Patients with stage D HF are offered more modest goals, such as improvement in quality of life. Enhancing quality of life is often achieved at the expense of expected survival. Treatment options include mechanical support, transplantation, and continuous use of intravenous (IV) vasoactive therapies, in addition to maintaining an optimal regimen of chronic oral medications as possible.

▸ *Diuretics*

Diuretics have been the mainstay for HF symptom management for many years. KEY CONCEPT Diuretics are used for relief of acute symptoms of congestion and maintenance of euvolemia. These agents increase urinary sodium and free water excretion. The primary role for diuretic therapy is maintenance of euvolemia in symptomatic or stages C and D HF. Diuretics are recommended for all patients with clinical evidence of fluid overload.

Table 7–6

Drug Dosing in the Pharmacologic Treatment of Heart Failure

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Loop Diuretics					
Furosemide	Lasix	20–40 mg once or twice daily	20–160 mg once or twice daily	CrCl 20–50 mL/min (0.33–0.83 mL/s): 160 mg once or twice daily CrCl < 20 mL/min (0.33 mL/s): 400 mg daily	Single doses exceeding those listed are unlikely to elicit additional response
Bumetanide	Bumex	0.5–1.0 mg once or twice daily	1–2 mg once or twice daily	CrCl 20–50 mL/min (0.33–0.83 mL/s): 2 mg once or twice daily CrCl < 20 mL/min (0.33 mL/s): 8–10 mg daily	Single doses exceeding those listed are unlikely to elicit additional response
Torsemide	Demadex	10–20 mg once daily	10–80 mg once daily	CrCl 20–50 mL/min (0.33–0.83 mL/s): 40 mg once daily CrCl < 20 mL/min (0.33 mL/s): 200 mg daily	Single doses exceeding those listed are unlikely to elicit additional response
ACE Inhibitors					
Captopril	Capoten	6.25 mg three times daily	50 mg three times daily[a]		
Enalapril	Vasotec	2.5 mg twice daily	10–20 mg twice daily[a]		
Lisinopril	Zestril, Prinivil	2.5–5.0 mg once daily	20–40 mg once daily[a]		
Quinapril	Accupril	5 mg twice daily	20–40 mg twice daily		
Ramipril	Altace	1.25–2.5 mg once daily	10 mg once daily[a]		
Fosinopril	Monopril	5–10 mg once daily	40 mg once daily		Undergoes both hepatic and renal elimination
Trandolapril	Mavik	1.0 mg once daily	4 mg once daily[a]		Undergoes both hepatic and renal elimination
Perindopril	Aceon	2 mg once daily	8–16 mg once daily		Undergoes both hepatic and renal elimination
Angiotensin Receptor Blockers					
Candesartan	Atacand	4–8 mg once daily	32 mg once daily[a]		
Valsartan	Diovan	20–40 mg twice daily	160 mg twice daily[a]		
Losartan	Cozaar	25–50 mg once daily	150 mg once daily[a]		
Angiotensin Receptor Neprilysin Inhibitor (ARNI)					
Sacubitril/valsartan	Entresto	49/51 mg sacubitril/valsartan twice daily	97/103 mg sacubitril/valsartan twice daily[a]	For patients taking a low dose of or not taking an ACE inhibitor or ARB or if eGFR is < 30 mL/min/1.73 m^2, the starting dose is 24/26 mg sacubitril/valsartan twice daily	Discontinue ACE inhibitors at least 36 hours before initiating sacubitril/valsartan treatment; allow 36 hours between discontinuing ARNI and starting ACE inhibitor
β-Blockers					
Bisoprolol	Zebeta	1.25 mg once daily	10 mg once daily[a]		
Carvedilol	Coreg	3.125 mg twice daily	25 mg twice daily[a]	Target dose for patients weighing > 85 kg (187 lb) is 50 mg twice daily	Take with food
Carvedilol phosphate	Coreg CR	10 mg once daily	80 mg once daily[a]		Take with food
Metoprolol succinate CR/XL	Toprol-XL	12.5–25 mg once daily	200 mg once daily[a]		
Aldosterone Receptor Antagonists					
Spironolactone	Aldactone	eGFR > 50 mL/min/1.73 m^2: 12.5–25 mg once daily	25–50 mg once daily[a]	eGFR 30–49 mL/min/1.73 m^2: 12.5 mg once daily or every other day	Risk of hyperkalemia increases if serum creatinine is > 1.6 mg/dL (141 μmol/L). Avoid if baseline potassium is > 5 mEq/L (mmol/L)

(Continued)

Table 7–6

Drug Dosing in the Pharmacologic Treatment of Heart Failure (*Continued*)

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Eplerenone	Inspra	eGFR > 50 mL/min/1.73 m^2: 25 mg once daily	50 mg once daily[a]	eGFR 30–49 mL/min/1.73 m^2: 25 mg every other day	Risk of hyperkalemia increases if serum creatinine is > 1.6 mg/dL (141 μmol/L). Avoid if baseline potassium is > 5 mEq/L (mmol/L)
Other					
Hydralazine-isosorbide dinitrate	Bidil	Hydralazine 37.5 mg three times daily; isosorbide dinitrate 20 mg three times daily	Hydralazine 75 mg three times daily[a]; isosorbide dinitrate 40 mg three times daily[a]		Indicated in conjunction with standard heart failure therapy to improve survival and reduce hospitalizations in self-identified African American patients
Digoxin	Lanoxin	0.125–0.25 mg once daily	0.125–0.25 mg once daily	Reduce dose in elderly patients with low lean body mass and patients with impaired renal function	Target plasma concentration range is 0.5–0.9 ng/mL (mcg/L; 0.6–1.2 nmol/L). Not shown to improve survival in patients with HFrEF
Ivabradine	Corlanor	5 mg twice daily	5–7.5 mg twice daily	Avoid if resting heart rate < 60 BPM before treatment	Indicated to reduce the risk of hospitalization in patients with HFrEF, in normal sinus rhythm, with a resting heart rate > 70 BPM receiving maximally tolerated β-blocker doses. Take with meals

[a] Regimens proven in large clinical trials to reduce mortality.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BPM, beats per minute; CrCl, creatinine clearance; eGFR, estimated glomerular filtration rate; HFrEF, heart failure with reduced ejection fraction.

Diuretics may be used on an as-needed basis in patients with mild congestion; however, scheduled doses will be required once edema is persistent.

Diuretics used for volume management in HF are thiazide and loop diuretics. Thiazide diuretics such as hydrochlorothiazide, chlorthalidone, and metolazone (thiazide-like diuretic) block sodium and chloride reabsorption in the distal convoluted tubule. Thiazides are weaker than loop diuretics for increasing urine output and therefore are not utilized frequently as monotherapy. Thiazides are optimally suited for patients with hypertension who have mild congestion. Additionally, the efficacy of thiazides is limited in patients with renal insufficiency (creatinine clearance [CrCl] < 30 mL/min [0.50 mL/s]) due to reduced tubular secretion. An exception is metolazone, which retains its action in renal insufficiency and is often used in combination with loop diuretics when patients exhibit diuretic resistance (edema unresponsive to escalating doses of loop diuretics alone).

Loop diuretics are the most widely used diuretics in HF. Loop diuretics, including furosemide, bumetanide, torsemide, and ethacrynic acid, block the $Na^+/K^+/2Cl^-$ cotransporter in the thick ascending loop of Henle. Loop diuretics are not filtered through the glomerulus but, instead, undergo active transport into the tubular lumen via the organic acid pathway. As a result, drugs that compete for this active transport (eg, probenecid and organic by-products of uremia) can lower the efficacy of loop diuretics. Loop diuretics increase sodium and water excretion and induce a prostaglandin-mediated increase in renal blood flow that contributes to natriuresis. Unlike thiazides, they retain their diuretic effect in the setting of reduced renal function. The various loop diuretics are equally effective when used at equipotent doses, although there are intrinsic differences in pharmacokinetics and pharmacodynamics (Table 7–6).[5] The choice of loop diuretic and route of administration depends on clinical factors such as the presence of intestinal edema and desired rapidity of effect. Oral efficacy may vary based on differing bioavailability, which is almost complete for bumetanide and torsemide but is approximately 50% for furosemide. Oral torsemide is a reasonable alternative to IV administration for patients who do not respond to oral furosemide. Onset of effect is slightly delayed with oral administration but occurs within minutes with IV administration. Consequently, bioequivalent doses of IV furosemide are half the oral dose, whereas bumetanide and torsemide IV doses are generally equivalent to the oral doses (note: torsemide IV is currently not available in the United States).

Table 7–7

Drug Monitoring

Drug Class	Adverse Effect	Monitoring Parameters	Comments
ACE inhibitors	Angioedema, cough, hyperkalemia, hypotension, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with bilateral renal artery stenosis, history of angioedema, or pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1–2 weeks after initiation or increase in dose. Goal is target dose from clinical trials or highest tolerated.
Angiotensin receptor blockers (ARBs)	Hyperkalemia, hypotension, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with bilateral renal artery stenosis or pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1–2 weeks after initiation or increase in dose. Use with caution in patients with a history of ACE inhibitor-associated angioedema. Goal is target dose from clinical trials or highest tolerated.
Sacubitril/valsartan	Angioedema, hyperkalemia, hypotension, dizziness, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with a history of angioedema associated with ACE inhibitor or ARB therapy or in pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1–2 weeks after initiation or increase in dose. Start with a low dose and double the dose every 2–4 weeks as tolerated based on BP, serum potassium, and renal function. Goal is target dose from clinical trials or highest tolerated.
Aldosterone receptor antagonists	Gynecomastia/breast tenderness/menstrual irregularities (spironolactone), hyperkalemia, worsening renal function	BP, electrolytes, BUN, and creatinine	Assess BP, BUN, creatinine, and electrolytes at baseline. Check potassium 3 days and 1 week after initiation and then monthly for the first 3 months, then every 3 months. Change to eplerenone if gynecomastia develops with spironolactone.
β-Blockers	Bradycardia, heart block, bronchospasm, hypotension, worsening HF	BP, HR, ECG, signs and symptoms of worsening HF, blood glucose	Start with low dose and titrate upward no more often than every 2 weeks as tolerated based on BP, HR, and symptoms. Goal is target dose from clinical trials or highest tolerated. Patients may feel worse before they feel better.
Digoxin	GI and CNS adverse effects, brady- and tachyarrhythmias	Electrolytes, BUN, creatinine, HR, ECG, serum digoxin concentration	Target serum digoxin concentration 0.5–0.9 ng/mL (mcg/L; 0.6–1.2 nmol/L).
Ivabradine	Bradycardia, hypertension, atrial fibrillation, luminous phenomena (phosphenes, transiently enhanced brightness in a portion of the visual field)	BP, HR, ECG	Start with 5 mg twice daily and after 2 weeks adjust dose to achieve a resting HR 50–60 BPM. Only use in patients in sinus rhythm.
Diuretics	Hypovolemia, hypotension, hyponatremia, hypokalemia, hypomagnesemia, hyperuricemia, renal dysfunction, thirst	BP, electrolytes, BUN, creatinine, glucose, uric acid, changes in weight, JVD	Dose should be adjusted based on volume status, renal function, electrolytes, and BP. Reassess these parameters 1–2 weeks after dose changes. Goal is lowest dose that maintains euvolemia.
Hydralazine	Hypotension, headache, rash, arthralgia, lupus, tachycardia	BP, HR	
Nitrates	Hypotension, headache, light-headedness	BP, HR	

ACE, angiotensin-converting enzyme; BP, blood pressure; BPM, beats per minute; BUN, blood urea nitrogen; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; HF, heart failure; HR, heart rate; JVD, jugular venous distention.

The lowest effective dose of diuretic should be used since they are used to improve symptoms and morbidity, not mortality. Once diuretic therapy is initiated, dosage adjustments are based on symptomatic improvement, net fluid balance, and daily body weight. Because body weight changes are a sensitive marker of fluid retention or loss, patients should weigh themselves daily. Once euvolemia ("dry weight") is achieved, diuretics may be tapered to a maintenance regimen. Select patients with mild volume retention may not require a scheduled diuretic. In stable, educated, and adherent patients, another option is self-adjusted diuretic dosing. Based on daily body weight, patients may temporarily increase their diuretic regimen to reduce the incidence of overt edema. Self-adjustment also avoids overuse of diuretics and possible complications of overdiuresis such as hypotension, fatigue, electrolyte imbalances, and renal impairment.

The maximal response to diuretics is reduced in chronic HF, creating a "ceiling dose" above which there is limited added benefit. This diuretic resistance is due to a compensatory increase in sodium reabsorption in the distal tubules, which decreases the effect of blocking sodium reabsorption in the loop of Henle. In addition, there is a simultaneous increase in the reabsorption of sodium from the proximal tubule, allowing less to reach the site of action for loop diuretics. Apart from increasing diuretic doses, strategies to improve diuretic efficacy include increasing the frequency of dosing to two or three times daily, and/or combining a loop diuretic with a thiazide diuretic. The latter strategy theoretically prevents sodium and water reabsorption at both the loop of Henle and the compensating distal convoluted tubule. Metolazone is used most often for this purpose because it retains its activity in settings of renal impairment. Metolazone can be dosed daily or as little as once weekly due to its long half-life. Clinicians must use metolazone cautiously because its potent activity predisposes to metabolic abnormalities as outlined next.

Diuretics cause numerous adverse effects and metabolic abnormalities, with severity linked to diuretic potency (Table 7–7). A particularly worrisome adverse effect is hypokalemia, which can predispose patients to arrhythmias and sudden death. Hypomagnesemia often occurs concomitantly with diuretic-induced hypokalemia, and therefore both should be assessed and replaced in patients needing correction of hypokalemia. Magnesium is an essential cofactor for movement of potassium intracellularly to restore body stores. Patients taking diuretics are also at risk for renal insufficiency due to overdiuresis and reflex activation of the renin-angiotensin system. The potential reduction in renal blood flow and glomerular pressure is amplified by concomitant use of ACE inhibitors or ARBs.

▶ *Neurohormonal Blocking Agents*

KEY CONCEPT Agents with proven benefits in improving symptoms, slowing disease progression, and improving survival in chronic HF target neurohormonal activation. These include ACE inhibitors, ARBs, ARNIs, β-blockers, and aldosterone receptor antagonists (Tables 7–6 and 7–7). The combination of hydralazine and isosorbide dinitrate is also discussed in this section based on their potential place in therapy although the proposed mechanisms of benefit do not directly target neurohormonal activation.

Angiotensin-Converting Enzyme Inhibitors ACE inhibitors are the cornerstone of treatment for HF. ACE inhibitors target RAAS activation by blocking the conversion of angiotensin I to angiotensin II. Simultaneously, ACE inhibition also prevents the breakdown of bradykinin, which enhances the release of vasodilatory prostaglandins and histamines. This results in arterial and venous dilation, reduction in preload and afterload, and a decrease in myocardial work. ACE inhibitors demonstrate favorable effects on cardiac hemodynamics such as improvement in **cardiac index** (CI), SV index, SVR, and mean arterial pressure.

There is extensive clinical experience with ACE inhibitors in HFrEF. Numerous studies show ACE inhibitor therapy is associated with improvements in clinical symptoms, exercise tolerance, NYHA FC, LV size and function, and quality of life as compared with placebo.[9-11] ACE inhibitors slow the development or progression of HF regardless of underlying disease severity or etiology. ACE inhibitors prevent HF development in high-risk patients (stage A). Studies in acute MI patients show a reduction in new-onset HF and death with ACE inhibitors whether they are initiated early (within 36 hours) or started later. ACE inhibitors decrease the risk of HF hospitalization and mortality through the entire HFrEF spectrum from asymptomatic LV dysfunction (stage B) to symptomatic HF (stages C and D). Mechanisms for improved prognosis are postulated to involve both the hemodynamic improvement and the inhibition of angiotensin II's growth promoting and remodeling effects. Therefore, all patients at risk for or with documented LV systolic dysfunction, regardless of existing HF symptoms (stages A to D), should receive an ACE inhibitor unless a contraindication or intolerance is present.

The benefit of ACE inhibitors is considered a class effect (no evidence that one ACE inhibitor is preferred over another). ACE inhibitors should be initiated using low doses and titrated up to target doses over several weeks depending on tolerability. The 2013 ACC/AHA HF guidelines advocate using doses that were proven to decrease mortality in clinical trials as the target doses (Table 7–6).[1] If the target dose cannot be attained, the highest tolerated dose should be used. Although there is incremental benefit with higher doses of ACE inhibitors, lower doses still provide much of the benefit.[12] Because ACE inhibitors are only one component of GDMT for HFrEF, targeting a high ACE inhibitor dose should not preclude starting a β-blocker or aldosterone receptor antagonist on the grounds of limited blood pressure.

Absolute contraindications to ACE inhibitors include a history of angioedema, bilateral renal artery stenosis, and pregnancy (Table 7–7). Relative contraindications include unilateral renal artery stenosis, renal insufficiency, hypotension, hyperkalemia, and cough. Relative contraindications should not preclude the use of ACE inhibitors in most patients considering their substantial benefit.

Renal insufficiency remains a concern. Note that ACE inhibitors can potentially contribute to both the preservation or decline of renal function depending on the clinical scenario. Through preferential efferent arteriole vasodilation, ACE inhibitors reduce intraglomerular pressure. Reduced glomerular pressures are renoprotective chronically; however, in situations of diminished or fixed renal blood flow this can lead to decreased filtration. In general, ACE inhibitors can be used in patients with serum creatinine less than 2.5 to 3.0 mg/dL (221–265 μmol/L). In HF, ACE inhibition can improve renal function through an increase in CO and renal perfusion. Although a small increase in serum creatinine (< 0.5 mg/dL [44 μmol/L]) is possible with the addition of an ACE inhibitor, it is usually transient or becomes the patient's new serum creatinine baseline level. However, ACE inhibition can cause acute worsening of renal function in the setting of reduced CO as glomerular filtration is maintained through angiotensin II's constriction of the efferent arteriole. Patients most dependent on angiotensin II for maintenance of glomerular filtration pressure, and hence most susceptible to ACE inhibitor worsening of renal function, include those with hyponatremia, severely depressed LV function, or dehydration. The most common reason for creatinine elevation in a patient without a history of renal dysfunction is overdiuresis. Therefore, consider decreasing or holding diuretic doses if an elevation in serum creatinine occurs concomitantly with a rise in blood urea nitrogen (BUN) or other evidence of hemoconcentration is present.

Hypotension occurs most commonly with initiation of therapy or with dosage escalation. Risk of hypotension is increased in the setting of volume depletion such as when ACE inhibitors are initiated or used concomitantly with high doses of diuretics. Therefore, in euvolemic patients, diuretic doses may often be decreased or withheld during ACE inhibitor dose titration. Initiating at a low dose and titrating slowly can also minimize hypotension. In patients at risk for hypotension, it may be advisable to initiate a short-acting ACE inhibitor, such as captopril, and subsequently switch to a longer-acting agent, such as lisinopril or enalapril, once the maximally tolerated dose is established.

Hyperkalemia results from reduced angiotensin II–stimulated aldosterone release. Risk of hyperkalemia with ACE inhibitors is also increased in HF due to a propensity for impaired renal function and additive effects with aldosterone receptor antagonists. ACE inhibitor doses may be reduced or withheld if serum potassium increases above 5 mEq/L (mmol/L). Persistent hyperkalemia in the setting of renal insufficiency may preclude use of an ACE inhibitor or consideration for the addition of a potassium-binder (eg, patiromer, sodium zirconium cyclosilicate) approved for chronic use. Assessment of potential causes of hyperkalemia should include dietary intake as well as potassium-containing salt substitutes.

Cough is commonly seen with ACE inhibitors (5%–15%) and may be related to accumulation of tissue bradykinins.[5] It can be challenging to distinguish a cough from ACE inhibition from pulmonary congestion. A productive or wet cough usually signifies congestion, whereas a dry, hacking cough is more indicative of a drug-related etiology. If a cough is determined to be ACE inhibitor–induced, its severity should be evaluated before deciding on a course of action. If the cough is truly bothersome, switching to an ARB is warranted.

Angiotensin Receptor Blockers ARBs selectively antagonize the effects of angiotensin II directly at the angiotensin type 1 (AT_1) receptor. AT_1 receptor stimulation is associated with vasoconstriction, release of aldosterone, and ventricular remodeling effects. The angiotensin type 2 (AT_2) receptor mediates vasodilation and inhibition of ventricular remodeling. Therefore, selective blockade at the AT_1 receptor blocks the detrimental effects of angiotensin II while sparing the compensatory actions at the AT_2 receptor. ARBs are considered an equally effective replacement for ACE inhibitors in patients who are intolerant or have a contraindication to an ACE inhibitor.

Clinical evidence suggests the efficacy of ARBs is similar to ACE inhibitors for reduction of hospitalizations for HF, sudden cardiac death, and all-cause mortality.[13-15] ARBs produce more complete inhibition of angiotensin II's detrimental effects than ACE inhibitors; however, ACE inhibitors also exert additional effects on the kallikrein-kinin system. Although ARBs produce clinical benefits equivalent to ACE inhibitors, they are considered second-line therapy due to the overwhelming clinical trial experience with ACE inhibitors.

Because the mechanism for long-term benefit appears different for ACE inhibitors and ARBs, their combination was studied for additive effect. The combination of an ACE inhibitor and ARB may reduce risk of HF hospitalizations but not mortality over ACE inhibition alone. However, since other therapies provide additional mortality advantages (eg, addition of mineralocorticoid receptor antagonists or switching to valsartan/sacubitril), the combination of ACE inhibitor and ARB has fallen out of favor and is not widely applied.[1]

ARBs show similar tolerability to ACE inhibitors with regard to hypotension and hyperkalemia but are less associated with cough because ARBs do not induce accumulation of bradykinin. ARBs can be considered in patients with ACE inhibitor–induced angioedema but should be initiated cautiously as cross-reactivity has been reported. Other considerations for use of ARBs are similar to those of ACE inhibitors, including the need for monitoring renal function, BP, and potassium. Contraindications are similar to ACE inhibitors (Table 7–7). In patients intolerant or contraindicated to ACE inhibitors or ARBs, the combination of hydralazine and isosorbide dinitrate should be considered.

Sacubitril/Valsartan Sacubitril/valsartan (formerly known as the compound, LCZ696) is a first in class ARNI.[16] Neprilysin is a neutral endopeptidase responsible for the breakdown of natriuretic peptides, in addition to substance P, adrenomedullin, bradykinin, and angiotensin II. Blockade of neprilysin increases circulating natriuretic peptide levels. Because neprilysin inhibition alone would also result in elevated levels of angiotensin II, combination of a neprilysin inhibitor with an ARB prevents this potentially deleterious effect. Sacubitril/valsartan is a crystalline complex composed of equal parts of the neprilysin inhibitor sacubitril and the ARB valsartan. Shortly after ingestion, sacubitril/valsartan breaks apart into sacubitril, a prodrug which is then cleaved to the active form of sacubitril and valsartan. The target dose is 97/103 mg twice daily, which was found to reduce the composite end point of cardiovascular death or hospitalization for HF by 20% compared to enalapril 10 mg twice daily in patients with symptomatic HF and reduced LVEF.[17] As such, the 2017 ACC/AHA/Heart Failure Society of America Focused Update of the 2013 American College of Cardiology Foundation/AHA Guideline for the Management of Heart Failure recommends that in patients with symptomatic HFrEF who are tolerating an ACE inhibitor or an ARB, replacement with sacubitril/valsartan is warranted to further reduce morbidity and mortality.[18] Compared to enalapril, patients taking sacubitril/valsartan experienced more symptomatic hypotension, necessitating caution with initiating or switching to this medication in patients with lower BP. Sacubitril/valsartan is contraindicated for use with an ACE inhibitor due to an increased risk for angioedema (Table 7–7), and a 36-hour washout period is necessary when switching to sacubitril/valsartan from an ACE inhibitor, or vice versa. The starting dose of sacubitril/valsartan is 49/51 mg twice daily, unless the patient has not previously been on an ACE inhibitor or ARB, or is taking a low dose of an ACE inhibitor, in which case the recommended initial dose is 24/26 mg twice daily (Table 7–6). Given the benefit observed in clinical trials, titration to a goal dose of 97/103 mg twice daily is recommended.

Hydralazine and Isosorbide Dinitrate Complementary hemodynamic actions originally led to the combination of nitrates and hydralazine. Nitrates reduce preload by causing primarily venous vasodilation through activating guanylate cyclase and a subsequent increase in cGMP in vascular smooth muscle. Hydralazine reduces afterload through direct arterial smooth muscle relaxation via an unknown mechanism. More recently, nitric oxide has been implicated in modulating numerous pathophysiological processes in the failing heart including inflammation, cardiac remodeling, and oxidative damage. Supplementation of nitric oxide via administration of nitrates has also been proposed as a mechanism for benefit from this combination. The beneficial effect of an exogenous nitric oxide source may be more apparent in the African American population, which appears to be predisposed to having an imbalance in nitric oxide production. In addition, hydralazine may reduce the development of nitrate tolerance when nitrates are given chronically.

The combination of hydralazine and isosorbide dinitrate was the first therapy shown to improve long-term survival in patients with HFrEF but was inferior with respect to mortality reduction when compared to the ACE inhibitor enalapril.[19,20] An additional niche for this combination was established in a prospective clinical trial in patients of African American descent.[21] **KEY CONCEPT** Combination therapy with hydralazine and isosorbide dinitrate is an appropriate substitute for angiotensin II antagonism in those unable to tolerate an ACE inhibitor or ARB (usually secondary to renal impairment, hyperkalemia, or angioedema) or as add-on therapy in African Americans. The 2013 ACC/AHA HF guidelines recommend considering the addition of hydralazine and isosorbide dinitrate in African Americans already on ACE inhibitors or ARBs.[1]

Combination therapy with hydralazine and isosorbide dinitrate should be initiated and titrated similarly to ACE inhibitors. Low doses are used to initiate therapy with subsequent titration toward target doses based on tolerability. Adverse effects such as hypotension and headache cause frequent discontinuations in patients taking this combination, and full doses often cannot be tolerated. Patients should be monitored for headache, hypotension, and tachycardia (Table 7–7). Hydralazine is also associated with a dose-dependent risk for lupus.

The frequent dosing of isosorbide dinitrate is not conducive to patient adherence; therefore, a once-daily isosorbide mononitrate is commonly substituted for isosorbide dinitrate to simplify the dosing regimen with the caveat that this form of oral nitrate has not been studied in a large outcome trial in HFrEF, and a clear target dose has not been established.

β-Adrenergic Antagonists β-Adrenergic antagonists, or β-blockers, competitively block the influence of the SNS at β-adrenergic receptors. β-blockers were previously thought to be detrimental in HFrEF due to their negative inotropic actions, potentially worsening symptoms. However, the benefits of inhibiting the SNS clearly outweigh the acute negative inotropic effects if used judiciously. Chronic β-blockade improves cardiac function through reverse modeling and has been shown to reduce ventricular mass, improve ventricular shape, and reduce LV end-systolic and diastolic volumes.[6] β-blockers also exhibit antiarrhythmic effects, decrease myocyte death from catecholamine-induced necrosis or apoptosis, and prevent myocardial fetal gene expression. Consequently, β-blockers improve LVEF, reduce all-cause and HF-related hospitalizations, and decrease all-cause mortality in patients with HFrEF (including sudden cardiac death and death due to progressive pump failure).[22-24]

The 2013 ACC/AHA HF guidelines recommend β-blockers be initiated in all HF patients with NYHA FC I to IV or ACC/AHA stages B through D if clinically stable.[1] Unlike with RAAS inhibition, the mortality reduction with β-blockers is not considered a drug class effect, and has only been demonstrated with the selective β_1-antagonists bisoprolol and metoprolol succinate and the nonselective β_1-, β_2-, and α_1-antagonist carvedilol.[22-24] Only metoprolol succinate and carvedilol have been approved by the Food and Drug Administration (FDA) to improve outcomes in patients with HFrEF. Other β-blockers either have not been studied or shown to reduce mortality for HFrEF. Nebivolol is approved for HFrEF in several countries outside of the United States.

Bisoprolol is not as commonly used since it does not carry an FDA-approved indication for HFrEF. Although metoprolol succinate and carvedilol are more commonly used, it is unknown whether one agent should be considered first line. Carvedilol was shown to lower all-cause mortality significantly more than metoprolol tartrate, but carvedilol has not yet been directly compared to metoprolol succinate.[25]

The key to utilizing β-blockers in HFrEF is initiation with low doses and slow titration to target doses over weeks to months. It is important the β-blocker be initiated when a patient is clinically stable and euvolemic. Volume overload at the time of β-blocker initiation increases the risk for worsening symptoms. β-Blockade should begin with the lowest possible dose (Table 7–6), after which the dose may be doubled every 2 to 4 weeks depending on patient tolerability. β-Blockers may cause an acute decrease in LVEF and short-term worsening of HF symptoms upon initiation and at each dosage titration. After each dose titration, if the patient experiences symptomatic hypotension, bradycardia, orthostasis, or worsening symptoms, further increases in dose should be withheld until the patient stabilizes. After stabilization, attempts to increase the dose should be reinstituted. If mild congestion ensues as a result of the β-blocker, an increase in diuretic dose may be warranted. If moderate or severe symptoms of congestion occur, a reduction in β-blocker dose should be considered. Dose titration should continue until target doses are achieved (Table 7–6) or until limited by repeated hemodynamic or symptomatic intolerance. Patient education regarding the possibility of acutely worsening symptoms but improved long-term function and survival is essential to ensure adherence.

Factors potentially affecting the selection of β-blockers for use in HFrEF include β-receptor selectivity, patient comorbidity, and pharmacokinetics. Carvedilol exhibits a more pronounced BP-lowering effect as a consequence of its α_1-receptor blocking activities and thus causes more frequent dizziness and hypotension. In patients predisposed to symptomatic hypotension, metoprolol succinate may be the more desirable whereas in patients with uncontrolled hypertension, carvedilol may be preferred. Patients with reactive airway disease may still use β-blockers; however, considerable caution should be made in those who display active respiratory symptoms. A selective β_1-blocker such as metoprolol succinate is a reasonable option for patients with reactive airway disease. The risk–benefit profile of using any β-blocker in peripheral vascular disease must be weighed based on the severity of the peripheral disease, and a selective β_1-blocker may be preferred. Both metoprolol and carvedilol are metabolized by the liver through cytochrome P-450 (CYP) 2D6 and undergo extensive first-pass metabolism. Therefore, β-blockers should be used cautiously in patients with severe hepatic failure.

As the guidelines recommend both an ACE inhibitor and β-blocker as initial therapy, a common question is whether it matters if one drug class is started before the other. A study evaluated whether the order of initiation affects all-cause mortality or hospitalization and found no difference. However, there were more events during the 6-month single-treatment phase of the study,[26] reinforcing the importance of having both ACE inhibition and β-blockade if possible. As such, dose titration of the agent initiated first should not prohibit initiation of the second class of agent (eg, having low doses of both an ACE inhibitor and β-blocker is generally regarded as providing greater benefit than having a high dose of only one drug class).

Mineralocorticoid Receptor Antagonists (MRAs) Both MRAs currently available, spironolactone and eplerenone, are inhibitors of aldosterone that produce weak diuretic effects while sparing potassium (potassium-sparing diuretics). Eplerenone is selective for the mineralocorticoid receptor and hence does not cause the endocrine adverse effects commonly seen with spironolactone. The rationale for specifically targeting aldosterone for treatment of HFrEF is based on knowledge that ACE inhibitors do not suppress the chronic production and release of aldosterone. Aldosterone is a key pathological neurohormone that exerts multiple detrimental effects in HF, most notably promoting fluid retention, cardiac fibrosis, and electrolyte abnormalities that predispose to arrhythmias (hypokalemia and hypomagnesemia). Similar to norepinephrine and angiotensin II, aldosterone levels are increased in HF and correlate with disease severity and poorer patient outcomes.

MRAs improved clinical outcomes, including mortality, across the spectrum of HFrEF in three separate clinical trials. These comprised patients who were post-MI with LVEF less than 40% (0.40), patients with NYHA FC II HF, and patients with NYHA FC III through IV HF.[27-29] It is postulated that MRAs reduce mortality at least in part through prevention of sudden cardiac death. The 2013 ACC/AHA HF guidelines recommend MRAs in symptomatic patients (NYHA FC II–IV) with LVEF less than or equal to 35% (0.35), or in patients post-MI with LVEF less than or equal to 40% (0.40) who develop symptoms of HF or have diabetes, unless contraindicated. For individuals with mild symptoms (NYHA FC II), it is recommended they also have a history of prior cardiovascular hospitalization or elevated plasma natriuretic peptide levels.[1]

The major risk related to MRAs is hyperkalemia (Table 7–7). Therefore, balancing the benefit of decreasing death and hospitalization from HF and the potential risks of life-threatening hyperkalemia must always be weighed. Serum potassium and renal function (or serum creatinine to estimate glomerular filtration rate [GFR]) should be assessed before, at day 3, and 1 week after initiating an MRA. MRAs should not be initiated in patients with serum potassium concentrations greater than 5 mEq/L (mmol/L). Likewise, these agents should not be given when estimated GFR is less than 30 mL/min/1.73 m^2 or serum creatinine is greater than 2.5 mg/dL (221 μmol/L) in men or 2 mg/dL (177 μmol/L) in women. In patients without contraindications, spironolactone is initiated at a dose of 12.5 to 25 mg daily (Table 7–6), or occasionally on alternate days for patients with baseline renal insufficiency. Eplerenone is initiated at 25 mg daily, with a target dose of 50 mg daily. Doses should be halved or switched to alternate-day dosing if the estimated GFR falls below 50 mL/min/1.73 m^2. Potassium supplementation is often decreased or discontinued after MRAs are initiated, and patients should be counseled to avoid high-potassium foods. At any time after initiation of therapy, if potassium concentrations exceed 5.5 to 6 mEq/L (mmol/L), MRA dose should be reduced or discontinued until the potassium falls to below 5 mEq/L (mmol/L). In addition, worsening renal function dictates consideration for stopping the MRA. Other adverse effects observed mainly with spironolactone include gynecomastia for men, and breast tenderness and menstrual irregularities for women. Gynecomastia leads to discontinuation in up to 10% of patients on spironolactone. Eplerenone is a CYP3A4 substrate and should not be used concomitantly with strong inhibitors of CYP3A4.

▸ *Digoxin*

Digoxin has been used for several decades in the treatment of HF. Traditionally, it was considered useful for its positive inotropic effects, but more recently its benefits are thought to be related to neurohormonal modulation. Digoxin exerts positive inotropic effects through inhibition of the sodium- and potassium-activated adenosine triphosphate (ATP) pumps, leading to increased intracellular sodium concentrations and subsequently more available intracellular calcium during systole. The mechanism of digoxin's neurohormonal blocking effect is less well understood but may be related to restoration of baroreceptor sensitivity and reduced central sympathetic outflow.[5]

The exact role of digoxin in therapy remains controversial largely due to disagreement on the risk versus benefit of routinely using this drug in patients with HFrEF. Digoxin has been shown to decrease HF-related hospitalizations but does not improve survival.[30] Moreover, digoxin is associated with an increased risk for concentration-related toxicity and numerous adverse effects. Post hoc analyses of the pivotal digoxin clinical trial in HFrEF demonstrated a clear relationship between digoxin plasma concentration and outcomes. Concentrations below 1 ng/mL (mcg/L; 1.3 nmol/L) were associated with no apparent adverse effect on survival, whereas higher concentrations increased the relative risk of mortality.[31] The current guidelines state that if digoxin is used, serum concentrations should be kept below 1 ng/mL (mcg/L; 1.3 nmol/L).

Current recommendations are to consider the addition of digoxin to decrease hospitalizations in patients who remain symptomatic despite optimal GDMT. In patients with concomitant atrial fibrillation, digoxin may occasionally be added to slow ventricular rate; however, β-blockers are more effective at controlling ventricular rate, especially in the setting of exercise. Clinicians may also consider adding digoxin in patients with severe HF who have not responded symptomatically to neurohormonal blockade.

Digoxin is initiated at a dose of 0.125 to 0.25 mg daily depending on age, renal function, weight, and risk for toxicity (Table 7–6). The lower dose should be used if the patient satisfies any of the following criteria: older than 65 years of age, CrCl less than 60 mL/min (1 mL/s), or ideal body weight less than 70 kg (154 lb). The 0.125-mg daily dose is adequate in most patients. Doses are halved or switched to alternate-day dosing in patients with moderate to severe renal failure. The desired concentration range for digoxin in HFrEF is 0.5 to 0.9 ng/mL (mcg/L; 0.6–1.2 nmol/L), preferably with concentrations at or less than 1 ng/mL (mcg/L; 1.3 nmol/L). Routine monitoring of serum drug concentrations is not required but recommended in those with changes in renal function, suspected toxicity, or after addition or subtraction of an interacting drug. Digoxin levels should be drawn at steady state (after three to five elimination half-lives) and a minimum of 6 to 8 hours after the administration of the last dose.

Digoxin toxicity may manifest as nonspecific findings such as fatigue or weakness and other central nervous system (CNS) effects such as confusion, delirium, and psychosis (Table 7–7). GI manifestations include nausea, vomiting, or anorexia, and visual disturbances may occur such as halos, photophobia, and color perception problems (red-green or yellow-green vision). Cardiac findings include numerous types of arrhythmias related to enhanced automaticity, slowed or accelerated conduction, or delayed after-depolarizations. These include ventricular tachycardia and fibrillation, atrioventricular nodal block, and sinus bradycardia. Risk of digoxin toxicity, in particular, the cardiac manifestations are increased with electrolyte disturbances such as hypokalemia, hypercalcemia, and hypomagnesemia. To reduce the proarrhythmic risk of digoxin, serum potassium and magnesium should be monitored closely and supplemented when appropriate to ensure adequate concentrations (potassium > 4 mEq/L [mmol/L] and magnesium > 2 mEq/L [1 mmol/L]). In patients with life-threatening digoxin toxicity due to cardiac or other findings, administration of digoxin-specific Fab antibody fragments usually reverses adverse effects within an hour in most cases.

▸ *Ivabradine*

In patients with HFrEF, an elevated resting HR is associated with higher rates of morbidity and mortality. Ivabradine is a novel HR-lowering medication that blocks the hyperpolarization-activated cyclic nucleotide-gated (HCN) channel, which inhibits the I_f current (otherwise referred to as the "funny" current) in the sinoatrial node. A major advantage of ivabradine is its ability to lower sinus HR without affecting BP or contractility. In the main study leading to ivabradine's approval for HF, ivabradine was shown to reduce the composite of cardiovascular death or hospitalization for HF, although results were mainly driven by a reduction in hospitalizations.[32] Ivabradine is indicated in patients with HFrEF with an LVEF less than or equal to 35% (0.35), NYHA FC II and III, in normal sinus rhythm (without atrial fibrillation), taking maximally tolerated doses or have a contraindication to β-blockers, and who have an HR 70 beats/min or greater. The current guidelines recommend considering ivabradine for patients already optimized on GDMT who meet the specific indication parameters. It is important the β-blocker is optimized prior to initiating therapy with ivabradine as β-blockers have proven benefits in lowering mortality; thus, reaching target doses of a β-blocker takes priority. The starting dose of ivabradine is 5 mg twice daily (or 2.5 mg twice daily in those with conduction defects or in whom a low HR could result in hemodynamic compromise), which may be titrated to 7.5 mg twice daily after 2 weeks (Table 7–6). Ivabradine is contraindicated for use in patients concomitantly taking strong CYP3A4 inhibitors. Frequently observed adverse effects in clinical trials included bradycardia, atrial fibrillation, hypertension, and visual phenomena (Table 7–7). Termed "phosphenes," these visual disturbances consist of temporarily enhanced brightness, usually in response to sudden variations in light (ie, headlights from other cars while driving). These occur in limited areas of the visual field and may also include halos, image decomposition (stroboscopic or kaleidoscopic effects), or colored bright lights. These visual effects may reduce in severity after a few months of therapy.

▶ *Calcium Channel Blockers*

Treatment with nondihydropyridine calcium channel blockers (diltiazem and verapamil) may worsen HF and increase the risk of death in patients with advanced LV systolic dysfunction due to their negative inotropic effects. Conversely, dihydropyridine calcium channel blockers, although negative inotropes in vitro, do not appear to decrease contractility in vivo. Amlodipine and felodipine are the two most extensively studied dihydropyridine calcium channel blockers for HFrEF.[33,34] These two agents have not been shown to alter patient survival, either positively or negatively. As such, they are not routinely recommended as part of a standard HF regimen; however, amlodipine and felodipine can safely be used in patients with HF to treat uncontrolled hypertension or angina if required.

▶ *Antiplatelets and Anticoagulants*

Patients with HFrEF are at increased risk of thromboembolic events as a result of increased activity of prothrombotic molecules such as fibrinogen and von Willebrand factor, stasis of blood within the cardiac chambers and peripheral blood vessels, and endothelial damage or dysfunction. However, clinical trials randomizing patients with HFrEF to aspirin and/or anticoagulation have not shown improved outcomes. In fact, aspirin use may be associated with an increased risk of HF hospitalizations due to a potential interaction with RAAS inhibitors. Therefore, aspirin is generally used in HF patients with an underlying ischemic etiology, a history of ischemic heart disease, or other compelling indications such as a history of embolic stroke. In patients with HFrEF, warfarin and non–vitamin K oral anticoagulants (NOACs) are mainly used in those with a compelling indication such as atrial fibrillation. NOACs are still being studied; however, the first trial, which was conducted in HF patients with concomitant ischemic heart disease, failed to demonstrate a reduction in any cardiovascular events.[35] The choice of anticoagulant (warfarin vs NOAC) should be individualized and based on risk factors, tolerability, cost, patient preference, and potential for drug–drug interactions.

▶ *Emerging Therapies for HFrEF*

The therapeutics of HFrEF are rapidly evolving. Promising data exist for soluble guanylate cyclase (sGC) stimulators, sodium glucose cotransporter-2 (SGLT2) inhibitors, and myosin ATPase activators (omecamtiv mecarbil).

Heart Failure With Preserved Left Ventricular Ejection Fraction

It is now recognized that up to half of patients exhibiting HF symptoms have relatively preserved LV systolic function and primarily impaired diastolic function (impaired ventricular relaxation and filling) characterized by an LVEF 50% (0.50) or greater, a syndrome commonly referred to as HF with preserved EF (HFpEF). Patients with HFpEF tend to be older, with hypertension being the greatest contributing etiology. Mortality rate is slightly lower, though the proportion of patients requiring hospitalizations for decompensations is greater in HFpEF compared to HFrEF. Importantly, the reasons for decompensations are more commonly due to noncardiovascular causes which contribute pathophysiologically to a greater degree in HFpEF. An assessment for HFpEF should be performed in any patient who presents with signs and symptoms consistent with HF. A diagnosis is based on echocardiographic evidence of preserved LVEF and elevated natriuretic peptides in the absence of ventricular dilation, valvular disease, or cardiac ischemia.[36] Once HFpEF is diagnosed, further workup (commonly requiring cardiac magnetic resonance imaging) is directed at determining the etiology for this heterogenous disorder. Common etiologies include hypertensive heart disease, hypertrophic cardiomyopathy, cardiac amyloidosis, and connective tissue disorders like scleroderma.

Unlike HFrEF, no therapies have been shown to improve survival in HFpEF. Studies conducted with ACE inhibitors, β-blockers, nitrates, phosphodiesterase-5 inhibitors, digoxin, and ivabradine have all failed to demonstrate improvement in outcomes in HFpEF. Agents that may be of benefit are ARBs and MRAs, which were found to modestly decrease risk of hospitalizations in clinical trials.[37,38] Potential emerging therapies currently being studied for HFpEF include sGC stimulators, SGLT2 inhibitors, and treatments targeting transthyretin cardiac amyloidosis (ATTR) (eg, tafamidis, diflunisal, patisiran).

The guideline recommended treatment approach for patients with HFpEF is (a) correction or control of underlying etiologies/comorbidities (including optimal management of hypertension, CAD, and atrial fibrillation) and (b) optimization of volume status with diuretics. Consideration for use of ARBs and MRAs to possibly reduce hospitalization is mentioned but with a lower strength of recommendation. Although diuretics are recommended to attenuate signs and symptoms of congestion, their use in HFpEF differs slightly from HFrEF. In HFpEF, the less compliant and stiffened LV results in a steeper pressure–volume relationship.

Patient Encounter Part 3

Based on the information presented and your problem-based assessment, create a care plan for the patient's HF. Your plan should include:

- Nonpharmacologic treatment options.
- Acute and chronic treatment plans to address symptoms and prevent disease deterioration.
- Monitoring plan for acute and chronic treatments.

Therefore, small increases in volume can lead to large increases in LV filling pressure and the development of HF symptoms. As a result, management of volume status in the setting of HFpEF can be difficult as these patients are very sensitive to changes in volume, and diuresis goals may need to be more conservative than for HFrEF.

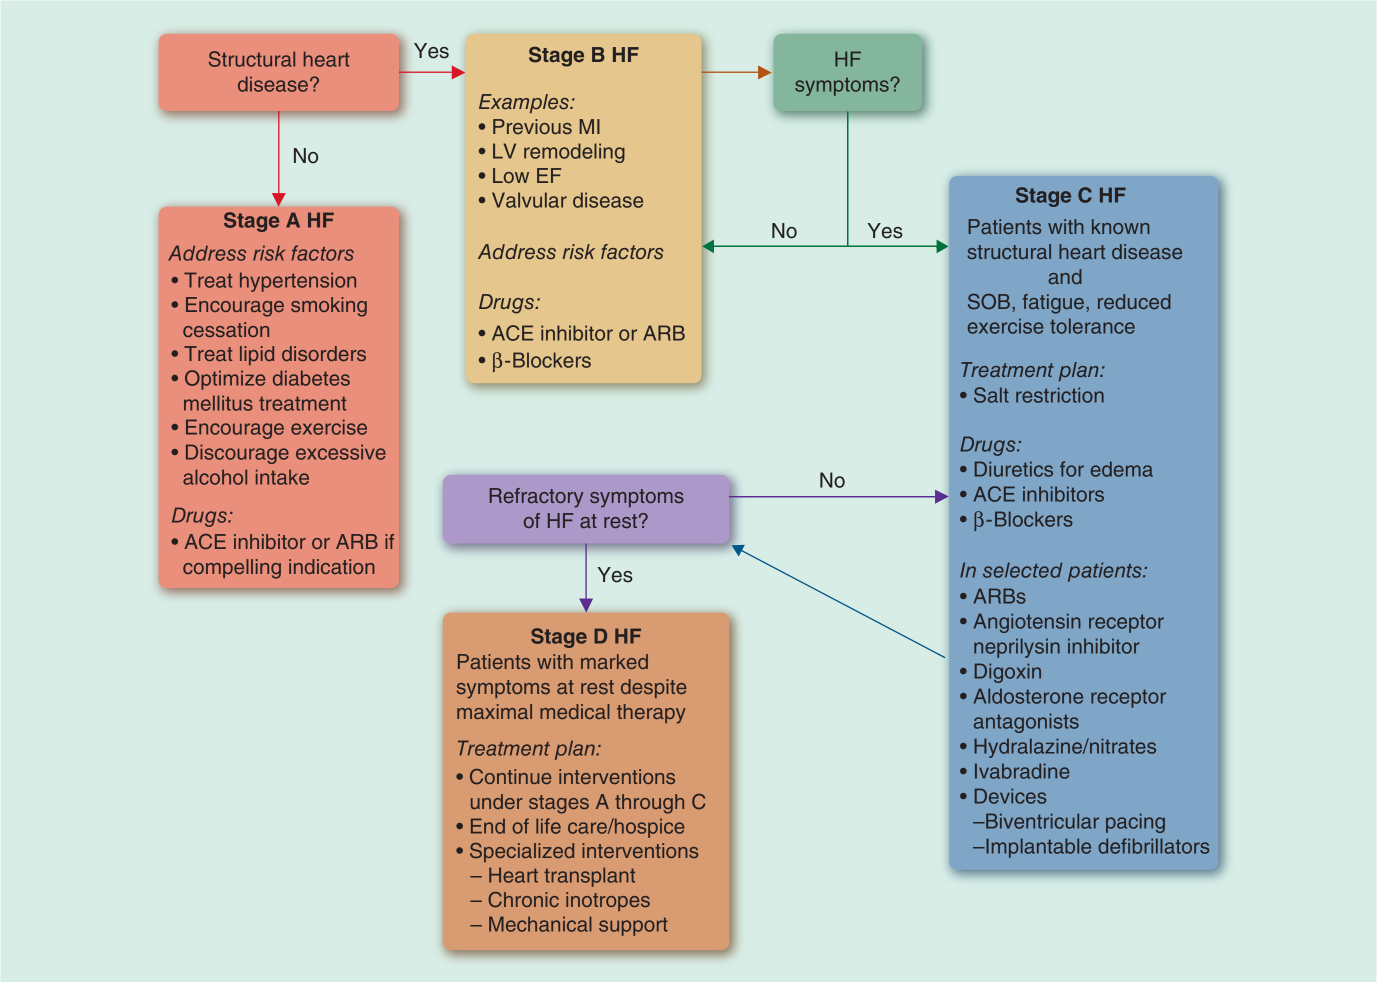
Outcome Evaluation of Chronic Heart Failure

- Evaluation of therapy is influenced by the ability of treatment to successfully reduce symptoms, improve quality of life, decrease frequency of hospitalizations for AHF, reduce disease progression, and prolong survival (Figure 7–2).
- The major outcome parameters focus on (a) volume status, (b) exercise tolerance, (c) overall symptoms/quality of life, (d) adverse drug reactions, and (e) preservation of cardiac function.
- Assess quality of life by evaluating patients' ability to continue their activities of daily living.
- Assess for symptoms of HF, including those related to both congestion and hypoperfusion.
- If diuretic therapy is warranted, monitor for therapeutic response by assessing weight and improvement of edema, as well as orthopnea and PND.
- Once therapy for preventing disease progression is initiated, continue to monitor for symptomatic improvement.
- Keep in mind that patients' symptoms can initially worsen with β-blockers, and it may take weeks or months before patients notice improvement.
- Monitoring for adverse drug reactions is especially important since patients tend to be on multiple medications that can affect BP, electrolytes, and kidney function.
- Occasional exercise testing or repeat echocardiography is conducted to ascertain disease prognosis or suitability for heart transplant. Keep in mind that improvement in symptoms does not always correlate directly to or necessitate improvement in cardiac function.

ACUTE AND ADVANCED HEART FAILURE

Clinical Presentation and Diagnosis of Acute Heart Failure

The 2019 ACC Expert Consensus Decision Pathway on Risk Assessment, Management, and Clinical Trajectory of Patients Hospitalized With Heart Failure provides the framework for management of AHF.[39] Patients with AHF present with symptoms of worsening fluid retention or decreasing exercise tolerance and fatigue (typically worsening of symptoms presented in



Structural heart disease?
Yes
No
Stage A HF
Address risk factors
• Treat hypertension
• Encourage smoking cessation
• Treat lipid disorders
• Optimize diabetes mellitus treatment
• Encourage exercise
• Discourage excessive alcohol intake
Drugs:
• ACE inhibitor or ARB if compelling indication
Stage B HF
Examples:
• Previous MI
• LV remodeling
• Low EF
• Valvular disease
Address risk factors
Drugs:
• ACE inhibitor or ARB
• β-Blockers
HF symptoms?
No
Yes
Stage C HF
Patients with known structural heart disease and SOB, fatigue, reduced exercise tolerance
Treatment plan:
• Salt restriction
Drugs:
• Diuretics for edema
• ACE inhibitors
• β-Blockers
In selected patients:
• ARBs
• Angiotensin receptor neprilysin inhibitor
• Digoxin
• Aldosterone receptor antagonists
• Hydralazine/nitrates
• Ivabradine
• Devices
–Biventricular pacing
–Implantable defibrillators
Refractory symptoms of HF at rest?
No
Yes
Stage D HF
Patients with marked symptoms at rest despite maximal medical therapy
Treatment plan:
• Continue interventions under stages A through C
• End of life care/hospice
• Specialized interventions
– Heart transplant
– Chronic inotropes
– Mechanical support

FIGURE 7–2. Treatment algorithm for heart failure with reduced ejection fraction. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; EF, ejection fraction; HF, heart failure; LV, left ventricular; MI, myocardial infarction; SOB, shortness of breath.) Table 7–5 describes the staging of heart failure.

the chronic HF clinical presentation textbox). These symptoms reflect congestion behind the failing ventricle and/or hypoperfusion. Patients can be categorized into hemodynamic subsets based on assessment of physical signs and symptoms of congestion and/or hypoperfusion.[40] Patients can be described as "wet" or "dry" depending on volume status as well as "warm" or "cool" based on adequacy of tissue perfusion. "Wet" refers to patients with volume/fluid overload (eg, edema and JVD), whereas "dry" refers to euvolemic patients. "Warm" refers to patients with adequate CO to perfuse peripheral tissues (skin will be warm to touch), whereas "cool" refers to patients with evidence of hypoperfusion (skin cool to touch with diminished pulses). Additionally, invasive hemodynamic monitoring can be used in some cases to provide objective data for assessing volume status (pulmonary capillary wedge pressure [PCWP]) and perfusion (CO). A CI below 2.2 L/min/m^2 (0.037 L/s/m^2) is consistent with reduced contractility and hypoperfusion, and a PCWP above 15 to 18 mm Hg (2–2.4 kPa) is indicative of elevated LV preload and congestion. The four possible hemodynamic subsets a patient may fall into are "warm and dry," "warm and wet," "cool and dry," or "cool and wet."

▶ *Precipitating Factors*

KEY CONCEPT It is important for the clinician to identify the cause(s) of AHF to maximize treatment efficacy and reduce future disease exacerbations. Cardiovascular, metabolic, and lifestyle factors can all precipitate AHF. The most common precipitating factors for acute decompensation and how they contribute pathophysiologically are listed in Tables 7–3 and 7–4.

▶ *Laboratory Assessment*

Routine laboratory testing of patients with AHF includes electrolytes and blood glucose, as well as serum creatinine and BUN to assess renal function. Complete blood cell count is measured to determine if anemia or infection is present. Troponin concentrations are prognostic and also used to diagnose possible acute myocardial injury. Liver function tests can help determine if congestive hepatopathy and/or hepatocellular necrosis may be present due to either congestion or hypoperfusion. Thyroid function tests are measured to assess hyperthyroidism or hypothyroidism as causes of AHF. Lactate levels may be increased in the setting of cardiogenic shock and are a marker of hypoperfusion that may indicate poor prognosis. A urinalysis is attained in patients with an unknown history of renal disease to rule out nephrotic syndrome. Lastly, a toxicology screen is obtained in patients in whom the use of illicit drugs is suspected.

Measuring BNP or its degradation product NT-proBNP is advocated in the current guidelines. BNP is synthesized, stored, and released from the ventricles in response to increased ventricular filling pressures, hence plasma levels of BNP can be used as a marker for volume overload. The most widely accepted indication for BNP measurement is as an adjunctive aid for diagnosing a cardiac etiology for dyspnea.[41] The current values for ruling out a cardiac etiology for dyspnea in the acute setting are a BNP less than 100 pg/mL (ng/L; 28.9 pmol/L) or NT-proBNP less than 300 pg/mL (ng/L; 35.4 pmol/L). BNP measurements require cautious interpretation because numerous conditions can also elevate BNP concentrations. These include older age, renal dysfunction, pulmonary embolism, and chronic pulmonary disease. Treatment with sacubitril/valsartan would also be expected to raise BNP levels based on the drug's inhibition of neprilysin. As such, monitoring of NT-proBNP should be utilized instead of BNP in patients taking sacubitril/valsartan as NT-proBNP is not a substrate for neprilysin. Natriuretic peptide levels may also be obtained to aid in further risk stratification, although it remains controversial whether they provide added value when titrating GDMT.

▶ *Other Diagnostic Tests*

Other diagnostic tests should also be obtained to rule out precipitating factors (chest radiograph, ECG) and to evaluate cardiac function (transthoracic echocardiogram). Invasive hemodynamic monitoring in patients with HF entails placement of a right heart catheter or pulmonary artery catheter (PAC). The catheter is inserted percutaneously through a central vein and advanced through the right side of the heart to the pulmonary artery. Inflation of a balloon proximal to the end port allows the catheter to "wedge," yielding the PCWP, which estimates pressures in the left ventricle during end diastole. Additionally, CO can be estimated and SVR calculated (Table 7–8).

There are no universally accepted guidelines dictating when invasive monitoring in HF is required, and invasive monitoring has not been shown to improve mortality or reduce hospitalizations. Nonetheless, the use of a PAC remains helpful in the assessment of hemodynamics when volume status and/or cardiac output is uncertain, or when there is disagreement between signs

Table 7–8

Hemodynamic Monitoring: Normal Values

Hemodynamic Variable	Normal Value
Central venous (right atrial) pressure, mean	< 5 mm Hg[a] (0.7 kPa)
Right ventricular pressure (systolic/diastolic)	25/0 mm Hg[a]
Pulmonary artery pressure (systolic/diastolic), PAS/PAD	25/10 mm Hg[a]
Pulmonary arterial pressure, mean, PAP	< 18 mm Hg[a] (2.4 kPa)
Pulmonary capillary wedge pressure, PCWP	< 12 mm Hg[a,b] (1.6 kPa)
Systemic arterial pressure (systolic/diastolic), SBP/DBP	120/80 mm Hg[a]
Mean arterial pressure, MAP = (DBP+[1/3(SBP−DBP])	70–110 mm Hg[a] (9.3–14.6 kPa)
Cardiac output, CO	4–6 L/min (0.07–0.10 L/s)
Cardiac index, CI = CO/BSA	2.8–4.2 L/min/m^2 (0.047–0.070 L/s/m^2)
Systemic vascular resistance, SVR = ([MAP−CVP]×80)/(CO)	900–1400 dyn·s·cm^{-5}[c] (90–140 MPa·s·m^{-3})
Pulmonary vascular resistance, PVR = ([PAP−CVP]×80)/(CO)	150–250 dyn·s·cm^{-5}[c] (15–25 Mpa·s·m^{-3})
Arterial oxygen saturation	90%–95% (0.90–0.95)
Mixed venous oxygen saturation	60%–80% (0.60–0.80)

[a] 1 mm Hg = 0.133 kPa; 1 mL/beat per square meter = 0.001 L·beat^{-1}·m^{-2}.

[b] A higher than normal PCWP (ie, 15–18 mm Hg or 2–2.4 kPa) is often accepted in patients with heart failure.

[c] 1 dyn·s·cm^{-5} = 0.1 MPa·s·m^{-3}; 1 mL/dL = 10 mL/L.

BSA, body surface area; CVP, central venous pressure; DBP, diastolic blood pressure; PAD, pulmonary artery diastolic; PAP, pulmonary arterial pressure; PAS, pulmonary artery systolic; SBP, systolic blood pressure.

Reproduced with permission from Reed BN, Rodgers JE. Acute decompensated heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020.

and symptoms and clinical response. In patients requiring IV vasoactive therapies such as inotropes and vasopressors, invasive hemodynamic monitoring is useful to guide dose titration and offers the advantage of immediate hemodynamic assessment of an intervention and prompt adjustments. However, use of these agents does not mandate the need for invasive monitoring. Risks with PACs include infection, bleeding, thrombosis, catheter malfunction, and ventricular ectopy.

Desired Therapeutic Outcomes

The goals of therapy for AHF are to (a) correct the underlying precipitating factor(s); (b) relieve patient symptoms; (c) improve or normalize hemodynamics; (d) optimize GDMT; and (e) educate the patient, reinforcing adherence to lifestyle modifications and the drug regimen. The ultimate goal for a patient hospitalized for AHF is return to a compensated HF state and transition to the outpatient setting on oral medications.[39] Only through aggressive management to achieve all of these goals will a patient's prognosis be improved and future hospitalizations for acute decompensations be prevented.

Clinical Presentation of Acute Heart Failure

Subset I (Warm and Dry)

- CI *greater than* 2.2 L/min/m^2 (0.037 L/s/m^2), PCWP *less than* 18 mm Hg (2.4 kPa)
- Patients considered well compensated and perfused, without evidence of congestion
- No immediate interventions necessary except optimizing oral medications and monitoring

Subset II (Warm and Wet)

- CI *greater than* 2.2 L/min/m^2 (0.037 L/s/m^2), PCWP *greater than* or equal to 18 mm Hg (2.4 kPa)
- Patients adequately perfused and display signs and symptoms of congestion
- Main goal is to reduce preload (PCWP) carefully with loop diuretics and vasodilators

Subset III (Cool and Dry)

- CI *less than* 2.2 L/min/m^2 (0.037 L/s/m^2), PCWP *less than* 18 mm Hg (2.4 kPa)
- Patients are inadequately perfused and not congested
- Hypoperfusion leads to increased mortality, elevating death rates fourfold compared with those who are adequately perfused
- Treatment focuses on increasing CO with positive inotropic agents and/or replacing intravascular fluids
- Fluid replacement must be performed cautiously because patients can rapidly become congested

Subset IV (Cool and Wet)

- CI *less than* 2.2 L/min/m^2 (0.037 L/s/m^2), PCWP *greater than* 18 mm Hg (2.4 kPa)
- Patients are inadequately perfused and congested
- Classified as the most complicated clinical presentation of AHF with the worst prognosis
- Most challenging to treat; therapy targets alleviating signs and symptoms of congestion by increasing CI as well as reducing PCWP while maintaining adequate mean arterial pressure
- Treatment involves a delicate balance between diuretics, vasodilators, and inotropic agents
- Use of vasopressors is sometimes necessary to maintain BP

Removal or control of precipitating factors is essential for an optimal response to pharmacologic therapy. Relief of symptoms should occur rapidly to minimize length of hospitalization. Although a rapid discharge from the hospital is desirable, a patient should not be discharged before ensuring that he or she is in a euvolemic, or nearly euvolemic, state with a body weight and functional capacity similar to before the acute decompensation. Oral agents such as β-blockers, ACE inhibitors or ARBs (and possibly an ARNI), and MRAs should be initiated as soon as possible during the hospitalization. These chronic oral medications not only improve mortality and prevent readmissions, but acutely also contribute to improvement in hemodynamics. Patient education prior to discharge from the hospital is recommended to assist in minimizing adverse effects and nonadherence. Dissemination of written information, in addition to verbal information, is helpful for patient comprehension and retention. This can include therapy goals, lifestyle modifications, drug regimen, dosage information, and relevant adverse effects, as well as symptom and diary cards. The addition of a transitions of care program in this patient population is particularly important in reducing 30-day readmission rates.

Pharmacologic Treatment

KEY CONCEPT Treatment of AHF targets relief of congestion and optimization of CO utilizing oral or IV diuretics, IV vasodilators, and when appropriate, inotropes based on presenting hemodynamics. Optimizing hemodynamics results in improved symptomology and preservation of organ function. A specific treatment approach is formulated depending on the patient's symptoms (congestion vs hypoperfusion) and hemodynamic indices (CI and PCWP).[42] If the patient primarily exhibits signs and symptoms of congestion, treatment entails use of diuretics as first-line agents to relieve congestion (reduce PCWP) by decreasing preload. IV vasodilators may be considered in patients with moderate to severe congestion to provide more rapid relief of congestion (and reduction in PCWP) by decreasing both preload and afterload. Reducing congestion in the heart (analogous to reducing LV filling pressure) indirectly may lead to improved contractile function increases in SV and CO and hence perfusion to vital organs. The patient's presenting BP can also help guide the clinician on choice of diuretic, vasodilator, or both. For the patient with a systolic BP of 120 to 160 mm Hg in the setting of progressive worsening of chronic HF with pulmonary and systemic congestion, aggressive diuresis can be beneficial. In the patient with systolic BP greater than 160 mm Hg and abrupt onset of pulmonary congestion, IV vasodilators may be indicated in addition to diuretics. For patients primarily displaying symptoms of hypoperfusion, treatment relies on use of agents that increase cardiac contractility, known as positive inotropes. Some patients present with both symptoms of congestion and hypoperfusion, often requiring a combination of therapies. One of the current challenges to the treatment of AHF is achieving hemodynamic improvement without adversely affecting organ function. In the case of inotropes, the increased contractility occurs at the expense of an increase in cardiac workload and potential for proarrhythmia.

Therefore, inotropes should only be used when absolutely necessary and for the shortest duration possible to establish hemodynamic stability. High-dose diuretic therapy is associated with a risk for acute worsening of kidney function (as indicated by increases in serum creatinine) and possibly neurohormonal activation, although whether this indicates permanent kidney injury or poorer patient outcomes remains an area of debate.

▶ *Diuretics*

Loop diuretics, including furosemide, bumetanide, and torsemide, are the diuretics of choice in the management of AHF. Diuretics decrease preload by functional venodilation within 5 to 15 minutes of administration and subsequently by an increase in sodium and water excretion. This may provide rapid improvement in symptoms of pulmonary congestion, although achieving euvolemia will generally take time depending on how volume overloaded the patient is and the negative fluid balance achieved. The reduction in preload will result in a decrease in PCWP, but diuresis alone generally does not increase CI like positive inotropes and arterial vasodilators. Patients who have significant volume overload often have impaired absorption of oral loop diuretics because of intestinal edema or altered transit time. Therefore, for patients in AHF, loop diuretics are usually administered via IV boluses or continuous IV infusions (Table 7–9). Higher doses may be required for patients with renal insufficiency due to decreased drug delivery to the site of action in the loop of Henle. A good rule of thumb is to initiate the IV diuretic at 1 to 2.5 times the outpatient oral dose. Data suggest doses 2.5 times the home oral dose given intravenously may be associated with better diuresis compared to simply using the home dose intravenously.[43]

There is limited evidence comparing the benefit of diuretics with other therapies for symptom relief or long-term outcomes. Careful monitoring of diuresis is needed as excessive preload reduction can lead to a decrease in CO, resulting in a reflex increase in sympathetic activation, renin release, and the expected consequences of vasoconstriction, tachycardia, and increased myocardial oxygen demand. Routine monitoring of serum electrolytes, serum creatinine, and BUN should be performed at a minimum of every 24 hours, and more frequently in patients undergoing more aggressive diuresis (eg, every 6–12 hours).

Occasionally, patients with HF do not respond to a diuretic, defined as failure to achieve a negative net fluid balance of at least 500 mL or greater depending on clinical need after several increasing bolus doses. Several strategies are used to overcome diuretic resistance. These include using larger doses, converting to IV administration after failing to respond to oral doses, increasing the frequency of administration, or using a combination of loop and thiazide diuretic. Current data suggest there is little difference in diuretic efficacy whether the loop diuretic is administered via a continuous infusion or intermittent boluses.[43] (See Table 7–9.) An effective strategy for overcoming diuretic resistance is combining two diuretics with different sites of action within the nephron. The most common combination is the use of a loop diuretic with a thiazide or thiazide-like diuretic such as metolazone. Diuretic resistance commonly occurs due to adaptation of the kidney to chronic inhibition of sodium reabsorption in the ascending limb of the loop of Henle by enhancing sodium reabsorption in the distal portion of the nephron. Therefore, adding a thiazide that acts in the distal nephron provides sequential blockade of sodium reabsorption and enhanced diuresis. Combining diuretics should be done cautiously due to an increased risk for cardiovascular collapse from rapid intravascular volume depletion and electrolyte wasting (especially potassium and magnesium). Diuretic resistance may also be a result of poor CO and diminished renal perfusion. In these patients, it may become necessary to add vasodilators or inotropes to enhance perfusion to the kidneys. Care must be taken because vasodilators can decrease renal blood flow despite increasing CO through dilation of central and peripheral vascular beds.

▶ *Vasodilators*

Vasodilators are commonly used in patients presenting with AHF accompanied by moderate to severe congestion, although their routine addition to diuretics has not been shown to improve outcomes in AHF. This class includes nitroglycerin, nitroprusside, and nesiritide. Hemodynamic effects and dosages for these agents are included in Tables 7–10 and 7–11, respectively. IV vasodilators cause a rapid decrease in arterial tone, resulting in a decrease in SVR and a potential increase in SV and CO. Additionally, vasodilators also cause venodilation, reducing ventricular filling pressures (PCWP) within 24 to 48 hours, and potentially reducing myocardial oxygen consumption (MVO_2) and ventricular workload. Although IV vasodilators are generally safe and effective, identification of the proper patient for use is important to minimize the risk of significant hypotension. In addition, vasodilators are contraindicated in patients whose cardiac filling (and hence CO) depends on venous return or intravascular volume, as well as in patients who present with cardiogenic shock. The 2013 ACC/AHA HF guidelines recommend considering IV vasodilators in addition to diuretic therapy for relief of dyspnea in patients with acutely decompensated HF and not symptomatically hypotensive.

Nitroglycerin Nitroglycerin acts as a source of nitric oxide, which through a cGMP pathway induces smooth muscle relaxation in venous and arterial vascular beds. Nitroglycerin is primarily a venous vasodilator at lower doses but can exert potent arterial vasodilatory effects at higher doses. At lower doses,

Table 7–9

Intravenous Diuretics Used to Treat Heart Failure–Related Fluid Retention

	Onset of Action (minutes)	Duration of Action (hours)	Relative Potency	Intermittent Bolus Dosing (mg)	Continuous Infusion Dosing (bolus/infusion)
Furosemide	2–5	4–8	40	20–200+	20–40/2.5–10
Torsemide	< 10	6–24	20	10–100	20/2–5
Bumetanide	2–3	4–6	0.5	1–10	1–4/0.5–1
Ethacrynic acid	5–15	2–7	50	0.5–1 mg/kg per dose up to 100 mg/dose

Milrinone	↑↑	↓↓	↓	↓	↑

BP, blood pressure; CO, cardiac output; HR, heart rate; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance; ↑, increase; ↓, decrease; 0, no or little change.

nitroglycerin causes a decrease in preload (or filling pressures) and improves coronary blood flow. At higher doses (> 100 mcg/min), additional reduction in preload is achieved, along with a decrease in afterload and subsequent increase in SV and CO. IV nitroglycerin may be used primarily for preload reduction (lower doses) in patients exhibiting mainly pulmonary congestion or in combination with inotropes for congested patients with severely reduced CO.

Continuous infusions of nitroglycerin should be initiated at a dose of 5 to 10 mcg/min and increased every 5 to 10 minutes until symptomatic or hemodynamic improvement. If the patient is profoundly hypertensive, higher starting doses may be reasonable. Effective doses range from 35 to 200 mcg/min. The most common adverse events reported are headache, dose-related hypotension, and tachycardia. Tachyphylaxis, or tolerance of effects, may occur within 12 hours of initiation, necessitating continual titration to higher doses.

Nitroprusside Nitroprusside, like nitroglycerin, leads to the formation of nitric oxide and vascular smooth muscle relaxation. In contrast to nitroglycerin, nitroprusside exerts significant venous and arterial vasodilation regardless of dosage. Nitroprusside causes a pronounced decrease in PCWP, SVR, and BP, with a modest increase in CO. Nitroprusside has been studied to a limited extent in AHF, and no studies have evaluated its effects on mortality. Nitroprusside is initiated at 0.3 mcg/kg/min, followed by dose adjustments in 0.1 to 0.2 mcg/kg/min increments if necessary to achieve desired effect. Because of its rapid onset of action and metabolism, nitroprusside administered as a continuous infusion is easy to titrate and provides predictable hemodynamic effects. Nitroprusside requires strict monitoring of BP and HR. Its use is limited in AHF due to recommended hemodynamic monitoring with an arterial line and mandatory intensive care unit admission at many institutions. Abrupt withdrawal of therapy should be avoided due to a risk of rebound neurohormonal activation. Therefore, the dose should be tapered when discontinuing therapy. Nitroprusside has the potential to cause cyanide and thiocyanate toxicity, especially in patients with hepatic and renal insufficiency, respectively. Toxicity is most common with use longer than 3 days and with higher doses. Nitroprusside should be avoided in patients with active ischemia because its powerful afterload-reducing effects within the myocardium can "steal" coronary blood flow from myocardial segments that are supplied by epicardial vessels with high-grade atherosclerotic lesions.

Nesiritide Recombinant BNP, or nesiritide, binds to guanylate cyclase receptors in vascular smooth muscle and endothelial cells, causing an increase in cGMP concentrations leading to vasodilation (venous and arterial) and natriuresis. Nesiritide also antagonizes the effects of the RAAS and endothelin. Nesiritide reduces PCWP, right atrial pressure, and SVR. Consequently, it also indirectly increases SV and CO without affecting HR. Continuous infusions result in sustained effects for 24 hours without tachyphylaxis, although experience with its use beyond 72 hours is limited.

Unlike nitroglycerin and nitroprusside, nesiritide has been studied in randomized clinical trials for AHF. Compared to

Table 7–11

Usual Doses and Monitoring of Commonly Used Hemodynamic Medications

Drug	Dose	Monitoring Variables[a]
Dopamine	0.5–20 mcg/kg/min	BP, HR, urinary output and kidney function, ECG, extremity perfusion (higher doses only)
Dobutamine	2.5–20 mcg/kg/min	BP, HR, urinary output and function, ECG
Milrinone	0.375–0.75 mcg/kg/min	BP, HR, urinary output and function, ECG, changes in ischemic symptoms (eg, chest pain), electrolytes
Nitroprusside	0.3–3 mcg/kg/min	BP, HR, liver and kidney function, blood cyanide and/or thiocyanate concentrations if toxicity suspected (nausea, vomiting, altered mental function)
Nitroglycerin	5–200+ mcg/min	BP, HR, ECG, changes in ischemic symptoms
Nesiritide[b]	Bolus: 2 mcg/kg; infusion: 0.01 mcg/kg/min	BP, HR, urinary output and kidney function, blood BNP/NT-proBNP concentrations

[a] In addition to pulmonary capillary wedge pressure and cardiac output.

[b] No longer manufactured in United States as of 2018.

BNP, B-type natriuretic peptide; BP, blood pressure; ECG, electrocardiogram; HR, heart rate; NT-proBNP, N-terminal proBNP.

standard care, it is associated with significant improvement in PCWP, but only modest improvements in dyspnea, and no significant effect on risk of death or rehospitalizations within 30 days.[44,45] Nesiritide is no longer being manufactured in the United States, although some supply may still be available.

▶ *Inotropic Agents*

Currently available positive inotropic agents act via increasing intracellular cyclic adenosine monophosphate (cAMP) concentrations through different mechanisms. β-Agonists, or catecholamine inotropes, activate adenylate cyclase through stimulation of β-adrenergic receptors, which subsequently catalyzes the conversion of ATP to cAMP. Phosphodiesterase inhibitors reduce degradation of cAMP. The resulting elevation in cAMP levels leads to enhanced phospholipase activity, which then increases the rate and extent of calcium influx during systole, thereby enhancing contractility. Additionally, cAMP promotes uptake of calcium by the sarcoplasmic reticulum during diastole, which improves cardiac relaxation. Routine use of inotropes during acute decompensations is less preferable to use of vasodilators, which should be attempted first for AHF. The 2013 ACC/AHA HF guidelines recommend the use of temporary inotropic support to maintain perfusion and preserve organ function in patients who are refractory as a bridge to definitive therapy.[1] Long-term use of inotropes may be considered in patients for the purposes of palliative care.

Dobutamine Dobutamine has historically been the inotrope of choice for AHF. As a synthetic catecholamine, it acts as an agonist mainly on β_1- and β_2-receptors and minimally on α_1-receptors. The resulting hemodynamic effects are due to both receptor- and reflex-mediated activities. These effects include increased contractility and HR through β_1- (and β_2-) receptors and vasodilation through a relatively greater effect on β_2-receptors than α_1-receptors. Dobutamine can increase, decrease, or cause little change in mean arterial pressure depending on whether the resulting increase in CO is enough to offset the modest vasodilation. Although dobutamine has a half-life of approximately 2 minutes, its positive hemodynamic effects can be observed for several days to months after administration. The use of dobutamine is supported by several small studies documenting improved hemodynamics, but large-scale clinical trials in AHF are lacking.

Dobutamine is initiated at a dose of 2.5 to 5 mcg/kg/min, which can be gradually titrated to 20 mcg/kg/min based on clinical response. There are several practical considerations to dobutamine therapy. First, owing to its vasodilatory potential, monotherapy with dobutamine is reserved for patients with systolic BP greater than 90 mm Hg. However, it may be used in combination with vasopressors in patients with lower systolic BP. Second, downregulation of β_1-receptors or uncoupling of β_2-receptors from adenylate cyclase with prolonged exposure has been reported with dobutamine and other catecholamine agents. This leads to an attenuation of hemodynamic effects as early as 48 hours after initiation of a continuous infusion, although tachyphylaxis is more evident with use longer than 72 hours. Full sensitivity to dobutamine's effects can be restored 7 to 10 days after the drug is withdrawn. Third, many patients with AHF will be taking β-blockers chronically. Because β-blockers exhibit high affinity for β-receptors, the effectiveness of β-agonists such as dobutamine will be reduced when administered concomitantly. In patients on β-blocker therapy, it is recommended that consideration be given to the use of phosphodiesterase inhibitors such as milrinone, which do not depend on β-receptors for effect.[46,47] Although commonly practiced, use of high doses of dobutamine to overcome the β-blockade should be discouraged because this negates any of the protective benefits of the β-blocker and may increase risk for arrhythmias.

Dopamine Dopamine is most commonly reserved for patients with low systolic BP and those approaching cardiogenic shock. Dopamine exerts its effects through direct stimulation of adrenergic receptors, as well as release of norepinephrine from adrenergic nerve terminals. Dopamine produces hemodynamic effects that differ based on dosing. At lower doses (< 3 mcg/kg/min), dopamine stimulates renal dopaminergic type 1 (D1) receptors, resulting in renal artery vasodilation and possible increases in renal blood flow. Positive inotropic effects are more pronounced at doses of 3 to 10 mcg/kg/min where predominantly β_1-receptors are activated. CI is increased due to increased SV and HR. At doses higher than 10 mcg/kg/min, chronotropic and α_1-mediated vasoconstriction effects predominate. This causes an increase in mean arterial pressure due to higher SVR. The ultimate effect on cardiac hemodynamics will depend largely on the dosage prescribed and must be individually tailored to the patient's clinical status. Dopamine is generally associated with an increase in CO and BP, with a concomitant increase in PCWP. Dopamine increases myocardial oxygen demand and may decrease coronary blood flow through vasoconstriction and increased wall tension. As with other inotropes, dopamine is associated with increased myocardial workload and an increased risk for arrhythmias.

Phosphodiesterase Inhibitors Milrinone and amrinone (or inamrinone) work by inhibiting phosphodiesterase III, the enzyme responsible for the breakdown of cAMP. The increase in cAMP levels leads to increased intracellular calcium concentrations and enhanced contractile force generation. Milrinone has replaced amrinone as the phosphodiesterase inhibitor of choice due to the higher frequency of thrombocytopenia seen with amrinone.

Milrinone has both positive inotropic and vasodilating properties and as such is referred to as an "inodilator." Its vasodilating activities are especially prominent on venous capacitance vessels and pulmonary vascular beds, although a reduction in arterial tone is also noted. IV administration results in an increase in SV and CO, and usually modest increases in HR. Milrinone also lowers PCWP through venodilation. Routine use of milrinone during acute decompensations in NYHA FC II to IV HF is not recommended, and milrinone use remains limited to patients who require inotropic support.[48]

Dosing recommendations for milrinone may include a loading dose of 50 mcg/kg, followed by an infusion beginning at 0.5 mcg/kg/min (range: 0.23 mcg/kg/min for patients with renal failure up to 0.75 mcg/kg/min). A loading dose is not necessary if immediate hemodynamic effects are not required or if patients have low systolic BP (< 90 mm Hg). Decreases in BP during an infusion may necessitate dose reductions as well. Doses need to be reduced in patients with renal insufficiency as milrinone is primarily renally excreted.

Milrinone is a good option for patients requiring an inotrope who are also chronically receiving β-blockers because the inotropic effects are achieved independent of β-adrenergic receptors. However, milrinone exhibits a long distribution and elimination half-life compared with β-agonists. Potential adverse effects include hypotension, arrhythmias, and less commonly, thrombocytopenia. Additionally, milrinone has been associated with increased risk for death in some studies. Milrinone should not be used in patients in whom vasodilation is contraindicated.

Mechanical, Surgical, and Device Therapies

▶ *Percutaneous Mechanical Circulatory Support Devices*

Intra-aortic balloon counterpulsation (IABC) or intra-aortic balloon pumps (IABPs) are widely used mechanical circulatory assistance devices for patients with cardiac failure who do not respond to standard therapies. An IABP is placed percutaneously into the femoral artery and advanced to the high descending thoracic aorta. Once in position, the balloon is programmed to inflate during diastole and deflate during systole. Two main beneficial mechanisms are (a) inflation during diastole increases aortic pressure and perfusion of the coronary arteries; and (b) deflation just prior to the aortic valve opening reduces afterload. As such, IABP increases myocardial oxygen supply and decreases oxygen demand. This device has many indications, including cardiogenic shock, high-risk unstable angina in conjunction with percutaneous interventions, preoperative stabilization of high-risk patients prior to surgery, and in patients who cannot be weaned from cardiopulmonary bypass. Possible complications include infection, bleeding, thrombosis, limb ischemia, and device malfunction. The device is typically useful for short-term therapy due to its invasiveness, need for limb immobilization, and requirement for anticoagulation.

Other support devices used in this setting are the Impella and TandemHeart. Both the Impella and TandemHeart are placed percutaneously with the Impella pumping blood directly from the LV into the aorta and the TandemHeart taking blood from the left atrium and returning it into the femoral artery. Unlike the IABP, the Impella and TandemHeart provide continuous blood flow and do not require timing with the cardiac cycle. Complications that occur with these devices are similar to that of the IABP. Additionally, given they are both dependent on LV preload, it is important to monitor for right ventricle failure. One potential advantage of the TandemHeart compared to the Impella is that it can be used in patients with LV thrombus.

▶ *Ventricular Assist Device*

The ventricular assist device (VAD) is a surgically implanted pump that reduces or replaces the work of the right, left, or both ventricles. VADs are indicated for short-term support in patients refractory to pharmacologic therapies, as long-term bridge therapy (a temporary transition treatment) in patients awaiting cardiac transplant, or in some instances, as destination therapy for patients who are not appropriate candidates for transplantation.[1] The most common complications are infection and thromboembolism. Other adverse effects include bleeding, right ventricle failure, air embolism, device failure, and multiorgan failure.

▶ *Heart Transplant*

Heart transplantation represents the final option for refractory end-stage HF patients who have exhausted medical and device therapies. Heart transplantation should be considered a trade between a life-threatening syndrome and the risks associated with the operation and long-term immunosuppression. Assessment of appropriate candidates includes comorbid illnesses, psychosocial behavior, available financial and social support, and patient willingness to adhere to lifelong therapy and close medical follow-up.[1] Overall, the transplant recipient's quality of life may be improved, but not all patients receive this benefit. Posttransplant survival continues to improve due to advances in immunosuppression, treatment and prevention of infection, and optimal management of patient comorbidities.

Outcome Evaluation of Acute Heart Failure

- Focus on (a) acute improvement of symptoms and hemodynamics using IV therapies and (b) optimization of oral therapies.
- Monitor for rapid relief of symptoms related to the chief complaint on admission. This includes improvement of

Patient Encounter Part 4

After 6 months, the patient presents to the emergency department complaining of extreme SOB and fatigue at rest. He sleeps sitting up due to severe orthopnea and states he has gained 22 lb (10 kg) from his baseline weight. He has had a fever, cough, and nausea for the past 2 days. He states he has been compliant with his medications but has been drinking a lot of canned soup. He is admitted to the cardiac intensive care unit.

SH: Denies smoking and illicit drug use. Has one beer a day.

Meds: Aspirin 81 mg once daily, carvedilol 6.25 mg twice daily, enalapril 5 mg twice daily, spironolactone 12.5 mg twice daily, digoxin 0.25 mg once daily, atorvastatin 20 mg once daily

VS: BP 106/54 mm Hg, pulse 112 beats/min and regular, respiratory rate 24 breaths/min, temperature 38.1°C (100.6°F), Wt 276 lb (125 kg), BMI 41.9 kg/m^2

Lungs: Decreased breath sounds and rales present bilaterally

CV: JVP is 18 cm above sternal angle. Tachycardic with regular rhythm, with normal S_1 and S_2; there is an S_3 and an S_4; a 4/6 systolic ejection murmur is present and heard best at the left lower sternal border; point of maximal impulse is displaced laterally

Abd: Tense, tender, and bowel sounds are present; 3+ pitting edema of extremities is observed

CXR: Bilateral pleural effusions and cardiomegaly

Echo: EF = 20% (0.20)

Pertinent labs: NT-proBNP 2210 pg/mL (ng/L; 261 pmol/L), K: 3.4 mEq/L (mmol/L), BUN 64 mg/dL (22.8 mmol/L), SCr 2.4 mg/dL (212 μmol/L), Mg 1.8 mEq/L (0.9 mmol/L), digoxin 1.4 ng/mL (mcg/L; 1.8 nmol/L); a pulmonary catheter is placed, revealing the following: PCWP 32 mm Hg (4.3 kPa); CI 1.9 L/min/m^2 (0.032 L/s/m^2)

What NYHA functional class, ACC/AHA stage, and hemodynamic subset is the patient currently in?

What are your initial treatment goals?

What pharmacologic interventions are appropriate at this time?

Identify a monitoring plan to assess for efficacy and toxicity of the recommended drug therapy.

Once symptoms are improved, how could the oral medication therapy for this patient's HF be further optimized?

Patient Care Process

Collect Information:

- Obtain a thorough history of prescription, nonprescription, and herbal medication use.
- Review the patient's lifestyle habits including salt and alcohol intake, tobacco product use, exercise routine.
- Gather recent history of symptoms of congestion and hypoperfusion, including weight gain, swelling in extremities, etc.

Assess the Information:

- Assess the severity and duration of the patient's symptoms of HF and hypoperfusion, including limitations in activity. Rule out potential exacerbating factors. See Clinical Presentation and Diagnosis of Chronic Heart Failure textbox and Tables 7–1, 7–3, and 7–4.
- Review available diagnostic information from the chest radiograph, ECG, and echocardiogram. Investigate the patient's underlying etiology of HF.

Develop a Care Plan:

- Determine whether additional adjustment or new therapy is needed to address patient's acute and chronic conditions.
- Develop a treatment plan to alleviate symptoms and maintain euvolemia with diuretics (Tables 7–6 and 7–7). Daily weights to assess fluid retention are recommended.
- Develop a medication regimen to slow the progression of HF with the use of neurohormonal blockers such as vasodilators (ACE inhibitors, ARBs, sacubitril/valsartan, or hydralazine/isosorbide dinitrate), β-blockers, and aldosterone receptor antagonists (Tables 7–6 and 7–7). Utilize digoxin if the patient remains symptomatic despite optimization of the therapies just described, and ivabradine in patients with HR of 70 beats/min or higher despite optimization of β-blocker.

Implement the Care Plan:

- Ensure the patient is at goal or maximally tolerated doses of vasodilator and β-blocker therapy (Table 7–6), or titrate to the next dosing level if possible.
- Educate the patient on lifestyle modifications such as salt restriction (maximum 2 g/day), fluid restriction if appropriate, limitation of alcohol, tobacco cessation, participation in a cardiac rehabilitation and exercise program, and proper immunizations such as the pneumococcal vaccine and yearly influenza vaccine.
- Stress the importance of adherence to the therapeutic regimen and lifestyle changes for maintenance of a compensated state and slowing of disease progression.

Follow-up: Monitor and Evaluate:

- Monitor patient, including appropriate hemodynamic monitoring for AHF (Table 7–8), for desired outcomes.
- Evaluate the patient for presence of adverse drug reactions, drug allergies, and drug interactions.
- Provide patient education with regard to disease state and drug therapy and reinforce medication adherence and self-monitoring for symptoms of HF (eg, daily weights). Emphasize follow-up with healthcare practitioners.
- Assess changes in echocardiographic parameters from a follow-up echocardiography, ideally performed 2 months after medication optimization. Has the LVEF risen to above 40% (0.40)?

dyspnea, oxygenation, fatigue, JVD, and other markers of congestion or distress.

- Monitor for adequate perfusion of vital organs through assessment of mental status, urine output, CrCl, liver function tests, serum lactate, a stable HR between 50 and 100 beats/min, and normal acid–base balance.
- Monitor changes in hemodynamic variables if available. PCWP should decrease in volume-overloaded patients to a goal of less than 18 mm Hg (2.4 kPa). CI should increase, with a goal to maintain above 2.2 L/min/m^2 (0.037 L/s/m^2).
- Closely monitor BP, renal function, and intravascular volume status while decreasing preload with diuretics and vasodilators.
- Ensure patients are euvolemic or nearly euvolemic prior to discharge.
- Because oral therapies can both improve symptoms and prolong survival, optimizing outpatient HF management is a priority when preparing a patient for hospital discharge. Ensure the patient's regimen includes an ACE inhibitor, ARB, or ARNI, β-blocker, a diuretic at an adequate dose to maintain euvolemia, and aldosterone antagonist if appropriate.

Abbreviations Introduced in This Chapter

ACC/AHA	American College of Cardiology/American Heart Association
ACE	Angiotensin-converting enzyme
AHF	Acute heart failure
ANP	Atrial natriuretic peptide
ARB	Angiotensin receptor blocker
ARNI	Angiotensin receptor neprilysin inhibitor
AT_1	Angiotensin type 1 receptor
AT_2	Angiotensin type 2 receptor
ATP	Adenosine triphosphate
ATTR	Transthyretin amyloidosis
BMI	Body mass index
BNP	B-type natriuretic peptide
BPM	Beats/min
BP	Blood pressure
BSA	Body surface area
BUN	Blood urea nitrogen
CAD	Coronary artery disease
cAMP	Cyclic adenosine monophosphate
cGMP	Cyclic guanosine monophosphate
CI	Cardiac index
CNS	Central nervous system

CO	Cardiac output
COX-2	Cyclooxygenase-2
CrCL	Creatinine clearance
CVP	Central venous pressure
CYP	Cytochrome P-450 isoenzyme
D1	Dopamine receptor type 1
DBP	Diastolic blood pressure
DPP-4	Dipeptidyl peptidase-4 inhibitors
ECG	Electrocardiogram
EF	Ejection fraction
eGFR	Estimated glomerular filtration rate
ET-1	Endothelin-1
ET-A	Endothelin-A
ET-B	Endothelin-B
FDA	Food and Drug Administration
Gal-3	Galectin-3
GDMT	Guideline-directed medical therapies
GI	Gastrointestinal
HCN	Hyperpolarization-activated cyclic nucleotide-gated
HF	Heart failure
HFmrEF	Heart failure with mid-range ejection fraction
HFpEF	Heart failure with preserved ejection fraction
HFrEF	Heart failure with reduced ejection fraction
HFrecEF	Heart failure with recovered ejection fraction
HJR	Hepatojugular reflux
HR	Heart rate
hsTn	High-sensitivity troponin
IABC	Intra-aortic balloon counterpulsation
IABP	Intra-aortic balloon pump
IL	Interleukin
iNOS	Inducible nitric oxide synthetase
IV	Intravenous
JVD	Jugular venous distention
JVP	Jugular venous pressure
LV	Left ventricular
LVEF	Left ventricular ejection fraction
LVF	Left ventricular failure
MAP	Mean arterial pressure
MI	Myocardial infarction
MRA	Mineralocorticoid receptor antagonist
MR-proADM	Midregional proadrenomedullin
MVO_2	Myocardial oxygen consumption
NGAL	Neutrophil gelatinase-associated lipocalin
NOAC	Non–vitamin K oral anticoagulant
NSAID	Nonsteroidal anti-inflammatory drug
NT-proBNP	N-terminal proBNP
NYHA FC	New York Heart Association Functional Classification
PAC	Pulmonary artery catheter
PAD	Pulmonary artery diastolic
PAP	Pulmonary arterial pressure
PAS	Pulmonary artery systolic
PCWP	Pulmonary capillary wedge pressure
PND	Paroxysmal nocturnal dyspnea
PVR	Pulmonary vascular resistance
RAAS	Renin-angiotensin-aldosterone system
RVF	Right ventricular failure
SBP	Systolic blood pressure
SCr	Serum creatinine
sGC	Soluble guanylate cyclase
SGLT2	Sodium glucose cotransporter-2
SNS	Sympathetic nervous system
SOB	Shortness of breath
sST2	Soluble suppression of tumorigenicity-2
SV	Stroke volume
SVR	Systemic vascular resistance
TGF-β	Transforming growth factor-β
TNF-α	Tumor necrosis factor-α
V_{1a}	Vasopressin type 1a
V_2	Vasopressin type 2
VAD	Ventricular assist device

Stable Ischemic Heart Disease

Dejan Landup and Dawn Havrda

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of ischemic heart disease (IHD).
2. Differentiate between the pathophysiology of chronic stable angina and acute coronary syndromes (ACS).
3. Recognize symptoms and diagnostic criteria of IHD in a specific patient.
4. Compare and contrast the diagnostic criteria of IHD and ACS.
5. Identify treatment goals of stable ischemic heart disease (SIHD).
6. Identify appropriate lifestyle modifications and pharmacologic therapy to address each treatment goal.
7. Design an appropriate treatment regimen for the management of SIHD based on patient-specific information.
8. Formulate a monitoring plan to assess effectiveness and adverse effects of a SIHD drug regimen.

INTRODUCTION

Ischemic heart disease (IHD) is also called coronary heart disease (CHD) or coronary artery disease (CAD). The term *ischemic* refers to a decreased supply of oxygenated blood to the heart muscle. IHD is caused by stenosis, or narrowing, in one or more of the major coronary arteries that supply blood to the heart, most commonly by atherosclerotic plaques. Atherosclerotic plaques may impede coronary blood flow to the extent that cardiac tissue distal to the coronary artery narrowing is deprived of sufficient oxygen to meet oxygen demand. **KEY CONCEPT** IHD results from an imbalance between myocardial oxygen supply and oxygen demand (Figure 8–1). Common clinical manifestations of IHD include chronic stable angina and the acute coronary syndromes (ACS) of unstable angina (UA), non–ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI).

Angina pectoris, or simply angina, is the most common symptom of IHD. Angina is discomfort in the chest that occurs when the blood supply to the myocardium is compromised. Chronic stable angina is a chronic occurrence of chest discomfort due to transient myocardial ischemia with physical exertion or other conditions that increase myocardial oxygen demand. The primary focus of this chapter is management of stable ischemic heart disease (SIHD), the most common manifestation of which is chronic stable angina. However, some information is also provided related to ACS, given the overlap between the two disease states. The American College of Cardiology (ACC), the American Heart Association (AHA), and several other organizations have jointly published practice guidelines for the management of SIHD. Refer to these and related guidelines for further information.[1-3]

EPIDEMIOLOGY AND ETIOLOGY

IHD affects over 18 million Americans and is the leading cause of death for both men and women in the United States.[4] Incidence of IHD is higher in middle-aged men compared with women. However, the rate of IHD increases twofold to threefold in women after menopause. Chronic stable angina is the initial manifestation of IHD in about 50% of patients, whereas ACS is the first sign of IHD in other patients. Patients with SIHD experience considerable morbidity and frequently require hospitalization for chest pain and evaluation for potential ACS. In addition, SIHD negatively impacts health-related quality of life. Thus, in patients with SIHD, it is important to optimize pharmacotherapy to reduce symptoms, improve quality of life, slow disease progression, and prevent ACS.

Conditions Associated with Angina

Figure 8–2 shows the anatomy of the coronary arteries. The major epicardial coronary arteries are the left main, left anterior descending, left circumflex, and right coronary arteries. Atherosclerosis leading to obstructive lesions in one or more of the major coronary arteries or their principal branches is the major cause of angina. Vasospasm at the site of an atherosclerotic plaque may further constrict blood flow and contribute to angina. Less commonly, vasospasm in coronary arteries with no or minimal atherosclerotic disease can produce angina and even precipitate ACS. This uncommon form of angina is referred to as variant or Prinzmetal angina. Other nonatherosclerotic conditions that can cause angina-like symptoms are listed in Table 8–1.[1] It is important to differentiate the etiology of chest discomfort because treatment varies depending on the underlying disease process.

⇔ = No change
⇓ = Decreases
⇑ = Increases

FIGURE 8–1. This illustration depicts the balance between myocardial oxygen supply and demand and various factors that affect each. It should be noted that diastolic filling time is not an independent predictor of myocardial oxygen supply per se but rather a determinant of coronary blood flow. On the left is myocardial oxygen supply and demand under normal circumstances. On the right is the mismatch between oxygen supply and demand in patients with IHD. In patients without IHD, coronary blood flow increases in response to increases in myocardial oxygen demand. However, in patients with IHD, coronary blood flow cannot sufficiently increase (and may decrease) in response to increased oxygen demand, resulting in angina. (IHD, ischemic heart disease; Po_2, partial pressure of oxygen.)

Risk Factors

Major risk factors that predispose an individual to IHD are listed in Table 8–2. Both modifiable and nonmodifiable risk factors may be present that increase the risk for development of IHD. Patients with multiple risk factors, particularly those with diabetes, are at greatest risk for IHD, experiencing fivefold to sevenfold higher risk compared to individuals without risk factors.[4] Optimization of modifiable risk factors can significantly reduce risk of myocardial infarction (MI).[1] Hypertension, diabetes, dyslipidemia, and cigarette smoking are associated with endothelial damage and dysfunction and contribute to development of atherosclerosis. Physical inactivity and obesity independently increase risk for IHD, in addition to predisposing individuals to hypertension, dyslipidemia, and diabetes. **KEY CONCEPT** Early detection and aggressive modification of risk factors are among the primary strategies for delaying IHD progression and preventing IHD-related events including death.

PATHOPHYSIOLOGY

Determinants of myocardial oxygen supply and demand are shown in Figure 8–1. Increases in heart rate, cardiac contractility, and left ventricular wall tension increase the rate of myocardial oxygen consumption (MVO_2). Ventricular wall tension is a function of blood pressure (BP), systemic vascular resistance, left ventricular end-diastolic volume, and ventricular wall thickness. Physical exertion increases MVO_2 and commonly precipitates symptoms of angina in patients with significant coronary atherosclerosis.

Reductions in coronary blood flow (secondary to atherosclerotic plaques, vasospasm, or thrombus formation) and arterial oxygen content (secondary to hypoxia) decrease myocardial oxygen supply. Because the coronary arteries fill during diastole, decreases in diastolic filling time (eg, tachycardia) can also reduce coronary perfusion and myocardial oxygen supply. Anemia, carbon monoxide poisoning, and cyanotic congenital heart disease are examples of conditions that can lead to diminished myocardial oxygen delivery and precipitate angina in the face of adequate coronary perfusion.

Coronary Atherosclerosis

The normal arterial wall is illustrated in panel A of Figure 8–3. The intima consists of a layer of endothelial cells that line the lumen of the artery and form a selective barrier between the vessel wall and blood contents. Vascular smooth muscle cells are found in the media. The vascular adventitia comprises the artery's outer layer. Atherosclerotic lesions form in the subendothelial space in the intimal layer.

Endothelial damage and dysfunction, commonly caused by hypertension, diabetes, and smoking, allow low-density lipoprotein (LDL) cholesterol and inflammatory cells (eg, monocytes and T lymphocytes) to migrate from the plasma to the subendothelial space, as illustrated in Figure 13–4 in Chapter 13, "Dyslipidemia." The process begins by monocyte-derived macrophages ingesting lipoproteins to form foam cells. Macrophages also secrete growth factors that promote smooth muscle cell migration from the media to the intima. The result is development of early atherosclerosis in the form of a fatty streak consisting of lipid-laden macrophages and smooth muscle cells.

The fatty streak enlarges as foam cells, smooth muscle cells, and necrotic debris accumulate in the subendothelial space. A collagen matrix forms a fibrous cap that covers the lipid core of the lesion to establish an atherosclerotic plaque. The atherosclerotic

Table 8–1

Nonatherosclerotic Conditions That Can Cause Angina-Like Symptoms[1]

Organ System	Condition
Cardiac	**Aortic dissection**, **aortic stenosis**, coronary artery vasospasm, **pericarditis**, **valvular heart disease**, severe uncontrolled hypertension
Noncardiac	Anemia, anxiety disorders, carbon monoxide poisoning, chest wall trauma, cocaine use, esophageal reflux or spasm, peptic ulcer disease, **pleuritis**, pneumonia, **pneumothorax**, **pulmonary embolus**, **pulmonary hypertension**, **thyrotoxicosis**

plaque may progress until it protrudes into the artery lumen and impedes blood flow. When the plaque occludes 70% or more of a major coronary artery or 50% or more of the left main coronary artery, the patient may experience angina during activities that increase myocardial oxygen demand.

Compared with men, women with angina are more likely to present with microvascular disease.[5] Microvascular angina, also called cardiac syndrome X, refers to disease of the smaller coronary vessels causing typical angina in the absence of obstructive CAD of the epicardial arteries. Endothelial dysfunction and reduced smooth muscle relaxation, resulting in reduced vasodilation and enhanced vasoconstriction, are proposed to contribute to microvascular disease.

Stable Versus Unstable Atherosclerotic Plaques

The hallmark feature in the pathophysiology of SIHD is an established atherosclerotic plaque in one or more of the major coronary arteries that impedes coronary blood flow such that myocardial oxygen supply can no longer meet myocardial oxygen demand. In contrast, the hallmark feature in the pathophysiology of ACS is atherosclerotic plaque rupture with subsequent thrombus formation. Plaque rupture refers to fissuring of the fibrous cap and exposure of the plaque contents to elements in the blood. Plaque composition, rather than the degree of coronary stenosis, determines the stability of the plaque and the likelihood of rupture and ACS. As depicted in Figure 8–3B, a stable lesion characteristic of SIHD consists of a small lipid core surrounded by a thick fibrous cap that protects the lesion from the shear stress of blood flow. In contrast, an unstable plaque consists of a thin, weak cap covering a large lipid-rich core that renders the plaque vulnerable to rupture (Figure 8–3C). Transformation of a stable plaque into an unstable plaque involves degradation of the fibrous cap by substances released from macrophages and other inflammatory cells. Following plaque rupture, platelets adhere to the site of rupture (Figure 8–3D), aggregate (Figure 8–3E), and generate thrombin leading to the development of a fibrin clot (Figure 8–3F). Coronary thrombi extend into the vessel lumen, where they partially or completely occlude blood flow, potentially resulting in UA or MI.

Unstable plaque often produces minimal occlusion of the coronary vessel, and the patient remains asymptomatic until the plaque ruptures. In fact, many ACS arise from vulnerable plaques that occlude less than 50% of the coronary lumen.[6]

Table 8–2

Major Risk Factors for Ischemic Heart Disease

Modifiable	Nonmodifiable
Cigarette smoking Dyslipidemia • Elevated LDL or total cholesterol • Reduced HDL cholesterol Diabetes mellitus Hypertension Physical inactivity Obesity (body mass index ≥ 30 kg/m^2) Low daily fruit and vegetable consumption Alcohol overconsumption	Age ≥ 45 years for men, age ≥ 55 years for women Gender (men and postmenopausal women) Family history of premature cardiovascular disease, defined as cardiovascular disease in a male first-degree relative (ie, father or brother) < 55 years or a female first-degree relative (ie, mother or sister) < 65 years

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Coronary Artery Vasospasm

Prinzmetal or variant angina results from spasm (or vasoconstriction) of a coronary artery in the absence of significant atherosclerosis. Variant angina usually occurs at rest, especially in the early morning hours. Although vasospasm is generally transient, it may persist long enough to cause myocardial ischemia and subsequent infarction. Patients with variant angina are typically younger than those with chronic stable angina and often do not possess the classic risk factors for IHD. The cause of variant angina is unclear but appears to involve vagal withdrawal, endothelial dysfunction, and paradoxical response to agents that normally cause vasodilation. Precipitants of variant angina include cigarette smoking, cocaine or amphetamine use, hyperventilation, and exposure to cold temperatures. Management of variant angina differs from that of classic angina, and it is important to distinguish between the two. However, patients with IHD may also present with vasospasm, and though the pathophysiology and management may differ, the two are not mutually exclusive.

CLINICAL PRESENTATION AND DIAGNOSIS

History

Evaluation of a patient with suspected IHD begins with a detailed history of symptoms. **KEY CONCEPT** The classic presentation of angina is described in the Clinical Presentation and Diagnosis text box. Patients may present with typical symptoms of angina, atypical symptoms of angina, or a combination of both. Identification of an atypical presentation is vital as some individuals with IHD may present without any of the classic symptoms of angina. Chronic stable angina should be distinguished from UA because the latter is associated with a greater risk for MI and death and requires hospitalization for more aggressive treatment. Because the pathophysiology of SIHD is due primarily to increases in oxygen demand rather than acute changes in oxygen supply, symptoms are typically reproducible when provoked by exertion, exercise, or stress. The exception may be a patient with coronary artery vasospasm, in whom symptoms may be more variable and unpredictable. In contrast to SIHD, ACS generally occurs in response to an acute decrease in coronary blood flow leading to inadequate oxygen supply. Consequently, ACS is marked by prolonged symptoms, often occurring at rest, or an escalation in the frequency or severity of angina over a short period of time. Presentation of UA is described in Table 8–3.[7]

FIGURE 8–3. Pathophysiology of chronic stable angina versus acute coronary syndromes. **Panel A** depicts the cross-section of a normal coronary artery. **Panel B** depicts the cross-section of a coronary artery with a stable atherosclerotic plaque. Note that the lipid core is relatively small in size and the fibrous cap is made up of several layers of smooth muscle cells. **Panel C** depicts an unstable atherosclerotic plaque with a larger lipid core, and a thin fibrous cap composed of a single layer of smooth muscle cells with a fissure or rupture. **Panel D** depicts platelet adhesion in response to the fissured plaque. Platelet activation may ensue, leading to platelet aggregation as fibrinogen binds platelets to one another to form a mesh-like occlusion in the coronary lumen (**Panel E**). At this stage, patients may experience symptoms of acute coronary syndrome. If endogenous anticoagulant proteins fail to halt this process, platelet aggregation continues and fibrinogen is converted to fibrin, resulting in an occlusive thrombus (**Panel F**).

Table 8–3

Presentations of Acute Coronary Syndromes[7]

- Angina at rest that is prolonged in duration, usually lasting 10 minutes or more
- Angina of recent onset that markedly limits usual activity
- Angina that increases in severity (ie, by Canadian Cardiovascular Society Classification System Class of one level or greater [Table 8–4]), frequency, or duration, or that occurs with less provocation over a short time period (ie, within 2 months)

Clinical Presentation and Diagnosis of Ischemic Heart Disease

General

- Patients with SIHD will generally be in no acute distress. In patients presenting in acute distress, the clinician should be suspicious of ACS.

Symptoms of Angina Pectoris

- The five components used to characterize chest pain are quality, location, duration, provoking factors, and mitigating factors.
- Patients typically describe pain as a sensation of pressure, heaviness, tightness, or squeezing in the anterior chest area. Sharp pain and pain reproducible by palpation are not typical symptoms of angina.
- Pain may radiate to the neck, jaw, shoulder, back, or arm.
- Pain may be accompanied by dyspnea, nausea, vomiting, or **diaphoresis**.
- Pain typically persists for several minutes.
- Symptoms are often provoked by exertion (eg, walking, climbing stairs) or emotional stress and relieved within minutes by rest or sublingual nitroglycerin. Other precipitating factors include exposure to cold temperatures and heavy meals. Pain that occurs at rest (without provocation) or that is prolonged and unrelieved by sublingual nitroglycerin is indicative of ACS.
- Some patients, most commonly women, the elderly, and patients with diabetes, may present with atypical symptoms including indigestion, gastric fullness, back pain, and shortness of breath. Patients with diabetes and the elderly may experience associated symptoms, such as dyspnea, diaphoresis, nausea, fatigue, and dizziness, without having any of the classic angina symptoms.
- In some cases, "silent ischemia" occurs in which patients are asymptomatic.

Signs

- Findings on physical examination are often normal with SIHD. However, during episodes of ischemia, patients may present with abnormal heart sounds, such as paradoxical splitting of the second heart sound, a third heart sound, or a loud fourth heart sound.

Laboratory Tests

- Cardiac troponin (troponin I or troponin T) is the most sensitive biomarker to detect myocardial damage and is elevated in MI but typically normal in SIHD and UA.
- Hemoglobin, fasting glucose, and fasting lipid profile should be determined for assessing cardiovascular risk factors and establishing the differential diagnosis.

Other Diagnostic Tests

- A 12-lead electrocardiogram (ECG) recorded during rest is often normal in patients with SIHD in the absence of active ischemia. Significant Q waves may indicate prior MI. ST-segment changes (ST-segment depression or elevation) or T-wave inversion in two or more contiguous leads during symptoms of angina support the diagnosis of IHD. ST-segment depression or T-wave inversion may be observed in chronic stable angina, UA, and NSTEMI, whereas ST-segment elevation occurs with STEMI and Prinzmetal (variant) angina.
- Treadmill or bicycle exercise ECG, commonly referred to as a "stress test," is considered positive for IHD if the ECG shows at least a 1-mm deviation of the ST segment (depression or elevation).
- Wall motion abnormalities or left ventricular dilation with stress echocardiography or cardiac magnetic resonance (MR) (exercise or pharmacological) are indicative of IHD.
- Perfusion abnormalities can be detected by stress myocardial perfusion imaging using either radionuclides technetium-99m sestamibi or thallium-201 or cardiac MR (with or without late gadolinium enhancement).
- Coronary angiography detects the location and degree of coronary atherosclerosis and is used to evaluate the potential benefit from revascularization procedures. Stenosis of at least 70% of the diameter of at least one of the major epicardial arteries (50% or greater for the left main coronary artery) on coronary angiography is indicative of significant IHD.
- Coronary angiography may be normal with microvascular angina.

Canadian Cardiovascular Society Classification System

The Canadian Cardiovascular Society Classification System (Table 8–4) is commonly used to assess the degree of disability resulting from IHD.[8] Patients are categorized into one of four classes depending on the extent of activity that produces angina. Grouping patients according to this or a similar method is commonly used to assess changes in IHD severity over time and the effectiveness of pharmacologic therapy.

Table 8–4

Canadian Cardiovascular Society Classification System of Angina[8]

Class	Description
I	Able to perform ordinary physical activity (eg, walking, climbing stairs) without symptoms. Strenuous, rapid, or prolonged exertion causes symptoms.
II	Symptoms slightly limit ordinary physical activity. Walking rapidly or for more than two blocks, climbing stairs rapidly, or climbing more than one flight of stairs causes symptoms.
III	Symptoms markedly limit ordinary physical activity. Walking less than two blocks or climbing one flight of stairs causes symptoms.
IV	Angina may occur at rest. Any physical activity causes symptoms.

Physical Findings and Laboratory Analysis

A thorough medical history, physical examination, and laboratory analysis are necessary to ascertain cardiovascular risk factors and to exclude nonischemic and noncardiac conditions that could mimic angina-like symptoms. Laboratory analyses should assess for glycemic control (ie, fasting glucose, hemoglobin A_{1c}), fasting lipids, hemoglobin, and organ function (ie, blood urea nitrogen, creatinine, liver function tests, thyroid function tests). For patients with ACS, serial measurements of cardiac troponin (usually 2–3 measurements over a period of 3–12 hours) are performed to exclude the diagnosis of an acute MI. Cardiac findings on the physical examination are often normal in patients with SIHD. However, findings such as carotid bruits, abdominal and/or renal bruits, or abnormal peripheral pulses would indicate atherosclerosis in other vessel systems and raise the suspicion for IHD.

Diagnostic Tests

A resting 12-lead ECG is indicated in all patients with new or worsening symptoms of ischemia. Patients with characteristic chest discomfort, accompanied by ST-segment elevation in two or more contiguous leads, or a new left bundle branch block are often diagnosed with MI (STEMI) and are at the highest risk of death. Consequently, STEMI is treated as a medical emergency. For patients with ACS, cardiac troponin is measured serially to distinguish between MI (elevated cardiac troponin) and either UA or noncardiac causes of chest discomfort (normal cardiac troponin).

"Stress" testing with either exercise or pharmacologic agents increases myocardial oxygen demand and is commonly used to evaluate the patient with suspected IHD. Approximately 50% of patients with IHD who have a normal ECG at rest will develop ECG changes with exercise on a treadmill or bicycle ergometer. Dobutamine is a common pharmacologic agent administered as an intravenous (IV) infusion to patients who are unable to exercise. Dobutamine increases oxygen demand by stimulating the β_1-receptor, increasing heart rate and contractility. Echocardiography is commonly performed along with exercise or dobutamine to identify stress-induced wall motion abnormalities of the left ventricle indicative of IHD.

Exercise or pharmacologic agents are also commonly combined with radionuclide myocardial perfusion imaging (nuclear imaging studies) or cardiac MR to detect IHD. An IV radioactive tracer is administered and accumulates in normal myocytes in proportion to coronary blood flow. Adenosine, dipyridamole, and regadenoson are coronary vasodilators that increase coronary blood flow in healthy arteries but not in atherosclerotic vessels. Radionuclide myocardial perfusion imaging is performed at rest and following exercise or pharmacologic stressor to detect perfusion defects indicative of IHD. Similar to other myocardial perfusion imaging, stress cardiac MR can detect wall motion abnormalities as well as perfusion defects, the latter often performed using late gadolinium enhancement, to determine the extent and severity of myocardial scarring that may be present.

Coronary artery calcium scoring via computed tomography (CT) may be performed as a noninvasive means to assess for IHD. Calcium deposits within the atherosclerotic coronary arteries are detected on CT, a calcium score is calculated, and risk for IHD-related events is estimated.

Coronary angiography (also referred to as a cardiac catheterization or "cardiac cath") is indicated when stress testing results are either abnormal or inconclusive, symptoms of angina are poorly controlled, or in patients for whom the clinical suspicion of IHD remains high despite a normal stress test result. Angiography involves catheter insertion into either the femoral or radial artery with advancement of the catheter into the ascending aorta near the coronary ostia. Contrast medium is injected through the catheter into the coronary arteries, and fluoroscopy is performed to visualize the coronary anatomy and detect IHD. The decision to establish the diagnosis of IHD via stress testing, coronary angiography, or both is often individualized for each patient based on several factors including baseline assessment of IHD risk (eg, pretest probability), sensitivity and specificity of the diagnostic test, results of previous diagnostic tests, and risk for complications (eg, contrast nephropathy).

TREATMENT

Desired Outcomes

Once a patient is diagnosed with IHD, the clinician should provide counseling on lifestyle modifications, institute appropriate pharmacologic therapy, and evaluate the need for revascularization. Optimal medical therapy is essential for managing patients with SIHD. **KEY CONCEPT** The major goals for the treatment of SIHD are to:

- Prevent ACS and death
- Alleviate acute symptoms of angina
- Prevent recurrent symptoms of angina
- Prevent progression of the disease
- Reduce complications of IHD
- Avoid or minimize adverse treatment effects

The treatment approach to address these goals is illustrated in Figure 8–4.

General Approach to Treatment

Primary strategies for preventing ACS and death (eg, primary or secondary prevention) are to:

- Aggressively modify cardiovascular risk factors
- Slow the progression of coronary atherosclerosis
- Stabilize existing atherosclerotic plaques

The treatment algorithm in Figure 8–5 summarizes the appropriate management of IHD. Risk factor modification is accomplished through lifestyle changes and pharmacologic therapy. **KEY CONCEPT** Both 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (HMG-CoA reductase inhibitors or statins) and angiotensin-converting enzyme (ACE) inhibitors possess vasculoprotective effects (eg, anti-inflammatory effects, antiplatelet effects, improvement in endothelial function, and/or improvement in arterial compliance and tone). Together with aspirin,

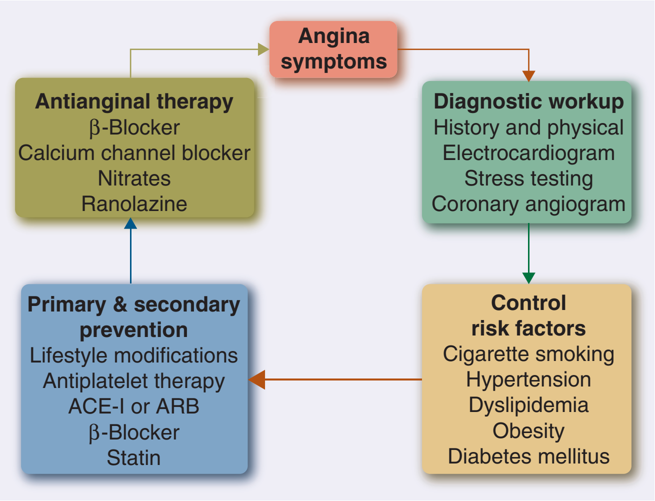

FIGURE 8–4. General treatment strategies for angina follow in clockwise fashion from the top center. (ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.)

Consider triple therapy β-blocker + CCB + LA nitrate or ranolazine
Consider revascularization (eg, PCI or CABG surgery)

FIGURE 8–5. Treatment algorithm for ischemic heart disease. It begins at the top (blue section), which suggests risk factor modifications as the first treatment modality. Moving down to the green section, appropriate antiplatelet therapy is selected. The purple section identifies patients at high risk for major adverse cardiac events (MACE) and suggests appropriate drug therapy to decrease cardiovascular risk. The orange section at the bottom recommends appropriate antianginal therapy. [a]The minimum duration of $P2Y_{12}$ inhibitors in combination with aspirin (dual antiplatelet therapy) following intracoronary stent placement is as follows: at least 1 month for BMSs and at least 6 months for DESs for patients with stable ischemic heart disease, and at least 12 months in patients with stents placed for ACS regardless of stent type. (ACE-I, angiotensin-converting enzyme inhibitor; ACS, acute coronary syndrome; ARB, angiotensin receptor blocker; BMS, bare metal stent; BP, blood pressure; CABG, coronary artery bypass graft; CCB, calcium channel blocker; DES, drug-eluting stent; HR, heart rate; IR, immediate release; LA, long acting; LV, left ventricular; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SL, sublingual.)

these drugs reduce the risk of acute coronary events and death in patients with SIHD. In select patients with IHD (following hospitalization for ACS ± percutaneous coronary intervention [PCI] and/or following intracoronary stent placement), dual antiplatelet therapy (DAPT) with aspirin and a $P2Y_{12}$ antagonist has also been shown to reduce ischemic events. Angiotensin receptor blockers (ARBs) may be used in patients who cannot tolerate ACE inhibitors because of side effects (eg, chronic cough). β-Blockers decrease morbidity and improve survival in patients who have suffered an MI, particularly in patients with concomitant heart failure with reduced ejection fraction (HFrEF).

The goal of therapies that alleviate and prevent angina is improving the balance between myocardial oxygen demand and supply. Drug treatment is primarily used to reduce oxygen

Patient Encounter Part 1

A 62-year-old woman with a history of hypertension, diabetes, and dyslipidemia presents to your clinic complaining of chest pain occurring several times in the past month. The pain is described as tightness in the anterior chest area and is accompanied by back pain, nausea, and shortness of breath. Occasionally, the pain extends down to her left arm. She first noticed the discomfort while walking up two flights of stairs. Since then, she experienced the same symptoms while exercising and carrying groceries from the store. In each instance, the pain resolved after 5 minutes of rest.

What information is suggestive of angina?

What tests would be beneficial in establishing a diagnosis?

What additional information do you need to create a treatment plan for this patient?

demand, whereas revascularization by PCI and coronary artery bypass graft (CABG) surgery effectively restore coronary blood flow, improving myocardial oxygen supply.

Adverse treatment effects can be averted by avoiding drug interactions and the use of drugs that may have unfavorable effects on comorbid diseases. Appropriate drug dosing and monitoring reduces the risk for adverse treatment effects. Drugs should be initiated in low doses, with careful uptitration as necessary to control symptoms of angina and cardiovascular risk factors.

Lifestyle Modifications

Lifestyle modifications (smoking cessation, dietary modifications, increased physical activity, and weight loss) reduce cardiovascular risk factors, slow the progression of IHD, and decrease the risk for SIHD-related complications. Cigarette smoking is one of the most preventable causes of SIHD and SIHD-related death. Smoking may also attenuate the antianginal effects of drug therapy. Clinicians should counsel patients and/or family members who smoke on the importance of smoking cessation at each encounter and offer referral to smoking cessation programs. There are several pharmacologic aids (transdermal nicotine replacement therapy, bupropion, and varenicline) for smoking cessation that are efficacious and safe in patients at risk for or with IHD.[9] Varenicline, a partial nicotine receptor agonist, and bupropion have been associated with worsening of preexisting depression and suicidal ideation. The drugs have been studied in smokers with and without psychiatric disorders, and no increase in neuropsychiatric adverse effects were found.[10] Weight loss, through lifestyle interventions of caloric restriction and increased physical activity, should be encouraged in patients who have a body mass index greater than 25 kg/m^2. Dietary counseling should be provided to all patients with newly diagnosed angina regardless of weight. The AHA recommends a diet that includes a variety of fruits, vegetables, whole grains, fish, nuts, and legumes. Processed meats, refined carbohydrates, and sweetened beverages should be minimized and *trans* fats should be avoided.[11] The addition of phytosterols (1–3 g/day) and/or soluble/viscous fiber (3.0–12.4 g/day) are effective in lowering LDL cholesterol.[12] Specific dietary recommendations for patients with IHD should include the following[1,11]:

- Limit cholesterol intake to less than 200 mg/day.
- Limit consumption of saturated fat to less than 7% and *trans* fatty acids to less than 1% of total calories.
- Limit daily sodium intake to less than 1500 mg for BP control.
- Limit alcohol consumption to one drink/day for women and one to two drinks/day for men unless otherwise contraindicated.

Exercise facilitates weight loss, BP reduction, and glycemic control. In addition, regular exercise in patients with SIHD improves functional capacity, reduces symptoms of angina, and reduces mortality.[1,13] Guidelines recommend moderate-intensity aerobic

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension, diagnosed 12 years ago; diabetes, diagnosed 6 years ago; dyslipidemia, diagnosed 6 years ago; osteoarthritis, diagnosed last year

FH: Father with CAD, died of MI at age 52 years; mother with CAD and heart failure diagnosed at age 60 years

SH: Active smoker, 30-year pack history; denies alcohol or illicit drug use; no regular exercise program

Meds: Aspirin 81 mg PO daily, chlorthalidone 25 mg PO daily, metoprolol extended-release 25 mg PO daily, metformin 1000 mg PO twice daily, simvastatin 20 mg PO daily, ibuprofen 600 mg PO twice daily

Allergies/intolerances (reaction): No known drug allergies nor intolerances

PE:

VS: BP 146/88 mm Hg, HR 80 beats/min, RR 18 breaths/min, T 37°C (98.6°F), Ht 5 ft 7 in (170 cm), Wt 230 lb (104.3 kg)

Cardiovascular: Regular rate and rhythm, normal S_1 and S_2, no S_3 or S_4; no murmurs, rubs, gallops; + carotid bruit

Lungs: Clear to auscultation and percussion

Abd: Nontender, nondistended, + bowel sounds

Ext: No clubbing, cyanosis, or edema

Labs: Fasting lipid profile: total cholesterol 200 mg/dL (5.17 mmol/L), HDL cholesterol 40 mg/dL (1.03 mmol/L), LDL cholesterol 134 mg/dL (3.47 mmol/L), triglycerides 130 mg/dL (1.47 mmol/L); fasting glucose 190 mg/dL (10.5 mmol/L); hemoglobin A_{1c} 8.4% (0.084; 68 mmol/mol Hb); other laboratory values within normal limits

Dobutamine stress echocardiography: Concentric left ventricular hypertrophy, left ventricular ejection fraction at rest 40% (0.4), regional wall motion abnormalities during peak exercise suggestive of ischemia

Identify the patient's risk factors for SIHD.

How might her current drug regimen adversely affect the patient's SIHD?

Does she appear to have any SIHD-related complications?

What therapeutic alternatives are available to manage her SIHD?

activity, such as brisk walking, ideally for at least 150 minutes per week (eg, 30–60 minutes at least 5 and preferably 7 days weekly) and reducing sedentary behaviors (low energy expenditure in a sitting or reclining posture).[1,11] Medically supervised cardiac rehabilitation programs are recommended for high-risk patients.

Interventional Approaches to Revascularization

▶ *Percutaneous Coronary Intervention*

For patients with SIHD, optimal medical therapy is equivalent to PCI in reducing major adverse cardiac events (MACE), which include death, nonfatal MI, and revascularization.[14] Therefore, medical therapy is preferred as the initial treatment strategy. However, when optimal medical therapy fails, symptoms are unstable, or extensive coronary atherosclerosis is present (eg, > 70% occlusion of coronary lumen), PCI is often performed to restore coronary blood flow and relieve symptoms. Several catheter-based interventions may be used during PCI, including:

- Percutaneous transluminal coronary angioplasty (PTCA)
- Intracoronary bare metal stent (BMS) placement
- Intracoronary drug-eluting stent (DES) placement
- Rotational atherectomy

During PCI, a catheter is advanced into the diseased coronary artery, as described for cardiac catheterization. If PTCA is performed, a balloon at the end of the catheter is inflated inside the artery at the site of the critical stenosis, compressing the atherosclerotic plaque from the coronary lumen and restoring normal myocardial blood flow. Most PCI procedures involve the placement of a stent, a small metal scaffold-like device similar in size and shape to the spring at the tip of a ballpoint pen, at the site of angioplasty. Either a BMS or a DES may be used. Drug-eluting stents are impregnated with low concentrations of an antiproliferative drug (paclitaxel, everolimus, sirolimus, or zotarolimus), which is released locally over a period of weeks to inhibit in-stent restenosis of the coronary artery after PCI. Compared to BMS, DESs have been associated with a significant reduction in all-cause mortality for patients with IHD.[15] Stents are thrombogenic, especially until they become endothelialized (covered in endothelial cells like a normal coronary artery). To reduce risk for in-stent thrombosis, MI, or death, DAPT (discussed later) is required until the stent becomes endothelialized. Lastly, rotational atherectomy may be performed wherein a special catheter is used to essentially cut away the atherosclerotic plaque, restoring coronary blood flow.

▶ *Coronary Artery Bypass Graft Surgery*

As an alternative to PCI, CABG surgery, or open-heart surgery, may be performed if the patient is found to have extensive coronary atherosclerosis (generally > 70% occlusion of three or more coronary arteries) or is refractory to optimal medical treatment. In the former case, evidence suggests that CABG surgery is associated with a reduction in both the need for revascularization and mortality compared with PCI, particularly in patients with diabetes.[16] During CABG surgery, veins from the leg (ie, saphenous veins) and/or arteries from the chest wall (ie, internal mammary arteries) or less commonly from the arm (ie, radial artery) or stomach (gastroepiploic artery) are harvested and used as conduits to restore coronary blood flow. A median sternotomy, in which an incision is made the length of the sternum followed by surgical division of the sternum with an oscillating saw, is commonly required to gain access to the thoracic cavity and expose the heart. As the "new" blood vessels are being engrafted, the patient is typically placed on cardiopulmonary bypass (ie, heart-lung machine) to maintain appropriate myocardial and systemic perfusion. Because of its extremely invasive nature, CABG surgery is generally reserved for patients with extensive IHD or as a treatment of last resort in patients with symptoms refractory to medical therapy.

Pharmacologic Therapy

▶ *Pharmacotherapy to Prevent Acute Coronary Syndromes and Death*

Control of Risk Factors

A major component of any SIHD treatment plan is control of modifiable risk factors, including dyslipidemia, hypertension, and diabetes. Treatment strategies for dyslipidemia, hypertension, and diabetes in the patient with IHD are summarized in the following paragraphs. Visit chapters in this textbook on the management of hypertension (see Chapter 6), dyslipidemia (see Chapter 13), and diabetes mellitus (see Chapter 44) for further information.

Because lipoprotein metabolism and the pathophysiology of atherosclerosis are closely linked, treatment of dyslipidemias is critical for both primary and secondary prevention of IHD-related cardiac events. In 2018, the ACC/AHA revised guidelines for the management of patients with dyslipidemia.[17] In addition to lifestyle modifications with diet and exercise, statins remain the foundation of pharmacologic therapy in patients with atherosclerotic cardiovascular disease (ASCVD). Ezetimibe, bile acid sequestrants, and proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors can be added to statin therapy in select cases. Recommendations for treatment of dyslipidemia in patients with IHD include:

- High-intensity or maximally tolerated statin in very high-risk patients with ASCVD, as defined by a history of multiple major ASCVD events or one major event and multiple high-risk conditions (see the 2018 ACC/AHA blood cholesterol guidelines for definitions of major ASCVD events and high-risk conditions).
- High-intensity statin in patients less than or equal to 75 years of age with ASCVD who are not considered very high risk. If high-intensity statin is not tolerated, a moderate-intensity statin can be used.
- Moderate- to high-intensity statin therapy for patients greater than 75 years of age with ASCVD who are not considered very high risk.
- Consideration for ezetimibe in individuals with clinical ASCVD on maximally tolerated statin therapy with LDL cholesterol greater than or equal to 70 mg/dL (1.81 mmol/L).
- Consideration for PCSK9 inhibitors in patients on maximally tolerated LDL-lowering therapy (maximally tolerated statin and ezetimibe) with LDL cholesterol greater than or equal to 70 mg/dL (1.81 mmol/L) or non-high-density lipoprotein (non-HDL) cholesterol greater than or equal to 100 mg/dL (2.59 mmol/L).

Hypertension is another major, modifiable risk factor for the development of IHD and related complications. Aggressive identification and management of hypertension are warranted in patients with SIHD to minimize the risk of MACE. In 2017, the ACC/AHA released updated guidelines for the management of hypertension in adults, with specific recommendations for patients with SIHD.[18] Patients with SIHD and a BP of 130/80 mm Hg or higher should be started on antihypertensive therapy to reduce BP to a target of less than 130/80 mm Hg. Selection of initial agent is guided by the presence of compelling indications (eg, chronic stable angina, HFrEF, previous MI). β-Blockers (except atenolol and β-blockers with intrinsic sympathomimetic activity), ACE inhibitors, or ARBs are all recommended as first-line therapy in these patients. For patients who remain hypertensive (BP > 130/80 mm Hg) despite treatment with a β-blocker, ACE inhibitor, or ARB, additional medications should be added to further reduce BP to target. Choice of agent is dependent on the presence of angina symptoms. For patients with uncontrolled hypertension with angina, addition of a dihydropyridine calcium channel blocker (CCB) is recommended. For patients with SIHD whose angina symptoms are controlled, addition of dihydropyridine CCBs, thiazide diuretics, and/or mineralocorticoid receptor antagonists (MRAs) may all be considered.

As with dyslipidemia and hypertension, diabetes is a significant, modifiable risk factor for IHD.[4] Cardiovascular disease remains the predominant cause of morbidity and mortality in patients with diabetes. Treatment guidelines now provide specific recommendations for patients with diabetes and cardiovascular disease with a focus on medications with a proven cardiovascular benefit.[19] Two classes of medications, sodium-glucose cotransporter 2 (SGLT2) inhibitors and glucagon-like peptide 1 (GLP-1) receptor agonists, have shown to improve cardiovascular outcomes in patients with clinical ASCVD or at high risk for IHD. The SGLT2 inhibitors empagliflozin and canagliflozin have both shown to decrease MACE in patients with diabetes and ASCVD. GLP-1 receptor agonists, specifically liraglutide, semaglutide, and dulaglutide, have demonstrated a reduction in MACE in patients with diabetes and IHD. Given the cardiovascular endpoints seen in trials with SGLT2 inhibitors and GLP-1 receptor agonists, treatment guidelines were updated to include specific recommendations based on the presence or absence of ASCVD. For patients with diabetes in whom ASCVD predominates, consideration for GLP-1 receptor agonists with a proven cardiovascular benefit is recommended, independent of hemoglobin A_{1c}, either as an addition to metformin or single therapy in patients intolerant to or unable to take metformin. For patients who cannot tolerate GLP-1 receptor agonists or if GLP-1 receptor agonists cannot be used, substitution with an SGLT2 inhibitor with a proven cardiovascular benefit is recommended, provided there are no contraindications. Lastly, in select patients requiring further glycemic control, a combination of SGLT2 inhibitors and GLP-1 receptor agonists may be utilized.

Antiplatelet Agents Platelets play a major role in the pathophysiology of ACS. Thromboxane A_2 (TXA_2) is a potent platelet activator. Aspirin inhibits cyclooxygenase, an enzyme responsible for the production of TXA_2, thereby inhibiting platelet activation and aggregation. In patients with IHD, aspirin has been consistently shown to reduce risk of MACE, particularly MI.[20] **KEY CONCEPT** Antiplatelet therapy with aspirin should be considered for all patients with SIHD, particularly in patients with a history of MI, in the absence of contraindications. Aspirin doses of 75 to 162 mg daily are recommended in patients with or at risk for SIHD.[1,3,21] Daily doses of aspirin above 162 mg offer no additional benefit but increase bleeding risk. If aspirin is contraindicated (eg, aspirin allergy) or is not tolerated by the patient, an alternative antiplatelet agent such as clopidogrel should be considered.[1]

Binding of adenosine diphosphate to the $P2Y_{12}$ receptors on platelets activates glycoprotein IIb/IIIa receptors leading to platelet aggregation and thrombus formation. **KEY CONCEPT** Inhibition of the $P2Y_{12}$ receptor with either a thienopyridine (clopidogrel, prasugrel) or ticagrelor prevents platelet aggregation and is indicated in combination with aspirin in select patients with IHD. DAPT with aspirin and a $P2Y_{12}$ inhibitor is recommended following hospitalization for ACS and/or following PCI with stent placement to prevent ischemic events, although indications for specific drugs differ slightly.[3,7,22] Clopidogrel is a prodrug that is converted via a two-step process to its active thiol metabolite. The cytochrome P450 (CYP) 2C19 enzyme is involved in both steps of the biotransformation. Individuals with reduced CYP2C19 activity, either from inherited deficiencies of CYP2C19 or use of CYP2C19 inhibitors (eg, proton pump inhibitors), may produce less of the active thiol metabolite. These individuals are at increased risk for stent thrombosis and MACE during clopidogrel treatment compared to those with "normal" CYP2C19 activity.[23] Clopidogrel labeling now warns of reduced effectiveness in CYP2C19 poor metabolizers, who carry two dysfunctional *CYP2C19* gene alleles. The *CYP2C19*2* and *CYP2C19*3* alleles are the most common alleles leading to reduced CYP2C19 activity.

Prasugrel is a thienopyridine that also requires biotransformation to its active metabolite. However, unlike clopidogrel, CYP2C19 deficiency does not alter its effectiveness. Ticagrelor is a direct-acting $P2Y_{12}$ inhibitor that does not require biotransformation to exert its antiplatelet effects and is unaffected by CYP2C19 activity. Thus, prasugrel or ticagrelor may be suitable alternatives to clopidogrel when reduced CYP2C19 activity is suspected.

Antiproliferative drugs in DES reduce the risk of in-stent restenosis but delay endothelialization. Until endothelialization occurs, platelets are exposed to the foreign surface of the stent and can stimulate platelet adhesion, activation, aggregation, and eventual thrombus formation within the implanted stent resulting in acute ischemia. Thus, a longer period of DAPT is recommended in patients with SIHD treated with DES compared with BMS to prevent in-stent thrombosis. Following BMS implantation, patients with SIHD should be treated with DAPT for a minimum of 1 month compared to a minimum of 6 months following DES implantation.[3] In contrast to patients with SIHD, a longer duration of DAPT (minimum of 12 months) is recommended for patients who have had stent implantation in the setting of ACS, regardless of the type of stent implanted. Select patients with IHD who have not experienced a bleeding complication on DAPT and are not at high risk for bleeding (eg, prior bleeding on DAPT, coagulopathy, oral anticoagulant use) may be considered for "prolonged" or "extended" duration of DAPT (> 1 month in SIHD with BMS, > 6 months in SIHD with DES, > 12 months in ACS with either BMS or DES) to further reduce the risk of ischemic complications, including late in-stent thrombosis and spontaneous MI, but at the expense of an increased risk of bleeding. Conversely, patients who experience a significant bleeding complication are at high risk for bleeding or have a high risk of severe bleeding complications (eg, major intracranial surgery) may be considered for a shorter duration of DAPT (3 months for SIHD with DES, 6 months after ACS with stent implantation). Given the delicate balance between benefit and harm associated with prolonged DAPT following stent implantation, risk stratification tools may be useful to individualize the decision on DAPT duration by predicting patients who will derive benefit.[3,24] Several scoring tools were developed to guide clinicians in the decision-making process regarding the ideal DAPT duration in an individual patient. The "PRECISE-DAPT score" and the "DAPT score" (Table 8–5) can be used to complement clinical decision making, with the former calculated at the time of PCI with coronary stenting and the latter after completing 12 months of DAPT.[3,25] Utilization of these risk scores can help individualize therapy, determine the net clinical benefit of a specific DAPT duration, and minimize ischemic and bleeding complications.

Table 8–5

"PRECISE-DAPT" and "DAPT" Score Calculation to Guide Dual Antiplatelet Therapy (DAPT) Duration Following Stent Implantation[3,24,25]

<table>
<tr><th></th><th>PRECISE-DAPT Score</th><th>DAPT Score</th></tr>

</table></td></tr>
<tr><td>Score range</td><td>0 to 100 points</td><td>−2 to 10 points</td></tr>
<tr><td>Clinical application</td><td>Score < 25 is associated with favorable benefit–risk ratio; consider standard/prolonged DAPT duration (12–24 months)
Score ≥ 25 is associated with unfavorable benefit–risk ratio; consider shorter DAPT duration (3–6 months)</td><td>Score ≥ 2 is associated with favorable benefit–risk ratio; consider prolonged DAPT duration
Score < 2 is associated with unfavorable benefit–risk ratio; prolonged DAPT generally not recommended</td></tr>
</table>

For the PRECISE-DAPT score calculation, use the nomogram by drawing a vertical line from the variable value down to the corresponding number of points for the given variable and add all the points together.

For the DAPT score calculation, add all of the positive values present and subtract value for age to obtain the total number of points.

CrCl, creatinine clearance (in mL/min; multiply by 60 if in units of mL/s); Hgb, hemoglobin (in g/dL; multiply values by 0.1 if in units of g/L or by 1.611 if in units of mmol/L); LVEF, left ventricular ejection fraction; MI, myocardial infarction; PCI, percutaneous coronary intervention; WBC, white blood cell count.

Adapted with permission from Valgimigli M, Bueno H, Byrne RA, et al. 2017 ESC focused update on dual antiplatelet therapy in coronary artery disease developed in collaboration with EACTS: The Task Force of dual antiplatelet therapy in coronary artery disease of the European Society of Cardiology (ESC) and of the European Association for Cardio-Thoracic Surgery (EACTS). Eur Heart J. 2018;39(3):213–260.

Clopidogrel, prasugrel, and ticagrelor are all indicated in combination with aspirin for at least 1 year in patients with ACS who undergo PCI.[3,7,22] Both clopidogrel and ticagrelor are also indicated in combination with aspirin in patients with NSTEMI who do not undergo PCI.[7] In patients with ACS, DAPT more effectively reduces the risk of death, MI, and stroke compared with aspirin alone even in patients who are managed medically (eg, in the absence of PCI).[26-28] Compared to clopidogrel, prasugrel and ticagrelor provide greater protection against cardiovascular events in ACS but increase risk for bleeding.[27,28] For more information regarding the use of DAPT in the setting of ACS, see Chapter 9.

Statins Statins are the preferred drugs to lower LDL cholesterol based on their potency and efficacy in preventing cardiac events. Studies in hundreds of thousands of patients with or at high risk for IHD demonstrate that lowering cholesterol with statins reduces the risk of MACE by 22% for each 39 mg/dL (1.01 mmol/L) of LDL cholesterol reduction.[29]

In addition to their LDL cholesterol-lowering effect, statins likely confer additional benefits in patients with SIHD.[30] Prompted by evidence that patients with "normal" LDL cholesterol derive benefit from statins, studies suggest statins modulate the following characteristics thought to contribute to the cardiovascular risk reduction seen with these drugs:

- Improve endothelial function and vascular tone by reducing smooth muscle cell proliferation and enhancing vasoactive response of the coronary arteries.
- Inhibit inflammation and oxidative stress by lowering C-reactive protein and other inflammatory mediators implicated in atherosclerosis.
- Improve atherosclerotic plaque stability via macrocalcification and increased fibrous cap thickness.
- Reduce platelet aggregation by decreasing platelet reactivity and TXA_2 synthesis.

KEY CONCEPT In summary, to control risk factors and prevent MACE, statin therapy should be considered in all patients with SIHD, particularly in those with elevated LDL cholesterol or diabetes. Statins are potent lipid-lowering agents, possess non–lipid-lowering effects that may provide additional benefit to patients with SIHD, and have been shown to reduce morbidity and mortality in patients with and at high risk for SIHD. Moreover, because statins improve outcomes in patients with SIHD and "normal"

LDL cholesterol, statins should be considered in all patients with SIHD, regardless of baseline LDL cholesterol.

ACE Inhibitors and Angiotensin Receptor Blockers Angiotensin II, a neurohormone produced primarily in the kidney, is a potent vasoconstrictor and stimulates the production of aldosterone. Together, angiotensin II and aldosterone increase BP and sodium and water retention (increasing ventricular wall tension), cause endothelial dysfunction, promote thrombus formation, and cause myocardial fibrosis.

ACE inhibitors decrease angiotensin II production and have consistently been shown to decrease morbidity and mortality in patients with HFrEF or history of MI.[31,32] In addition, there is evidence that ACE inhibitors reduce the risk of vascular events in patients with chronic stable angina or risk factors for SIHD.[33,34] In patients with vascular disease (including SIHD) or risk factors for vascular disease, both ramipril and perindopril reduced the risk of MACE by 20% or more in separate studies.

KEY CONCEPT In the absence of contraindications, ACE inhibitors should be considered in all patients with SIHD, particularly those individuals who also have hypertension, diabetes mellitus, chronic kidney disease, left ventricular dysfunction, history of MI, or any combination of these.[1] Additionally, ACE inhibitors should also be considered in patients at high risk for developing SIHD based on findings from the studies summarized above. ARBs may be used in patients with indications for ACE inhibitors but who cannot tolerate them due to side effects (eg, chronic cough). ARBs also antagonize the effects of angiotensin II. In one large trial, valsartan was as effective as captopril at reducing morbidity and mortality in post-MI patients.[31] However, there are far more data supporting the use of ACE inhibitors in SIHD. Therefore, ACE inhibitors are preferred over ARBs in patients with a history of MI, diabetes, chronic kidney disease, or left ventricular dysfunction. The ACE inhibitors and ARBs with indications for patients with or at risk for SIHD or IHD-related complications are listed in Table 8–6.

Table 8–6

Doses of Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers Indicated in Ischemic Heart Disease (IHD)

Drug	Indications	Usual Dosage in IHD[a]
Angiotensin-Converting Enzyme Inhibitors		
Captopril	HTN, HF, post-MI, diabetic nephropathy	6.25–50 mg three times daily
Enalapril	HTN, HF	2.5–40 mg daily in one to two divided doses
Fosinopril	HTN, HF	10–80 mg daily in one to two divided doses
Lisinopril	HTN, HF, post-MI	2.5–40 mg daily
Perindopril	HTN, IHD	4–8 mg daily
Quinapril	HTN, HF, post-MI	5–20 mg twice daily
Ramipril	HTN, high risk for IHD, HF, post-MI	2.5–10 mg daily in one to two divided doses
Trandolapril	HTN, HF, post-MI	1–4 mg daily
Angiotensin Receptor Blockers		
Candesartan	HTN, HF	4–32 mg daily
Valsartan	HTN, HF, post-MI	40–320 mg daily in one to two divided doses
Telmisartan	HTN, high risk for IHD	20–80 mg daily

[a] Reduce initial dose and gradually titrate upward as tolerated in renal impairment.

HF, heart failure; HTN, hypertension; MI, myocardial infarction.

Side effects with ACE inhibitors and ARBs include hyperkalemia, deterioration in renal function, and angioedema. Serum potassium increases are secondary to aldosterone inhibition and are more likely in the presence of preexisting renal impairment, diabetes, or concomitant therapy with nonsteroidal anti-inflammatory drugs (NSAIDs), potassium supplements, or potassium-sparing diuretics. Reductions in glomerular filtration may occur during ACE inhibitor or ARB initiation or uptitration due to inhibition of angiotensin II-mediated vasoconstriction of the efferent arteriole. This type of renal impairment is usually temporary and more common in patients with preexisting renal dysfunction or unilateral renal artery stenosis. Bilateral renal artery stenosis is a contraindication for ACE inhibitors and ARBs because of the risk for overt renal failure. Angioedema is a potentially life-threatening adverse effect that occurs in less than 1% of White patients but up to 8% of African Americans treated with ACE inhibitors. Angioedema may also occur with the administration of ARBs. Patients treated with ACE inhibitors may develop a chronic cough secondary to bradykinin accumulation. For patients who develop a persistent ACE inhibitor–induced cough or mild angioedema, substitution of an ARB for an ACE inhibitor may be appropriate. Both ACE inhibitors and ARBs can cause fetal injury and death and are contraindicated in pregnancy.

▶ *Nitroglycerin to Relieve Acute Symptoms*

Short-acting nitrates are first-line treatment to terminate acute episodes of angina. **KEY CONCEPT** Patients with SIHD should have sublingual nitroglycerin tablets or spray to relieve acute ischemic symptoms. Nitrates undergo biotransformation to nitric oxide. Nitric oxide activates smooth muscle guanylate cyclase, leading to increased intracellular concentrations of cyclic guanosine monophosphate (cGMP), release of calcium from the muscle cell, and ultimately, to smooth muscle relaxation. Nitrates primarily cause venodilation, leading to reductions in preload. The resultant decrease in ventricular volume and wall tension leads to a reduction in myocardial oxygen demand. In higher doses, nitrates cause arterial dilation and reduce afterload and BP. In addition to reducing oxygen demand, nitrates increase myocardial oxygen supply by dilating the epicardial coronary arteries and collateral vessels, as well as relieving vasospasm.

Short-acting nitrates are available in tablet and spray formulations for sublingual administration. Sublingual nitroglycerin tablets are well absorbed across the oral mucosa, produce an antianginal effect within 1 to 3 minutes, and are less expensive than the spray. However, the spray is preferred for patients who have difficulty opening the tablet container or produce insufficient saliva for rapid dissolution of sublingual tablets. At the onset of an angina attack, a 0.3 to 0.4 mg dose of nitroglycerin (tablet or spray) should be administered sublingually and repeated every 5 minutes up to three times or until symptoms resolve. Standing enhances venous pooling and may contribute to hypotension, dizziness, or light-headedness. Sublingual nitroglycerin may be used to prevent effort- or exertion-induced angina. In this case, the patient should use sublingual nitroglycerin 2 to 5 minutes prior to an activity known to cause angina, with the effects persisting for approximately 30 minutes. Isosorbide dinitrate, also available in sublingual form, has a longer half-life with antianginal effects lasting up to 2 hours. The use of short-acting nitrates alone, without concomitant long-acting antianginal therapy, may be acceptable for patients who experience angina symptoms once every few days. However, for patients with more frequent attacks, other antianginal therapies are recommended.

The use of nitrates within 24 to 48 hours of a phosphodiesterase type 5 inhibitor (eg, sildenafil, vardenafil, and tadalafil) is contraindicated. Phosphodiesterase degrades cGMP, which is responsible for the vasodilatory effects of nitrates. Concomitant use of nitrates and phosphodiesterase type 5 inhibitors enhances cGMP-mediated vasodilation and can result in serious hypotension, decreased coronary perfusion, and even death. All patients with SIHD should be prescribed sublingual nitroglycerin and educated regarding its use. Points to emphasize when counseling a patient on sublingual nitroglycerin use include:

- The seated position is generally preferred when using nitroglycerin because the drug may cause dizziness.
- Call 911 if symptoms are unimproved or worsen 5 minutes after the first dose.
- Keep nitroglycerin tablets in the original glass container and close the cap tightly after use.
- Nitroglycerin should not be stored in the same container as other medications because this may reduce nitroglycerin's effectiveness.
- Repeated use of nitroglycerin is not harmful or addictive and does not result in any long-term side effects. Patients should not hesitate to use nitroglycerin whenever needed.
- Nitroglycerin should not be used within 24 hours of taking sildenafil or vardenafil or within 48 hours of taking tadalafil because of the potential for life-threatening hypotension.

▶ *Pharmacotherapy to Prevent Recurrent Ischemic Symptoms*

The overall goal of antianginal therapy is to allow patients with IHD to resume normal activities without symptoms of angina and to experience minimal to no adverse drug effects. The drugs used to prevent ischemic symptoms are β-blockers, CCBs, nitrates, and ranolazine. These drugs exert their antianginal effects by improving the balance between myocardial oxygen supply and demand, with specific effects listed in Table 8–7. β-Blockers, CCBs, nitrates, and ranolazine decrease the frequency of angina and delay the onset of angina during exercise. However, there is no evidence that any of these agents prevent ACS or improve survival in patients with SIHD. Combination therapy with two or three antianginal drugs is often needed.

β-Blockers β-Blockers antagonize β_1- and β_2-adrenergic receptors in the heart, reducing heart rate and cardiac contractility, and decreasing myocardial oxygen demand. β-Blockers may also reduce oxygen demand by lowering BP and ventricular wall tension through inhibition of renin release from juxtaglomerular cells. By slowing heart rate, β-blockers prolong diastole, thus increasing coronary blood flow. However, β-blockers do not improve myocardial oxygen supply.

β-Blockers with intrinsic sympathomimetic activity (eg, acebutolol, pindolol, and penbutolol) have partial β-agonist effects and cause lesser reductions in heart rate at rest. As a result, β-blockers with intrinsic sympathomimetic activity may produce lesser reductions in myocardial oxygen demand and should be avoided in patients with SIHD. Other β-blockers appear equally effective at controlling symptoms of angina. The properties and recommended doses of various β-blockers used to prevent angina are summarized in Table 8–8. Frequency of dosing and drug cost should be taken into consideration when choosing a particular drug. Most β-blockers are available in inexpensive generic versions. β-Blockers should be initiated in doses at the lower end of the usual dosing range, with titration according to symptom and hemodynamic response. β-Blocker dose is commonly titrated to achieve the following:

- Resting heart rate between 55 and 60 beats/min.
- Maximum heart rate with exercise of 100 beats/min or less or 20 beats/min above the resting heart rate.

KEY CONCEPT In the absence of contraindications, β-blockers are the preferred initial therapy to prevent symptoms of angina in patients with SIHD because of their potential cardioprotective effects (eg, after MI and/or in patients with HFrEF). Long-term effects of β-blockers on morbidity and mortality in patients with SIHD are largely unknown. Yet, β-blockers decrease risk of reinfarction and death by 23% in patients who have suffered an MI.[35] However, controversy exists regarding the role of β-blockers as first-line therapy for all patients with SIHD. In an observational study, β-blockers did not lower risk of MACE in patients with SIHD or IHD risk factors, and in 2011, recommendations for using β-blockers for risk reduction in patients with SIHD or other vascular disease, in the absence of MI or heart failure, were downgraded.[36,37]

β-Blockers are contraindicated in patients with severe bradycardia (heart rate < 50 beats/min) or atrioventricular (AV) conduction defects in the absence of a pacemaker. β-Blockers should be used with particular caution in combination with other agents

Table 8–7

Effects of Antianginal Medications on Myocardial Oxygen Demand and Supply

	Oxygen Demand			
Antianginal Agent	Heart Rate	Wall Tension	Cardiac Contractility	Oxygen Supply
β-Blockers	↓	↔ or ↓	↓	↔

Table 8–8

Properties and Dosing of β-Blockers in Ischemic Heart Disease

Drug	Receptor Affinity	Usual Dose Range	Dose Adjust in Hepatic Impairment	Dose Adjust in Renal Impairment
Atenolol	β_1-Selective	25–200 mg once daily	No	Yes
Betaxolol	β_1-Selective	5–20 mg once daily	No	Yes
Bisoprolol	β_1-Selective	2.5–10 mg once daily	Yes	Yes
Carvedilol	α_1, β_1, and β_2	3.125–25 mg twice daily	Avoid in severe impairment	No
Carvedilol phosphate	α_1, β_1, and β_2	10–80 mg once daily	Avoid in severe impairment	No
Labetalol	α_1, β_1, and β_2	100–400 mg twice daily	Yes	No
Metoprolol	β_1-Selective	50–200 mg twice daily (once daily for extended release)	Yes	No
Nadolol	β_1 and β_2	40–120 mg once daily	No	Yes
Nebivolol	β_1-Selective	5–10 mg once daily	Yes, avoid in severe impairment	Yes
Propranolol	β_1 and β_2	20–120 mg twice daily (60–240 mg once daily for long-acting formulation)	Yes	No
Timolol	β_1 and β_2	10–20 mg twice daily	Yes	Yes

that depress AV conduction (eg, digoxin, verapamil, and diltiazem) because of increased risk for bradycardia and heart block. Relative contraindications include asthma, bronchospastic disease, and severe depression. β_1-selective blockers are preferred in patients with asthma or chronic obstructive pulmonary disease. However, selectivity is dose dependent, and β_1-selective agents may induce bronchospasm in higher doses.

There are several precautions to consider with use of β-blockers in patients with diabetes or heart failure. All β-blockers may mask tachycardia and tremor (but not sweating) that commonly accompany episodes of hypoglycemia in diabetes. In addition, nonselective β-blockers may alter glucose metabolism and slow recovery from hypoglycemia in insulin-dependent diabetes. β_1-selective agents are preferred because they are less likely to prolong recovery from hypoglycemia. Importantly, β-blockers should not be avoided in patients with SIHD and diabetes, particularly in patients with a history of MI who are at high risk for recurrent cardiovascular events. β-blockers are indicated in patients with chronic HFrEF who are euvolemic due to their mortality benefit in this population. However, β-blockers are negative inotropes (ie, they decrease cardiac contractility), and may worsen symptoms of heart failure in patients with left ventricular dysfunction (ie, ejection fraction < 40% [0.40]). Initiation or titration should be delayed in patients with acute heart failure until symptoms have resolved. In particular, when used for the management of SIHD in a patient with heart failure, β-blockers should be initiated in very low doses with slow uptitration to avoid worsening heart failure symptoms.

Other potential adverse effects from β-blockers include fatigue, sleep disturbances, malaise, depression, and sexual dysfunction. Abrupt β-blocker withdrawal may increase the frequency and severity of angina, possibly because of increased receptor sensitivity to catecholamines after long-term β-blockade. If the decision is made to stop β-blocker therapy, the dose should be tapered over several days to weeks to avoid exacerbating angina.

Calcium Channel Blockers CCBs inhibit calcium entry into vascular smooth muscle and cardiac cells, resulting in the inhibition of the actin-myosin complex and contraction of the cell. Inhibition of calcium entry into the vascular smooth muscle cells leads to systemic vasodilation and reductions in afterload. Inhibition of calcium entry into the cardiac cells leads to reductions in cardiac contractility. Thus, CCBs reduce myocardial oxygen demand by lowering both wall tension (through reductions in afterload) and cardiac contractility. The nondihydropyridine CCBs, verapamil and diltiazem, slow sinoatrial and AV nodal conduction, decrease heart rate, and further decrease myocardial oxygen demand. Because of their negative chronotropic effects, verapamil and diltiazem are generally more effective antianginal agents than the dihydropyridine CCBs. In contrast, dihydropyridine CCBs, nifedipine in particular, inhibit calcium in the vasculature and are potent vasodilators that can cause baroreflex-mediated increases in sympathetic tone and heart rate. In addition to decreasing myocardial oxygen demand, all CCBs increase myocardial oxygen supply by dilating coronary arteries, thus increasing coronary blood flow and relieving vasospasm.

CCBs are as effective as β-blockers at preventing ischemic symptoms. **KEY CONCEPT** CCBs are recommended as alternative treatment in SIHD when β-blockers are contraindicated or not tolerated. In addition, CCBs may be used in combination with β-blockers when initial treatment is unsuccessful. The combination of a β-blocker and a dihydropyridine CCB may improve symptoms better than either drug used alone.[38] However, the combination should be used with caution because both drugs decrease AV nodal conduction, increasing the risk for severe bradycardia or AV block when used together. If combination therapy is warranted, a long-acting dihydropyridine CCB is preferred. β-Blockers will prevent reflex increases in sympathetic tone and heart rate with the use of CCBs with potent vasodilatory effects. For patients with variable and unpredictable occurrences of angina, indicating possible coronary vasospasm, CCBs may be more effective than β-blockers in preventing angina episodes. The dosing of CCBs in IHD is described in Table 8–9.

Verapamil and diltiazem are contraindicated in patients with bradycardia and preexisting conduction disease in the absence of a pacemaker. As previously noted, verapamil and diltiazem should be used with particular caution in combination with other drugs that depress AV nodal conduction (eg, β-blockers and digoxin). Because of their negative inotropic effects, CCBs may cause or exacerbate heart failure in patients with HFrEF and should be avoided in this population. The exceptions are amlodipine and felodipine that have less negative inotropic effects compared with other CCBs and appear to be safe in patients with left ventricular systolic dysfunction.[39,40] Finally, there is some evidence that short-acting CCBs (particularly short-acting nifedipine and

Table 8–9

Dosing of Calcium Channel Blockers in Ischemic Heart Disease

Drug	Usual Dose Range
Nondihydropyridines	
Diltiazem, extended release	120–360 mg once daily; consider dose adjustment in hepatic dysfunction
Verapamil, extended release	180–480 mg once daily; use initial dose of 120 mg in hepatic dysfunction
Dihydropyridines	
Amlodipine	5–10 mg once daily
Felodipine	5–10 mg once daily; use initial dose of 2.5 mg once daily in hepatic dysfunction
Nifedipine, extended release	30–90 mg once daily; dose adjust and monitor closely in hepatic dysfunction
Nicardipine	20–40 mg thrice daily; dose twice daily in hepatic dysfunction and up-titrate slowly in both hepatic and renal dysfunction

nicardipine) may increase the risk of cardiovascular events.[41] Therefore, short-acting agents should be avoided in the management of SIHD.

Long-Acting Nitrates Nitrate products are available in both oral and transdermal formulations for chronic use. Commonly used products are listed in Table 8–10. All long-acting nitrate products produce effects within 30 to 60 minutes and are equally effective at preventing the recurrence of angina when used appropriately.

Table 8–10

Nitrate Formulations and Dosing for Chronic Use

Formulation	Dose
Oral	
Nitroglycerin extended-release capsules	2.5 mg thrice daily initially, with up-titration according to symptoms and tolerance; allow a 10- to 12-hour nitrate-free interval
Isosorbide dinitrate tablets	5–20 mg two to three times daily, with a daily nitrate-free interval of at least 14 hours (eg, dose at 7 AM, noon, and 5 PM)
Isosorbide dinitrate slow-release capsules	40 mg one to two times daily, with a daily nitrate-free interval of at least 18 hours (eg, dose at 8 AM and 2 PM)
Isosorbide mononitrate tablets	5–20 mg twice daily initially, with up-titration according to symptoms and tolerance; doses should be taken 7 hours apart (eg, 8 AM and 3 PM)
Isosorbide mononitrate extended-release tablets	30–120 mg once daily
Transdermal	
Nitroglycerin extended-release film	0.2–0.8 mg/hour, on for 12–14 hours, off for 10–12 hours

The major limitation of nitrate therapy is the development of tolerance with continuous use. Loss of antianginal effects may occur within the first 24 hours of continuous nitrate therapy. Although the cause of tolerance is unclear, several mechanisms have been proposed, including the generation of free radicals that degrade nitric oxide. The most effective method to avoid tolerance and maintain the antianginal efficacy of nitrates is to allow a daily nitrate-free interval of at least 8 to 12 hours. Nitrates do not provide protection from ischemia during the nitrate-free period. Therefore, the nitrate-free interval should occur when the patient is least likely to experience angina, which is generally during the nighttime hours when the patient is sleeping, and myocardial oxygen demand is reduced. Thus, it is common to dose long-acting nitrates so that the nitrate-free interval begins in the evening. For example, isosorbide dinitrate is typically dosed on awakening and again 6 to 7 hours later.

Monotherapy with nitrates for the prevention of ischemia should generally be avoided. Reflex increases in sympathetic activity and heart rate, with resultant increases in myocardial oxygen demand, may occur secondary to nitrate-induced venodilation. In addition, patients are unprotected from ischemia during the nitrate-free interval. KEY CONCEPT Treatment with long-acting nitrates should be added to baseline therapy with either a β-blocker or CCB, or a combination of the two. β-Blockers attenuate the increase in sympathetic tone and heart rate that occurs during nitrate therapy. As a result, the combination of β-blockers and nitrates is particularly effective at preventing angina and provides greater protection from ischemia than therapy with either agent alone. Monotherapy with nitrates may be appropriate in patients who have low BP at baseline or who experience symptomatic hypotension with low doses of β-blockers or CCBs.

Common adverse effects of nitrates include postural hypotension, dizziness, flushing, and headache secondary to venodilation. Headache often resolves with continued therapy and may be treated with acetaminophen. Hypotension is generally of no serious consequence. However, in patients with hypertrophic obstructive cardiomyopathy or severe aortic valve stenosis, nitroglycerin may cause serious hypotension and syncope. Therefore, long-acting nitrates are relatively contraindicated in these conditions. Because life-threatening hypotension may occur with concomitant use of nitrates and phosphodiesterase type 5 inhibitors, nitrates should not be used within 24 hours of taking sildenafil or vardenafil, or within 48 hours of taking tadalafil. Skin erythema and inflammation may occur with transdermal nitroglycerin administration and may be minimized by rotating the application site.

Ranolazine Ranolazine is an anti-ischemic agent indicated for the management of chronic angina. The mechanism of action is unclear, but it is believed to inhibit the late inward sodium current during the plateau phase of the cardiac action potential. Under ischemic conditions, excess sodium may enter the myocardial cell during systole. The resultant intracellular sodium overload leads to intracellular calcium accumulation (calcium overload) through a sodium-calcium exchange mechanism. Calcium overload results in increases in left ventricular wall tension and MVO_2. By reducing intracellular sodium concentrations in ischemic myocytes, ranolazine decreases intracellular calcium overload, left ventricular wall tension, and MVO_2.

Similar to other antianginal drugs, ranolazine reduces angina and increases exercise capacity but does not reduce incidence of MACE. Ranolazine has minimal effects on heart rate or BP; thus, it may be an option in SIHD patients with low baseline BP or heart rate. Ranolazine is often reserved for patients with angina refractory to other antianginal medications due to its excessive cost. Ranolazine can prolong the QT interval. However, when used at recommended doses, the mean prolongation of QT interval is minimal (2.4 ms).[42] The risk for QT interval prolongation is elevated in patients with hepatic impairment or taking other medications known to interact with ranolazine or prolong QT interval. Ranolazine should be started at a dose of 500 mg twice daily and increased to 1000 mg twice daily if needed for symptom relief. Higher doses are poorly tolerated and should be avoided. Contraindications to ranolazine are shown in Table 8–11. Common adverse effects with ranolazine include dizziness, constipation, headache, and nausea. Syncope may occur infrequently. Ranolazine is a CYP3A4 substrate, weak CYP2D6 substrate, CYP2D6 inhibitor, organic cation transporter 2 (OCT2) inhibitor, and both an inhibitor and substrate of P-glycoprotein (P-gp). Concomitant use of ranolazine with potent CYP3A4 inhibitors (eg, ketoconazole, clarithromycin, and nelfinavir) or inducers (eg, rifampin) is contraindicated. The use of ranolazine is contraindicated in patients with significant hepatic disease. The ranolazine dose should be limited to 500 mg twice daily when combined with moderate CYP3A4 inhibitors including diltiazem and verapamil. Ranolazine should be used cautiously with P-gp inhibitors (eg, cyclosporine) and substrates (eg, digoxin). The maximum doses of simvastatin (20 mg daily) and metformin (1700 mg daily) are lower during concomitant treatment with ranolazine.

Table 8–11

Contraindications and Precautions with Ranolazine

Contraindications	Precautions
Liver cirrhosis increases ranolazine plasma concentrations by 30%–80%, resulting in increased risk for QT interval prolongation Treatment with potent CYP3A4 inhibitors (including ketoconazole, clarithromycin, and nelfinavir) increases ranolazine concentrations (3.2-fold with ketoconazole) Treatment with CYP3A4 inducers (including rifampin, phenobarbital, phenytoin, carbamazepine, and St. John's wort) may significantly decrease the efficacy of ranolazine (by 95% with rifampin)	Treatment with moderate CYP3A4 inhibitors including diltiazem, verapamil, grapefruit juice, erythromycin, and fluconazole increases ranolazine plasma concentrations (twofold with diltiazem and verapamil) Preexisting QT prolongation, history of torsades de pointes, or treatment with other QT-prolonging drugs as QT interval prolongation may occur with ranolazine Treatment with a P-gp inhibitor, such as cyclosporine, may increase ranolazine absorption Up to a 50% increase in ranolazine plasma concentration has been observed in renal impairment Ranolazine may increase bioavailability of P-gp substrates (increases digoxin plasma concentrations by 1.5-fold) Ranolazine may cause reduced metabolism of CYP2D6 substrates Ranolazine may increase exposure to drugs transported by OCT2; metformin doses should not exceed 1700 mg/day in patients treated with ranolazine 1000 mg twice daily Ranolazine may reduce the metabolism of CYP3A4 substrates; the dose of simvastatin should not exceed 20 mg in patients treated with ranolazine

CYP, cytochrome P450; OCT2, organic cation transporter 2; P-gp, P-glycoprotein.

▶ *Pharmacotherapy with No Benefit or Potentially Harmful Effects*

Hormone Replacement Therapy, Folic Acid, and Antioxidants Current guidelines recommend against the use of hormone replacement therapy (HRT), folic acid, or antioxidants for reducing cardiovascular risk.[1] Early evidence from observational studies with each of these suggested potential benefit in SIHD. However, no benefit was observed in randomized controlled clinical trials.[43,44] In the case of HRT, there was evidence of harm, with an increased risk of thromboembolic events and breast cancer with HRT in postmenopausal women.[44] Clinicians should consider discontinuing HRT therapy in women who suffer an acute coronary event while receiving such therapy.

Herbal Supplements Herbal products are widely used for their purported cardiovascular benefits. Strong evidence supporting their benefits in cardiovascular disease is generally lacking and the potential for drug interactions and the lack of standardization limits the products' usefulness in clinical practice. Safety with herbal supplements in patients with SIHD is a major concern. Numerous case reports of adverse cardiovascular events led the Food and Drug Administration (FDA) to ban ephedra-containing products (eg, ma huang) in 2004. Some herbal supplements, such as feverfew and garlic, may interact with antiplatelet and antithrombotic therapy and increase bleeding risk. Dietary supplements purported to enhance sexual performance may contain phosphodiesterase-like chemicals and increase risk for serious hypotension with nitroglycerin. Other agents may reduce the effectiveness of antianginal medications, such as St. John's wort with ranolazine. Thus, it is important to assess the use of herbal products in patients with SIHD and to counsel patients about the potential for drug interactions and adverse events with herbal therapies.

Cyclooxygenase-2 Inhibitors and Nonsteroidal Anti-inflammatory Drugs Data suggest that cyclooxygenase-2 (COX-2) inhibitors and nonselective NSAIDs may increase the risk for MI and stroke.[45] The cardiovascular risk with COX-2 inhibitors and NSAIDs may be greatest in patients with a history of, or with risk factors for, cardiovascular disease. The COX-2 inhibitors rofecoxib and valdecoxib were withdrawn from the market because of safety concerns. Product labeling for other COX-2 and nonselective NSAIDs (prescription and over-the-counter) now includes boxed warning about potential adverse cardiovascular effects. The AHA recommends the use of COX-2

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a specific plan for the management of the patient's SIHD. Your plan should include (a) the goals of therapy, (b) patient-specific nonpharmacologic and pharmacologic interventions to address these goals, and (c) a plan for follow-up to assess drug tolerance and whether the therapeutic goals have been achieved.

inhibitors be limited to low-dose, short-term therapy in patients for whom there is no appropriate alternative. Patients with cardiovascular disease should consult a clinician before using over-the-counter NSAIDs.

Special Populations

▶ *Variant Angina*

Vasospasm as sole etiology of angina (Prinzmetal or variant angina) is relatively uncommon. As a result, treatment options are not well studied. Nevertheless, based on the pharmacology of available drugs, several recommendations can be made. First, β-blockers should be avoided in patients with variant angina because of their potential to worsen vasospasm due to unopposed α-adrenergic receptor stimulation. In contrast, both CCBs and nitrates are effective in relieving vasospasm and are preferred in the management of variant angina. Because nitrates require an 8- to 12-hour nitrate-free interval, their role as monotherapy for prophylaxis of anginal attacks due to vasospasm is limited. However, immediate-release nitroglycerin is effective at terminating acute anginal attacks due to vasospasm. Therefore, all patients diagnosed with variant angina should be prescribed immediate-release nitroglycerin. CCBs are effective for monotherapy of variant angina. Because short-acting CCBs have been associated with increased risk of adverse cardiac events, they should be avoided.[41] Long-acting nitrates may be added to CCB therapy if needed.

▶ *Microvascular Angina*

There are limited data on optimal therapy in patients with microvascular disease. Both ACE inhibitors and statins may produce beneficial effects on endothelial function and improve microvascular angina.[5] Short-acting nitrates remain the treatment of choice for relieving acute symptoms, although they may be less effective in microvascular disease. Similar to obstructive CAD, β-blockers are first line to control symptoms of angina in patients with microvascular disease and may be more effective than CCBs and long-acting nitrates in this setting. Ranolazine may also produce favorable antianginal effects for patients with continued symptoms.

▶ *Elderly Patients with IHD*

Elderly patients are more likely to have other comorbidities that may influence drug selection for the treatment of angina than younger patients. As a result, polypharmacy is more common in elderly patients, increasing the risk of drug–drug interactions, and perhaps decreasing medication adherence. Additionally, elderly patients are often more susceptible to adverse effects of antianginal therapies, particularly the negative chronotropic and inotropic effects of β-blockers and CCBs. Therefore, drugs should be initiated in low doses with close monitoring of elderly patients with IHD.

▶ *Acute Coronary Syndromes*

Management of ACS is discussed in further detail in Chapter 9. It is important to educate patients with SIHD on the signs of ACS and steps to take if signs or symptoms occur. Importantly, patients should be instructed to seek emergent care if symptoms of angina last longer than 20 to 30 minutes, do not improve after 5 minutes of using sublingual nitroglycerin, or worsen after 5 minutes of using sublingual nitroglycerin. In patients with a history of ACS, it is crucial to select appropriate pharmacotherapy to prevent recurrent ACS and death. Appropriate pharmacotherapy for patients with a history of ACS includes aspirin (often in combination with a $P2Y_{12}$ inhibitor), ACE inhibitors or ARBs, β-blockers, statins, and sublingual nitroglycerin. In addition, control of cardiovascular risk factors (eg, dyslipidemia, hypertension, and diabetes) with lifestyle modifications and pharmacotherapy is critical.

OUTCOME EVALUATION

Assessing for Drug Effectiveness and Safety

- In general, patients with SIHD should have follow-up evaluations every 4 to 12 months.[1] Early in the treatment course (eg, first year), more frequent evaluations (every 4–6 months) are recommended. Length of the follow-up period may differ based on frequency and severity of symptoms, care coordination with other providers, regional practice patterns, patient preference, and physician availability.
- **KEY CONCEPT** Monitor symptoms of angina at baseline and at each clinic visit to assess frequency and intensity of anginal symptoms and effectiveness of antianginal therapy.[1] Determining frequency of sublingual nitroglycerin use is helpful in making this assessment. If angina is occurring with increasing frequency or intensity, adjust antianginal therapy and refer the patient for additional diagnostic testing and possibly coronary intervention (eg, PCI or CABG surgery), if indicated.
- Assess the patient for IHD-related complications, such as heart failure and arrhythmias.[1]
- Routinely monitor hemodynamic parameters to assess drug tolerance. Assess BP at baseline, after drug initiation, and after dose titration. BP should be monitored periodically in patients treated with β-blockers, CCBs, nitrates, ACE inhibitors, and/or ARBs.
- Routinely assess adherence to medical therapy and recommended lifestyle changes.
- Because of the potential for postural hypotension, warn patients that dizziness, presyncope, and even syncope may result from abrupt changes in body position during initiation or uptitration of drugs with α-blocking effects.
- Closely monitor heart rate in patients treated with drugs that have negative chronotropic effects (eg, β-blockers, verapamil, or diltiazem) or drugs that may cause reflex tachycardia (eg, nitrates or dihydropyridine CCBs). Treatment with β-blockers, verapamil, or diltiazem can usually be continued in patients with asymptomatic bradycardia. However, reduce or discontinue treatment with these agents in patients who develop symptomatic bradycardia or serious conduction abnormalities.
- Regularly assess control of existing risk factors and the presence of new risk factors for SIHD.[1] Modify the pharmacotherapy regimen to control these risk factors and lower the risk of IHD-related adverse events.
- In patients treated with ACE inhibitors and/or ARBs, routinely monitor renal function and potassium levels at baseline, after drug initiation and dose titration, and periodically thereafter. This is particularly important in patients with preexisting renal impairment or diabetes because they may be more susceptible to these adverse events.

Duration of Therapy

- Because these therapies reduce the risk for coronary events and death, treatment with antiplatelet (aspirin or clopidogrel), lipid-lowering, and neurohormonal-modifying medications for SIHD is generally lifelong.
- Antianginal therapy with a β-blocker, CCB, and/or nitrate is usually long term.
- A patient with severe symptoms managed with combination antianginal drugs who undergoes successful coronary revascularization may be able to reduce antianginal therapy. However, treatment with at least one agent is usually warranted.

Patient Care Process

Collect Information:

- Identify any patient complaints/symptoms, including recent chest pain. (See Tables 8–3 and 8–4.)
- Elicit information on the quality, location, and duration of chest pain; determine factors that provoke or relieve the pain.
- Perform a thorough medication history.
- Identify allergies and intolerances.
- Identify barriers that may affect adherence to care plan.
- Identify SIHD risk factors. (See Table 8–2.)
- Obtain vital signs and perform a physical examination.
- Collect laboratory and diagnostic information. (See Clinical Presentation and Diagnosis of Ischemic Heart Disease, and Figure 8–4.)

Assess the Information:

- Evaluate available information about chest pain and create a differential diagnosis.
- Consider potential noncardiac conditions that can explain the patient's symptoms. (See Table 8–1.)
- Evaluate available laboratory and diagnostic information for SIHD. Do they suggest or confirm SIHD? Was PCI performed? Were there any stents placed and in what setting (ACS or SIHD)?
- Assess the appropriateness, efficacy, and safety of the patient's previous SIHD drug regimen, if applicable.
- Identify medications that may interact with antianginal drug therapy.
- Assess adherence to medical therapy and recommended lifestyle modifications.
- Assess for the presence of SIHD-related complications.
- Assess preexisting and newly detected patient-specific risk factors for SIHD. (See Table 8–2 and Figure 8–4.)
- Determine patient-centered goals of therapy for SIHD.

Develop a Care Plan:

- Treat modifiable risk factors for SIHD; initiate appropriate lifestyle modifications.
- Treat hypertension, dyslipidemia, and diabetes.
- Initiate and/or modify therapy to prevent MACE. (See Figure 8–5.)
- Initiate and/or modify therapy to treat acute symptoms and prevent chronic angina symptoms. (See Figure 8–5.)

Implement the Care Plan:

- Refer patients with ACS to the hospital. (See Table 8–3.)
- Stress the importance of adherence to the care plan.
- Provide education on the following: consequences of untreated SIHD, lifestyle modifications, medication administration, potential adverse effects, potential drug interactions, signs and symptoms of worsening angina, signs and symptoms of IHD-related complications, and when to seek emergent care.

Follow-up: Monitor and Evaluate:

- Reassess the care plan at least every 4 to 12 months, more often if necessary (eg, first year of therapy, persistent symptoms, intolerance to medical therapy).
- During each subsequent visit, assess control of preexisting risk factors and development of new risk factors, control of angina symptoms, presence of SIHD complications, adherence to the care plan, development of adverse drug reactions, and drug interactions.
- Reevaluate the efficacy and safety of the medical regimen assuring it includes appropriate therapy to prevent MACE and prevent angina symptoms. (See Figures 8–4 and 8–5.)
- Reassess barriers to treatment affecting adherence and modify the care plan, if necessary.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. Robert J. DiDomenico, an author of this chapter in previous editions of this book.

Abbreviations Introduced in This Chapter

ACC	American College of Cardiology
ACE	Angiotensin-converting enzyme
ACS	Acute coronary syndromes
AHA	American Heart Association
ARB	Angiotensin receptor blocker
ASCVD	Atherosclerotic cardiovascular disease
AV	Atrioventricular
BMS	Bare metal stent
BP	Blood pressure
CABG	Coronary artery bypass graft
CAD	Coronary artery disease
CCB	Calcium channel blocker
cGMP	Cyclic guanosine monophosphate
CHD	Coronary heart disease
COX-2	Cyclooxygenase-2
CrCl	Creatinine clearance
CT	Computed tomography
CYP	Cytochrome P450
DAPT	Dual antiplatelet therapy
DES	Drug-eluting stent
EBCT	Electron beam computed tomography
ECG	Electrocardiogram
FDA	Food and Drug Administration
GLP-1	Glucagon-like peptide 1
HDL	High-density lipoprotein
HF	Heart failure
HFrEF	Heart failure with reduced ejection fraction
Hgb	Hemoglobin
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A
HRT	Hormone replacement therapy
HTN	Hypertension
IHD	Ischemic heart disease
IV	Intravenous
LDL	Low-density lipoprotein
LVEF	Left ventricular ejection fraction
MACE	Major adverse cardiac events
MI	Myocardial infarction
MR	Magnetic resonance
MRA	Mineralocorticoid receptor antagonist
ms	Milliseconds
MVO_2	Myocardial oxygen consumption
NSTEMI	Non–ST-segment elevation myocardial infarction
NSAID	Nonsteroidal anti-inflammatory drug
OCT2	Organic cation transporter 2
PCI	Percutaneous coronary intervention
PCSK9	Proprotein convertase subtilisin/kexin type 9
P-gp	P-glycoprotein
PTCA	Percutaneous transluminal coronary angioplasty
SIHD	Stable ischemic heart disease
SGLT2	Sodium-glucose cotransporter 2
STEMI	ST-segment elevation myocardial infarction
TXA_2	Thromboxane A_2
UA	Unstable angina
WBC	White blood cell

9 Acute Coronary Syndromes

Kelly C. Rogers and Sarah A. Spinler

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Define the role of atherosclerotic plaque, platelets, and the coagulation system in an acute coronary syndrome (ACS).
2. List key electrocardiographic (ECG), biomarker, and clinical features identifying a patient with non–ST-segment elevation (NSTE)-ACS and ST-segment elevation myocardial infarction (STEMI).
3. Devise an initial, early pharmacotherapy treatment and monitoring plan for a patient presenting with either NSTE-ACS or STEMI given patient-specific data.
4. Devise an antithrombotic pharmacotherapy treatment and monitoring plan for a patient with NSTE-ACS or STEMI undergoing percutaneous coronary intervention (PCI) given patient-specific data.
5. Devise an antithrombotic pharmacotherapy treatment and monitoring plan for a patient with NSTE-ACS or STEMI not undergoing PCI given patient-specific data.
6. Develop a pharmacotherapy and risk factor modification treatment plan for secondary prevention of coronary heart disease (CHD) events in a patient following NSTE-ACS or STEMI.

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death in the United States and one of the major causes of death worldwide.[1] Acute coronary syndromes (ACSs), including unstable angina (UA) and myocardial infarction (MI), are a form of coronary heart disease (CHD) that comprises the most common cause of CVD death.[1] KEY CONCEPT ACS is primarily caused by rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and the activation of the clotting cascade. Ultimately, a thrombus composed of fibrin and platelets may develop, resulting in incomplete or complete occlusion of a coronary artery.[2] ACS is a spectrum of disease encompassing ST-segment elevation MI (STEMI) or non–ST-segment elevation (NSTE)-ACS, which are classified according to electrocardiogram (ECG) changes and underlying pathophysiology.[3,4] The American Heart Association (AHA), American College of Cardiology (ACC), and American College of Cardiology Foundation (ACCF) recommend strategies or guidelines for ACS patient care for STEMI and NSTE-ACS which include both UA and non–ST-elevation MI (NSTEMI). In collaboration with the Society for Cardiovascular Angiography and Interventions (SCAI), the ACCF and AHA issue joint guidelines for percutaneous coronary intervention (PCI), including PCI in the setting of ACS. These practice guidelines are based on a review of available clinical evidence, have graded recommendations based on evidence and expert opinion, and are updated periodically. In the United States, these guidelines form the cornerstone for quality care of the ACS patient.[3-5]

EPIDEMIOLOGY

Each year, approximately 720,000 Americans will have a new coronary event, defined as a first hospitalization for MI or CHD death, while 335,000 will have a recurrent event.[1] The risks of CHD events, such as death, recurrent MI, and stroke, are higher for patients with established CHD and a history of MI than for patients without CHD.

The incidence rate of MI in the United States has been decreasing since 2007.[1] Particularly, patients presenting with STEMI have significantly decreased (from 133 to 50 cases per 100,000 person-years). Nevertheless, 110,346 Americans died of an MI in 2017.[1] One in seven deaths is secondary to CHD, which is the leading cause of hospitalization in the United States.[1] With median length of hospital stay being 3.1 days, the cost of CHD is high.[6] Estimated direct and indirect costs are more than $218.7 billion with both MI and CHD ranked in the top 10 most expensive conditions treated in the United States.[1]

Mortality rates have declined since the 1990s. Improvements in care that may have contributed to this reduction include greater use of guideline-recommended drugs (eg, aspirin [ASA], β-blockers, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors [statins], $P2Y_{12}$ inhibitors); reductions in median times for administering fibrinolytics and performing primary PCI; and increased use of early coronary angiography and PCI for high-risk patients with NSTE-ACS.[1,7] In patients with STEMI, in-hospital death rates in the United States are approximately 3% in patients receiving primary PCI, 7% for patients treated with fibrinolytics, and 16% for patients who do not receive reperfusion therapy.[7] In patients with NSTEMI, in-hospital mortality is less than 4%.[7] Other than persistent ST-segment changes and troponin, predictors of in-hospital mortality include older age, elevated serum creatinine (SCr), tachycardia, and heart failure (HF).[8,9]

ETIOLOGY

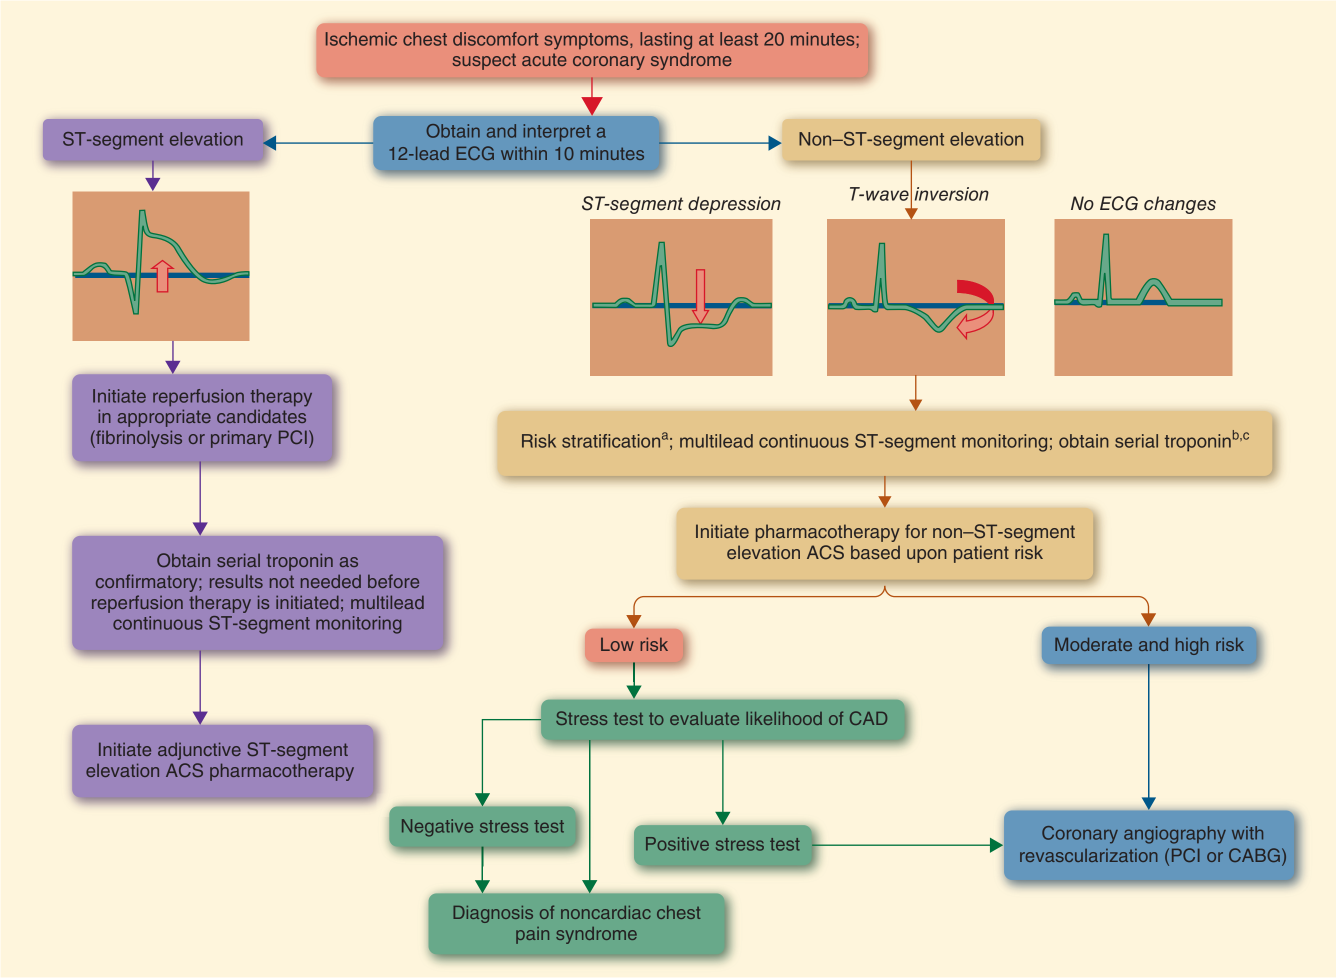
Endothelial dysfunction, inflammation, and formation of fatty streaks contribute to the formation of atherosclerotic coronary artery plaques, the underlying cause of coronary artery disease (CAD).[10] **KEY CONCEPT** The predominant cause of ACS in more than 90% of patients is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque followed by thrombus formation that reduces blood flow and results in myocardial ischemia.[2,10] If the ischemia persists long enough, MI can occur. This is called MI type 1, which generally occurs in coronary arteries where the stenosis occludes less than 50% of the lumen prior to the event, rather than a more stable 70% to 90% stenosis of the coronary artery.[4,11] Stable stenoses are characteristic of stable angina, are not considered an ACS, and are discussed in Chapter 8, "Stable Ischemic Heart Disease." MI type 2 is related to a reduction in myocardial oxygen supply or an increase in myocardial demand in the absence of a coronary artery process (eg, severe anemia, coronary vasospasm, sustained tachycardia, coronary artery dissection). MI type 3 is defined as an MI resulting in sudden cardiac death when biomarker measurement is not possible, while MI types 4 and 5 occur during revascularization procedures, including PCI or coronary artery bypass graft (CABG) surgery, respectively.[11]

PATHOPHYSIOLOGY

The term ACS encompasses all clinical syndromes compatible with acute myocardial ischemia and/or MI resulting from an imbalance between myocardial oxygen demand and supply. In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. ACSs are classified according to ECG changes into STEMI or NSTE-ACS (ie, NSTEMI and UA) (Figure 9–1).[3,4] An injury that transects the entire thickness of the myocardial wall results in a STEMI which will result in the release of biomarkers, mainly troponins T or I, from the necrotic myocytes into the bloodstream. An NSTEMI is limited to the subendocardial myocardium, and is usually smaller than a STEMI, resulting in lower mortality and complications. NSTEMI differs from UA in that ischemia is severe enough to result in the release of troponins. The clinical significance of serum markers is discussed in greater detail in later sections of this chapter.

Plaque Rupture and Clot Formation

Plaques that rupture are generally characterized by a soft lipid-rich necrotic core, a thin fibrous cap, adventitial and perivascular inflammation, intraplaque hemorrhage, angiogenesis, and



Ischemic chest discomfort symptoms, lasting at least 20 minutes; suspect acute coronary syndrome
Obtain and interpret a 12-lead ECG within 10 minutes
ST-segment elevation
Non–ST-segment elevation
ST-segment depression
T-wave inversion
No ECG changes
Initiate reperfusion therapy in appropriate candidates (fibrinolysis or primary PCI)
Risk stratification[a]; multilead continuous ST-segment monitoring; obtain serial troponin[b,c]
Obtain serial troponin as confirmatory; results not needed before reperfusion therapy is initiated; multilead continuous ST-segment monitoring
Initiate pharmacotherapy for non–ST-segment elevation ACS based upon patient risk
Low risk
Moderate and high risk
Initiate adjunctive ST-segment elevation ACS pharmacotherapy
Stress test to evaluate likelihood of CAD
Negative stress test
Positive stress test
Coronary angiography with revascularization (PCI or CABG)
Diagnosis of noncardiac chest pain syndrome

FIGURE 9–1. Evaluation of the acute coronary syndrome patient. [a]As described in Table 9–1. [b]"Positive": Above the myocardial infarction decision limit. [c]"Negative": Below the myocardial infarction decision limit. (ACS, acute coronary syndrome; CABG, coronary artery bypass graft; CAD, coronary artery disease; ECG, electrocardiogram; PCI, percutaneous coronary intervention.) (Reproduced with permission from: Rogers KC, de Denus S, Finks SW, Spinler SA. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:167.)

expansive vascular remodeling. The latter explains why these plaques only show minimal luminal obstruction, despite being larger than plaques that characterize stable angina which are associated with more severe luminal narrowing.[2,10] Following plaque rupture, a clot (a partially or completely occlusive thrombus) forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of collagen and tissue factor induce platelet adhesion and activation, which promote the release of platelet-derived vasoactive substances, including adenosine diphosphate (ADP) and thromboxane A_2 (TXA_2).[10] These produce vasoconstriction and potentiate platelet activation. Furthermore, during platelet activation, a change in the conformation in the glycoprotein (GP) IIb/IIIa surface receptors of platelets occurs that cross-links platelets to each other through fibrinogen bridges. This is considered the final common pathway of platelet aggregation. Inclusion of platelets gives the clot a white appearance. Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and disrupted endothelium, which are rich in tissue factor. This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity. Fibrin stabilizes the clot and traps red blood cells, which gives the clot a red appearance. Therefore, the clot is composed of cross-linked platelets and fibrin strands.[2,10]

Ventricular Remodeling Following an Acute MI

Adverse ventricular remodeling is a process of structural and functional changes caused by loss of viable myocardium, enhanced inflammatory response, neurohormonal activation, and enhanced wall stress that occurs in several cardiovascular (CV) conditions including HF and MI. It is characterized by left ventricular dilation and reduced pumping function of the left ventricle, leading to cardiac failure.[12] Because HF represents one of the principal causes of morbidity and mortality following an MI, preventing ventricular remodeling is an important therapeutic goal. Infarct size is the greatest predictor of adverse ventricular remodeling and survival. Therefore, early reperfusion and blockade of neurohormonal activation play key roles in treatment.

Use of ACE inhibitors, ARBs, β-blockers, and aldosterone antagonists can slow down or reverse ventricular remodeling through inhibition of the renin-angiotensin aldosterone system and/or through improvement in hemodynamics (decreasing preload or afterload).[12] These agents also significantly improve survival in patients with ACS.[3,4]

At some point during hospitalization, prior to discharge, patients with a definite ACS should have their left ventricular function (LVF) evaluated.[3,4] The most common way LVF is measured is using an echocardiogram to calculate the patient's left ventricular ejection fraction (LVEF, percent of blood pumped out of the left ventricle with each contraction). LVF, a measure of infarct size, is one of the strongest predictors of mortality following MI. Patients with LVEF less than 40% (0.40) are at high risk of death and ventricular arrhythmias.[3,4] LVEF is an important factor to consider when contemplating the use of several drugs, such as ACE inhibitors and aldosterone antagonists.

Complications

This chapter focuses on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of an acute MI as these may increase the risk of mortality. The most serious early complication of MI is cardiogenic shock, occurring in approximately 5% to 8% of hospitalized patients presenting with STEMI with mortality rates approaching 40%.[13] Other complications that may result from MI are HF, valvular dysfunction, bradycardia, heart block, **pericarditis**, stroke secondary to left ventricular thrombus embolization, venous thromboembolism, left ventricular free wall rupture, and ventricular and atrial tachyarrhythmias.[3] In fact, many patients die, presumably from ventricular fibrillation, prior to reaching the hospital. Patients with ventricular fibrillation or sustained ventricular tachycardia occurring more than 2 days following MI (which are not due to transient and reversible ischemia, reinfarction, or metabolic abnormalities), those with LVEF less than 30% (0.30; measured at least 40 days after STEMI) regardless of symptoms, or those with LVEF less than or equal to 35% (0.35) with New York Heart Association functional classes II to III may experience a mortality benefit against sudden cardiac death from placement of an implantable cardioverter-defibrillator (ICD).[3] Life-threatening bleeding secondary to fibrinolytics, anticoagulants and antiplatelets especially in the setting of catheterization and PCI, may also complicate the management of an MI.

CLINICAL PRESENTATION AND DIAGNOSIS

Symptoms and Physical Examination Findings

The classic symptom of ACS is severe new-onset or increasing substernal angina that is at least 10 minutes in duration, most often occurring at rest. The pain may radiate to the shoulder, down the left arm, and to the back or jaw, and this radiation pain may also occur without associated chest pain. Other symptoms include nausea, vomiting, **diaphoresis**, or shortness of breath. Although similar to stable angina, the duration may be longer and intensity may be greater.[3,4] Elderly, female patients, and patients with diabetes may present with a more atypical presentation, including epigastric pain, unexplained shortness of breath, or indigestion in the absence of chest pain which are often referred to as anginal equivalents. All healthcare professionals should review these warning symptoms with patients at high risk for CHD. On physical examination, no specific features are indicative of ACS. Patients with suspected ACS should be referred immediately to an emergency department (ED).

12-Lead ECG

KEY CONCEPT There are key features of a 12-lead ECG that identify and risk-stratify a patient with ACS. Within 10 minutes of presentation to an ED with symptoms of ischemic chest discomfort, a 12-lead ECG should be obtained and interpreted. If the first ECG is not diagnostic, additional ECGs should be performed every 15 to 30 minutes for the first hour if the patient is still symptomatic and the clinician has a high suspicion of ACS.[4] **KEY CONCEPT** When possible, an ECG should be performed by emergency medical system providers to reduce the delay until myocardial reperfusion. If available, a prior ECG should be reviewed to identify whether ischemic changes are new or old, with new findings being more indicative of an ACS. Key findings on review of an ECG that indicate myocardial ischemia or infarction are ST-segment elevation (STE), ST-segment depression, and T-wave inversion (see Figure 9–1).[3,4] ST-segment and/or T-wave changes in certain groupings of ECG leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle-branch block accompanied by chest discomfort is highly specific for acute STEMI. Approximately one-third of patients diagnosed with MI present with STE on their ECG, with the remainder having ST-segment depression, T-wave inversion, or in some instances, no ECG changes.[4,7] According to the latest guidelines, the diagnosis of STE, in the absence of left bundle-branch block or left ventricular hypertrophy, is a new STE in at least two contiguous leads of greater than or equal to 2 mm in men and greater than or equal to 1.5 mm in women in leads V_2-V_3 and/or of greater than or equal to 1 mm in other leads. Some parts of the heart are more "electrically silent" than others, and myocardial ischemia may not be detected on an ECG. Therefore, it is important to review findings from the ECG in conjunction with biochemical markers of myocardial necrosis, such as high-sensitivity cardiac troponin I (hs-cTnI) or T (hs-cTnT), clinical symptoms, and other risk factors for CHD to determine the patient's risk for experiencing a new MI or having other complications.

Biochemical Markers/Cardiac Enzymes

Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. **KEY CONCEPT** Diagnosis of MI is confirmed when the following conditions are met in a clinical setting consistent with myocardial ischemia: "Detection of a rise and/or fall of cardiac biomarkers with at least one value above the 99th percentile of the upper reference limit and with at least one of the following: (a) symptoms of ischemia; (b) ECG changes of new ischemia or development of pathological Q waves; (c) imaging evidence of new loss of viable myocardium; (d) new regional wall motion abnormality; or (e) identification of an intracoronary thrombus by angiography or autopsy."[11] The most recent guidelines indicate that only the use of troponin assays is recommended to assess myocardial necrosis.[4] Troponins are released into the bloodstream approximately 2 to 4 hours after an MI and generally peak around 18 to 24 hours. Troponins can stay elevated for up to 2 weeks. A single measurement of non–high-sensitivity troponin is not adequate to exclude a diagnosis of MI, as up to 15% of values that were initially below the level of detection (a "negative" test) rise to the level of detection (a "positive" test) in subsequent hours. Additionally, a single "positive" troponin may not be secondary to an MI as elevations can occur in other clinical conditions, such as pulmonary embolus, tachyarrhythmias, pericarditis, myocarditis, and sepsis, which can complicate diagnosis. Measurement of N-terminal pro B-type natriuretic peptide (BNP) may help predict long-term risk of mortality in patients with ACS but does not aid with acute diagnosis.[4]

The advent of hs-cTnI and hs-cTnT permits measurement well below the 99th percentile of the reference range. The lowest level the assay can detect is called the "level of detection." If the initial hs-cTn is below the level of detection, the diagnosis of MI can be excluded, and no further risk stratification is needed.

Clinical Presentation and Diagnosis

General

- The patient is typically in acute distress and may develop or present with acute HF, cardiogenic shock, or cardiac arrest.

Symptoms

- The classic symptom of ACS is acute onset of substernal chest pain or discomfort. Accompanying symptoms may include radiation of pain to either arm, back, or jaw, nausea, vomiting, diaphoresis, anxiety, or shortness of breath.
- Elderly, women, patients with diabetes, renal impairment, and dementia are more likely to present with atypical symptoms such as indigestion, epigastric pain, shortness of breath, or anxiety and less likely to present with classic symptoms.

Physical Signs

- There are no "classic" physical signs specific for ACS.
- Patients with ACS may present with signs of acute HF, including jugular venous distention, an S_3 sound on auscultation, or pulmonary edema on a chest X-ray.
- Patients may also present with arrhythmias such as tachycardia, bradycardia, or heart block.

Laboratory Tests

- High-sensitivity cardiac troponin I (hs-cTnI) or T (hs-cTnT) is measured at presentation and repeated at 1 to 6 hours to ascertain heart muscle damage, confirmatory for the diagnosis of an infarction. For patients with NSTE-ACS, an elevated troponin is diagnostic for MI, differentiating NSTEMI from UA. Patients presenting with suspected NSTE-ACS who do not have an MI undergo further diagnostic testing to determine whether they have UA or another diagnosis.
- Blood chemistry tests are performed with particular attention given to potassium and magnesium, which may affect heart rhythm.
- SCr is measured, and creatinine clearance (CrCl) is used to identify patients who may need dosing adjustments for medications, as well as those who are at high risk of morbidity and mortality.
- Baseline complete blood count (CBC) and coagulation tests (activated partial thromboplastin time [aPTT] and international normalized ratio [INR]) should be obtained because most patients will receive antithrombotic therapy that increases the risk for bleeding.
- Fasting lipid panel.

Other Diagnostic Tests

- The 12-lead ECG is the first step in management. Patients are risk-stratified into two groups: STEMI or NSTE-ACS.
- High-risk ACS patients, especially those with STEMI and those with recurrent chest discomfort will undergo coronary angiography via left heart catheterization and injection of contrast dye into the coronary arteries to determine the presence and extent of coronary artery stenoses and often undergo PCI to relieve the stenoses.
- During hospitalization, a measurement of LVF such as an echocardiogram is performed to identify patients with ejection fraction (EF) less than or equal to 40% (0.40) who are at high risk of death following hospital discharge.
- Selected low-risk patients may undergo early stress testing.

(Modified with permission from Rogers KC, de Denus S, Finks SW, Spinler SA. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:168.)

For patients presenting with an hs-cTn above the level of detection but below the 99th percentile, a second level at 1 to 6 hours should be obtained and risk stratification performed (see "Risk Stratification" section). If there is no change when comparing the second hs-cTn level to the first, the diagnosis of MI can be reliably excluded. A third level is recommended if the first two levels are above the level of detection but below the 99th percentile, and the patient presented to the hospital less than 3 hours after the onset of symptoms. At any time, a level above the 99th percentile confirms the diagnosis of MI.[14,15]

Risk Stratification

KEY CONCEPT Patient symptoms, past medical history, ECG, and troponins are utilized to stratify patients into low, medium, or high risk of death, MI, or likelihood of failing pharmacotherapy and needing urgent coronary angiography and PCI (see Table 9–1). Initial treatment according to risk stratification should be performed as soon as possible to determine which patients may benefit from a reperfusion strategy for STEMI or an early invasive or medical management approach for NSTE-ACS and is depicted in Figure 9–1. For example, patients with STEMI are at the highest short-term risk of death; therefore, immediate reperfusion strategies should be initiated. The ACCF/AHA/SCAI PCI guidelines define a target time to initiate reperfusion treatment as less than or equal to 30 minutes of hospital arrival for fibrinolytics (eg, alteplase, reteplase, and tenecteplase) and within 90 minutes from first medical contact for primary PCI.[5] The sooner the infarct-related coronary artery is opened, the lower the mortality and the greater the amount of myocardium that is preserved. For patients who present to a facility without PCI capability, it is recommended they be transferred to another hospital within 120 minutes of first medical contact for primary PCI.[5] Although all patients should be evaluated for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy are described in the treatment section of this chapter and Table 9–2. If patients with STEMI are not eligible for reperfusion therapy, additional pharmacotherapy should be initiated in the ED and the patient transferred to a coronary intensive care unit.[3]

Risk-stratification of the patient with NSTE-ACS is more complex because outcomes may vary between UA and NSTEMI.

Table 9–1

Risk Stratification for Acute Coronary Syndromes[4,16]

TIMI Risk Score for NSTE-ACS

One point is assigned for each of the seven medical history and clinical presentation findings below. The point total is calculated, and the patient is assigned a risk for experiencing the composite endpoint of death, MI, or urgent need for revascularization

A clinical application tool is available at https://timi.org/calculators/timi-risk-score-calculator-for-ua-nstemi/

- Age 65 years or older
- Three or more CAD risk factors: smoking, hypercholesterolemia, HTN, DM, family history of premature CAD death/events
- Known CAD (50% or greater stenosis of at least one major coronary artery on coronary angiogram)
- Aspirin use within the past 7 days
- Two or more episodes of chest discomfort within the past 24 hours
- ST-segment depression 0.5 mm or greater
- Positive biochemical marker for infarction

High Risk	Intermediate Risk	Low Risk
TIMI Risk Score 5–7 points	TIMI Risk Score 3–4 points	TIMI Risk Score 0–2 points

TIMI Risk Score	Mortality, MI, or Severe Recurrent Ischemia Requiring Urgent Revascularization Through 14 Days
0/1	5%
2	8%
3	13%
4	20%
5	26%
6/7	41%

GRACE Risk Factors for Increased Mortality and the Composite of Death or MI in ACS

Signs and symptoms of HF
Low systolic BP
Elevated heart rate
Older age
Elevated SCr
Baseline risk factors on clinical evaluation: cardiac arrest at admission, ST-segment deviation, elevated troponin
A high-risk patient is defined as a GRACE Risk Score more than 140 points (for in-hospital mortality)
The clinical application tool is available at https://www.outcomes-umassmed.org/GRACE/default.aspx

HEART Score is composed of 5 components: History, **E**lectrocardiogram (ECG), **A**ge, **R**isk factors, and **T**roponin. For each component 0, 1, or 2 points are given.

Low Risk: 0–3 points
Intermediate Risk: 4–6 points
High Risk: ≥ 7 points
A clinical application tool is available at https://www.mdcalc.com/heart-score-major-cardiac-events

ACS, acute coronary syndrome; BP, blood pressure; CAD, coronary artery disease; DM, diabetes mellitus; GRACE, Global Registry of Acute Coronary Events; HF, heart failure; HTN, hypertension; MI, myocardial infarction; NSTE, non–ST-segment elevation; SCr, serum creatinine; TIMI, thrombolysis in myocardial infarction.

ALGRAWANY

Table 9–2

Indications and Contraindications to Fibrinolytic Therapy for Management of ST-Segment Elevation Myocardial Infarction[3]

Indications

1. Ischemic symptoms for at least 20 minutes in duration but 12 hours or less since symptom onset
   and
   ST-segment elevation of at least two contiguous leads of ≥ 2 mm in men and ≥ 1.5 mm in women in leads V_2-V_3 and/or of ≥ 1 mm in other leads, or new or presumed new left bundle-branch block
2. Ongoing ischemic chest discomfort at least 20 minutes in duration 12–24 hours since symptom onset
   and
   ST-segment elevation of at least two contiguous leads of ≥ 2 mm in men and ≥ 1.5 mm in women in leads V_2-V_3 and/or of ≥ 1 mm in other leads

Absolute Contraindications

- Active internal bleeding (not including menses)
- Previous intracranial hemorrhage or stroke of unknown origin at any time
- Previous ischemic stroke within 3 months
- Intracranial neoplasm or arteriovenous malformation
- Suspected aortic dissection
- Significant closed head or facial trauma within 3 months
- Intracranial or intraspinal surgery in prior 2 months
- Severe uncontrolled hypertension unresponsive to emergency therapy

Relative Contraindications

- History of ischemic stroke > 3 months prior
- Refractory hypertension (SBP >180 and/or DBP > 110 mm Hg)
- Oral anticoagulant therapy
- Active peptic ulcer
- Prolonged (> 10 minutes) or traumatic resuscitation
- Recent (within 2–4 weeks) internal bleeding
- Major surgery < 3 weeks prior
- Noncompressible vascular punctures
- Dementia
- Pregnancy

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Modified with permission from Rogers KC, de Denus S, Finks SW, Spinler SA. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:177.

Patients with a high likelihood of coronary ischemia have a greater risk of adverse cardiac events but not all patients presenting with suspected NSTE-ACS have CAD. Some are eventually diagnosed with chest discomfort and nonobstructive CAD or microvascular disease.[4] In general, patients with NSTE-ACS, those with ST-segment depression (see Figure 9–1) and/or elevated troponin are at higher risk of death or new/recurrent MI. Various risk scores are available and should be used at presentation to predict the short-term and long-term event rates of patients presenting with NSTE-ACS.[4] These include the Thrombolysis in Myocardial Infarction (TIMI) risk score for NSTE-ACS, the Global Registry of Acute Coronary Events (GRACE) score, and the History, ECG, Age, Risk factors, and Troponin (HEART) score (Table 9–1).[4,16] There is a linear relationship between increasing scores and short-term risk (2–6 weeks) of adverse cardiac events including mortality, new or recurrent MI, or need for urgent revascularization.[17]

Based on the risk assessment, a management strategy is chosen and patients are either treated using (1) an early invasive strategy, which involves coronary angiography in patients classified as high-risk of CV events based on clinical characteristics (eg, high TIMI score 5–7), or (2) an ischemia-guided strategy in which patients initially receive medication therapy only and will undergo an invasive evaluation if they fail medical therapy (eg, continued ischemia despite optimal medical treatment) or have objective evidence of ischemia on noninvasive stress testing.[4] The ischemia-guided strategy is generally reserved for patients stratified as low-risk (eg, TIMI score 0–3). Moderate- to high-risk patients are typically referred for an invasive strategy of early coronary angiography.[4]

TREATMENT

Desired Outcomes

Short-term desired outcomes in a patient with ACS are (a) early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in UA); (b) prevention of death and other MI complications; (c) prevention of coronary artery reocclusion; (d) relief of ischemic chest discomfort; and (e) resolution of ST-segment and T-wave changes on the ECG. Long-term desired outcomes are control of CV risk factors, prevention of additional CV events, including reinfarction, stroke, and HF, and improvement in quality of life.

General Approach to Treatment

Selecting evidence-based therapies described in the guidelines for patients without contraindications results in lower mortality.[3,4] Regardless of whether patients receive emergent PCI or a more conservative, ischemia-guided strategy, general treatment measures for intermediate- to high-risk patients include admission to hospital, initiation of antithrombotics, oxygen administration (if oxygen saturation is low (< 90% [0.90], or respiratory distress), continuous multilead ST-segment monitoring for arrhythmias and ischemia (termed "telemetry"), frequent measurement of vital signs, bed rest for 12 hours in hemodynamically stable patients, avoidance of the Valsalva maneuver (prescribe stool softeners routinely), and pain relief (Figures 9–2 and 9–3).[3,4]

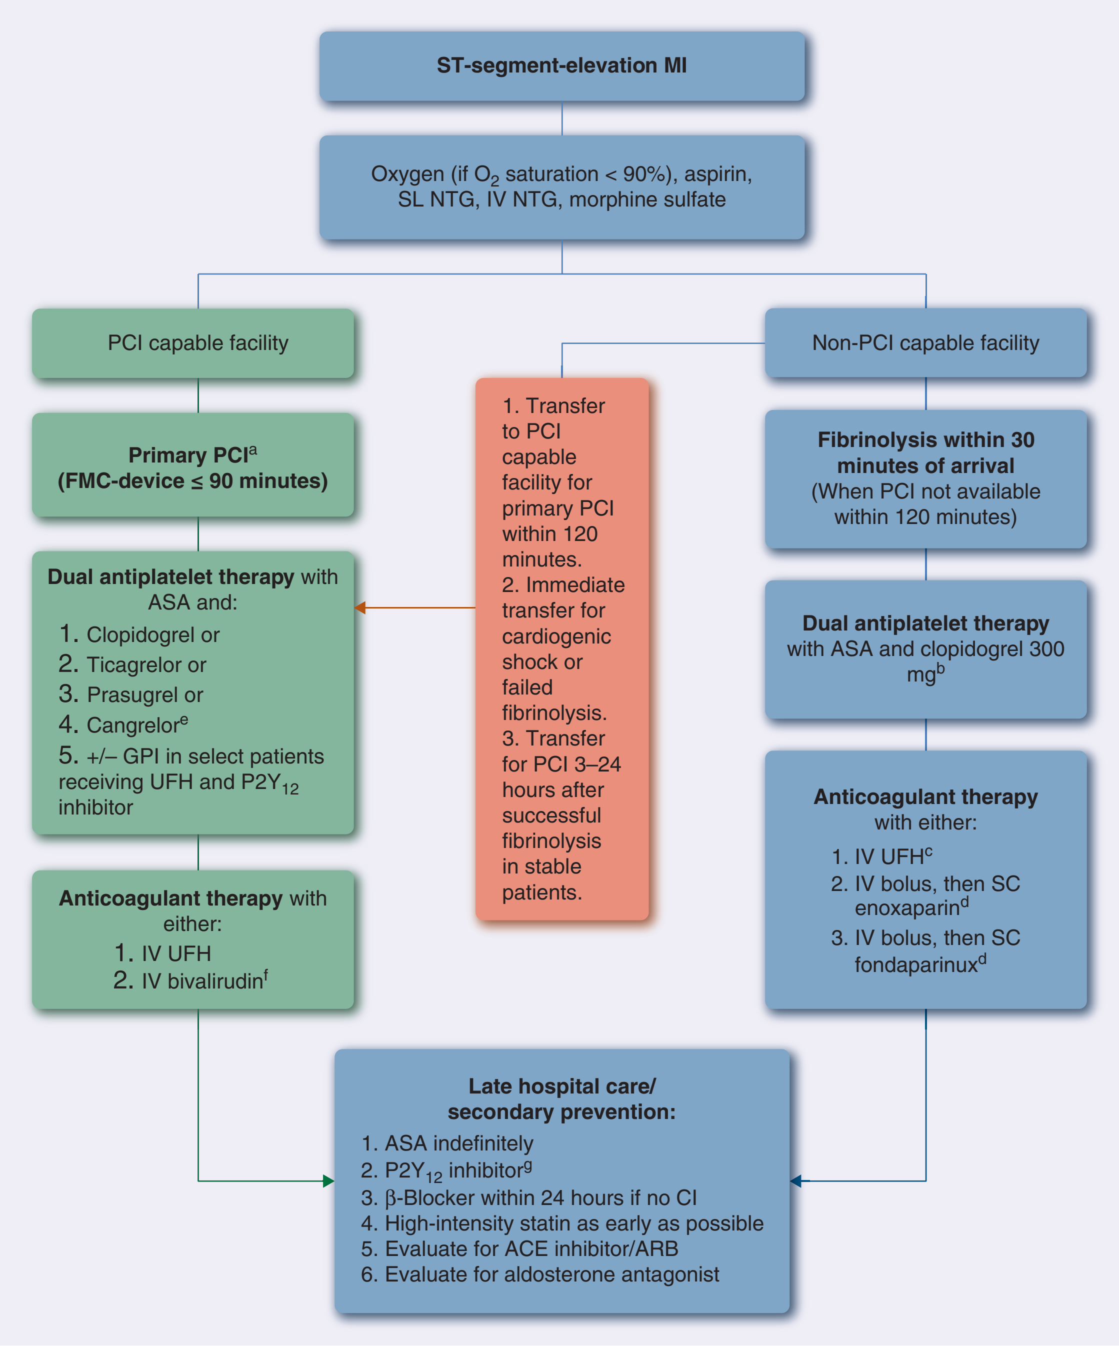
It is important to triage and treat patients according to their risk category. Patients with STE are at high risk of death, and efforts to reestablish coronary perfusion as well as adjunctive pharmacotherapy should be initiated immediately beginning prehospital and in the ED. Features identifying low-, intermediate-, and high-risk patients with NSTE-ACS are described in Table 9–1.[4] Initial approaches to treatment of STEMI and NSTE-ACS patients are outlined in Figures 9–2 and 9–3.

Reperfusion Strategies for ACS

▶ *Reperfusion Strategies for STEMIs*

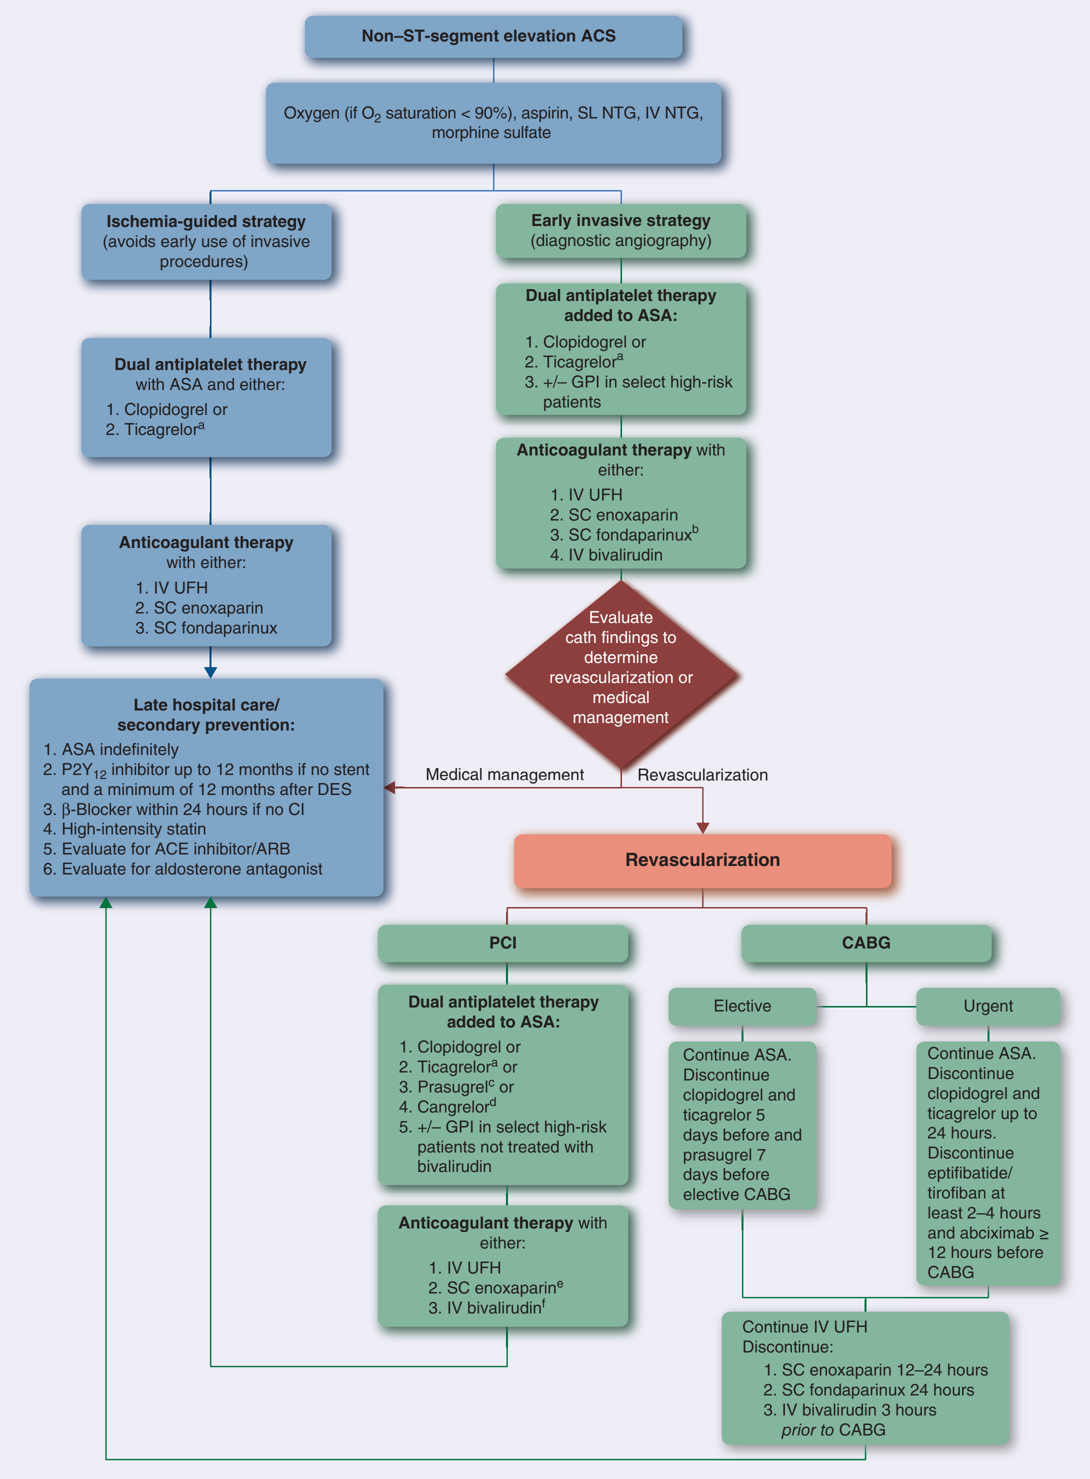
KEY CONCEPT Early reperfusion therapy with primary PCI of the infarct artery within 90 minutes from the time of first medical contact is the reperfusion treatment of choice for patients with STEMI who present within 12 hours of symptom onset (see Figure 9–2).[3] Patients may not often recognize the importance of seeking immediate medical care for a variety of reasons, which include self-treatment and preconception regarding the importance or presentation of a heart attack. Thus, education for patients and their families about the symptoms of ACS is paramount to reduce delays in reperfusion.

For primary PCI in STEMI, the patient is taken from the ED to the cardiac catheterization laboratory and undergoes coronary



ST-segment-elevation MI
Oxygen (if O_2 saturation < 90%), aspirin, SL NTG, IV NTG, morphine sulfate
PCI capable facility
Primary PCI[a] (FMC-device ≤ 90 minutes)
Dual antiplatelet therapy with ASA and:
1. Clopidogrel or
2. Ticagrelor or
3. Prasugrel or
4. Cangrelor[e]
5. +/– GPI in select patients receiving UFH and $P2Y_{12}$ inhibitor
Anticoagulant therapy with either:
1. IV UFH
2. IV bivalirudin[f]
Non-PCI capable facility
1. Transfer to PCI capable facility for primary PCI within 120 minutes.
2. Immediate transfer for cardiogenic shock or failed fibrinolysis.
3. Transfer for PCI 3–24 hours after successful fibrinolysis in stable patients.
Fibrinolysis within 30 minutes of arrival (When PCI not available within 120 minutes)
Dual antiplatelet therapy with ASA and clopidogrel 300 mg[b]
Anticoagulant therapy with either:
1. IV UFH[c]
2. IV bolus, then SC enoxaparin[d]
3. IV bolus, then SC fondaparinux[d]
Late hospital care/ secondary prevention:
1. ASA indefinitely
2. $P2Y_{12}$ inhibitor[g]
3. β-Blocker within 24 hours if no CI
4. High-intensity statin as early as possible
5. Evaluate for ACE inhibitor/ARB
6. Evaluate for aldosterone antagonist

FIGURE 9–2. Initial pharmacotherapy for ST-segment elevation myocardial infarction (STEMI). See **Table 9–3** for dosing recommendations and contraindications to specific therapies. [a]Options after coronary angiography also include medical management alone or coronary artery bypass graft surgery. [b]Clopidogrel preferred $P2Y_{12}$ when fibrinolytic therapy is utilized. No loading dose recommended if age older than 75 years. [c]Given for up to 48 hours or until revascularization. [d]Given for the duration of hospitalization, up to 8 days or until revascularization. [e]For use as adjunct therapy during PCI only. Administer ticagrelor at any time prior to or during the cangrelor infusion. Administer prasugrel or clopidogrel after the cangrelor infusion. [f]If pretreated with UFH, stop UFH infusion for 30 minutes prior to administration of bivalirudin (bolus plus infusion). [g]In patients with STEMI receiving a fibrinolytic or who do not receive reperfusion therapy, administer clopidogrel for at least 14 days and ideally up to 1 year. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ASA, aspirin; CI, contraindication; FMC, first medical contact; GPI, glycoprotein IIb/IIIa inhibitor; IV, intravenous; MI, myocardial infarction; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.)



Non–ST-segment elevation ACS
Oxygen (if O_2 saturation < 90%), aspirin, SL NTG, IV NTG, morphine sulfate
Ischemia-guided strategy (avoids early use of invasive procedures)
Early invasive strategy (diagnostic angiography)
Dual antiplatelet therapy with ASA and either:
1. Clopidogrel or
2. Ticagrelor[a]
Anticoagulant therapy with either:
1. IV UFH
2. SC enoxaparin
3. SC fondaparinux
Dual antiplatelet therapy added to ASA:
1. Clopidogrel or
2. Ticagrelor[a]
3. +/– GPI in select high-risk patients
Anticoagulant therapy with either:
1. IV UFH
2. SC enoxaparin
3. SC fondaparinux[b]
4. IV bivalirudin
Evaluate cath findings to determine revascularization or medical management
Medical management
Revascularization
Late hospital care/ secondary prevention:
1. ASA indefinitely
2. $P2Y_{12}$ inhibitor up to 12 months if no stent and a minimum of 12 months after DES
3. β-Blocker within 24 hours if no CI
4. High-intensity statin
5. Evaluate for ACE inhibitor/ARB
6. Evaluate for aldosterone antagonist
Revascularization
PCI
CABG
Dual antiplatelet therapy added to ASA:
1. Clopidogrel or
2. Ticagrelor[a] or
3. Prasugrel[c] or
4. Cangrelor[d]
5. +/– GPI in select high-risk patients not treated with bivalirudin
Anticoagulant therapy with either:
1. IV UFH
2. SC enoxaparin[e]
3. IV bivalirudin[f]
Elective
Urgent
Continue ASA. Discontinue clopidogrel and ticagrelor 5 days before and prasugrel 7 days before elective CABG
Continue ASA. Discontinue clopidogrel and ticagrelor up to 24 hours. Discontinue eptifibatide/ tirofiban at least 2–4 hours and abciximab ≥ 12 hours before CABG
Continue IV UFH
Discontinue:
1. SC enoxaparin 12–24 hours
2. SC fondaparinux 24 hours
3. IV bivalirudin 3 hours
prior to CABG

FIGURE 9–3. Initial pharmacotherapy for non–ST-segment elevation (NSTE) ACS. See **Table 9–3** for dosing recommendations and contraindications to specific therapies. [a]Reasonable to choose ticagrelor over clopidogrel for maintenance $P2Y_{12}$ for NSTE-ACS patients treated with an early invasive or ischemia-guided strategy. [b]Not to be used as the sole anticoagulant during PCI. Give additional UFH 85 units/kg IV without GPI and 60 units/kg IV with GPI. [c]Reasonable to choose prasugrel over clopidogrel for maintenance $P2Y_{12}$ for NSTE-ACS patients undergoing PCI who are not at high risk for bleeding. Do not use if prior history of stroke/transient ischemic attack (TIA), age older than 75 years, or body weight less than or equal to 60 kg (132 lb). [d]Adjunct agent to be used during PCI only. Administer ticagrelor at any time prior to or during the cangrelor infusion. Administer prasugrel or clopidogrel after the cangrelor infusion. [e]May require IV supplemental dose of enoxaparin; see **Table 9–3**. [f]If pretreated with UFH, stop UFH infusion for 30 minutes prior to administration of bivalirudin bolus plus infusion. (ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; ARB, angiotensin receptor blocker; ASA, aspirin; CABG, coronary artery bypass graft; CI, contraindication; DES, drug-eluting stent; GPI, glycoprotein IIb/IIIa inhibitor; IV, intravenous; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin).

Patient Encounter 1, Part 1

A 71-year-old, 80 kg (176 lb) man developed substernal chest tightness and left arm and shoulder pain while shopping with his wife. When it was not relieved by rest, his wife called 911. Local paramedics arrived and ST-segment elevation was found on 12-lead ECG. He was given a total of three 0.4 mg sublingual nitroglycerin tablets by mouth over three successive doses, 325 mg ASA by mouth, and morphine 2-mg intravenous (IV) push without relief of discomfort upon transport to the ED. He was taken to a facility with a cardiac catheterization laboratory with the intent of performing primary PCI.

PMH: Hypertension (HTN) for 10 years; dyslipidemia for 10 years; diabetes mellitus (DM) type 2 for 15 years; chronic kidney disease (CKD) for 2 years

FH: Mother with DM; father with MI at age 55 years; siblings with HTN and DM

SH: Nonsmoker, never smoked

Allergies: NKDA

Meds: Ramipril 5 mg by mouth once daily; hydrochlorothiazide 25 mg by mouth once daily; ASA 81 mg by mouth once daily; atorvastatin 20 mg by mouth once daily

ROS: substernal chest discomfort

PE:

HEENT: Normocephalic atraumatic

CV: Regular rate and rhythm; S_1, S_2, no S_3, no S_4; no murmurs or rubs

VS: BP 150/90 mm Hg; HR 92 beats/min; T 37°C (98.6°F)

Lungs: Fine crackles at the lower bases

Abd: Nontender, nondistended

GI: Normal bowel sounds

GU: Stool guaiac negative

Exts: No bruits, no peripheral edema, pulses 2+, femoral pulses present, good range of motion

Neuro: Alert and oriented × 3, cranial nerves intact

Labs: Sodium 144 mEq/L (mmol/L), potassium 4.4 mEq/L (mmol/L), chloride 103 mEq/L (mmol/L), bicarbonate 21 mEq/L (mmol/L), SCr 1.6 mg/dL (141 μmol/L), glucose 155 mg/dL (8.6 mmol/L), WBC $8.9 \times 10^3/\text{mm}^3$ (8.9×10^9/L), hemoglobin 14.7 g/dL (147 g/L or 9.12 mmol/L), hematocrit 45% (0.45), platelets $210 \times 10^3/\text{mm}^3$ (210×10^9/L), hs-cTnI 8.9 ng/L (99th percentile 5 ng/L), oxygen saturation 98% (0.98) on room air, N-terminal proBNP 500 pg/mL (ng/L; 59 pmol/L)

ECG: Normal sinus rhythm, PR 0.16 seconds, QRS 0.08 seconds, QTc 0.38 seconds, 2-mm ST-segment elevation in two or more contiguous anterior leads

CXR: No active disease

Echo: Anterior wall dyskinesis, LVEF 40% (0.40)

What information is suggestive of acute MI?

Are any complications of MI present?

angiography with either balloon angioplasty or, preferably, placement of a drug-eluting intracoronary stent in the artery associated with the infarct. In most cases, drug-eluting stents are preferred over bare metal stents.[5,9] Because of the high likelihood of a complete coronary artery occlusion in patients presenting with symptoms and ST-segment elevation, results of a troponin blood test do not need to be available when the decision to proceed to primary PCI is made. Findings from a meta-analysis of trials comparing fibrinolysis with primary PCI indicate a lower mortality rate with primary PCI.[18] One reason for the superiority of primary PCI compared with fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared with fewer than 60% with fibrinolytics.[3,5] In addition, intracranial hemorrhage (ICH) and major bleeding risks from primary PCI are lower than the risks of severe bleeding events following fibrinolysis.[19] A strategy of primary PCI is generally preferred in patients presenting to institutions with skilled interventional cardiologists and a catheterization laboratory immediately available, those in cardiogenic shock, those with contraindications to fibrinolytics, and those with continuing symptoms 12 to 24 hours after symptom onset.[3] Primary PCI is more commonly used in the United States compared to fibrinolysis. Current guidelines indicate the time from first medical contact-to-device should be less than or equal to 90 minutes, with every effort made to ensure the time to reperfusion is as short as possible.

Patients presenting to facilities that do not have interventional cardiology services can be transferred when a protocol that minimizes delays has been established between institutions and if primary PCI can be performed within the first 120 minutes of first medical contact.[3,19] Immediate transfer to a PCI-capable facility is recommended for patients who develop cardiogenic shock or acute severe HF, irrespective of the timing of presentation. PCI during hospitalization for STEMI, or transfer to a PCI-capable hospital, is also appropriate in those in whom fibrinolysis is not successful and those with persistent rest ischemia or signs of ischemia on stress testing following MI.[3,5]

▶ *Fibrinolytic Therapy for STEMI*

Administration of a fibrinolytic agent is indicated in patients with STEMI who present to the hospital within 12 hours of the onset of chest discomfort, who are initially seen at a non–PCI-capable hospital, and who have an anticipated time from first medical contact-to-device greater than 120 minutes if transferred to a PCI-capable hospital (see Figure 9–2).[3] The reduction in mortality with fibrinolysis is greatest with early administration and diminishes after 12 hours. The use of fibrinolytics between 12 and 24 hours after symptom onset should be limited to patients with ongoing ischemia. Fibrinolytic therapy is preferred over primary PCI when there is no cardiac catheterization laboratory in a hospital and the delay from first medical contact-to-device would exceed 120 minutes if the patient was transferred to a PCI-capable hospital.[3] Guidelines recommend the fibrinolytic agent be administered within 30 minutes of hospital arrival. All hospitals should have protocols addressing fibrinolysis eligibility, dosing, and monitoring. Medication errors are common in patients receiving fibrinolytics as dosing regimens are different for different indications (eg, alteplase dosing in acute ischemic stroke vs MI) and are less commonly used for MI. Indications and contraindications for

Patient Encounter 1, Part 2

Identify your acute treatment goals for this patient with STEMI.

What adjunctive pharmacotherapy should be administered in the ED prior to proceeding to the cardiac catheterization laboratory?

What additional pharmacotherapy should be initiated on the first day of this patient's hospitalization following successful PCI/intracoronary stenting?

fibrinolysis in MI are listed in Table 9–2. It is not necessary to obtain the results of biochemical markers before initiating fibrinolytic therapy.

Because administration of fibrinolytics results in clot lysis, patients who are at high risk of major bleeding (including ICH) presenting with an absolute contraindication should not receive fibrinolytic therapy; primary PCI is preferred. Alteplase, reteplase, and tenecteplase are fibrinolytics approved for treatment of MI. Streptokinase was formerly used but is no longer available in the United States. ICH and major bleeding are the most serious side effects of fibrinolytic agents. The risk of ICH was higher with alteplase versus tenecteplase in one study.[20] Fibrinolytic therapy is not indicated and should not be used in patients with NSTE-ACS because increased mortality has been reported with these agents compared with controls in clinical trials.[3,4]

▶ *Early Invasive Therapy for NSTE-ACS*

KEY CONCEPT Clinical practice guidelines recommend coronary angiography followed by either PCI or CABG surgery revascularization as an early treatment (early invasive strategy) for patients with NSTE-ACS at an elevated risk for death or MI including those with confirmed MI (by troponin or hs-troponin), a high-risk score (see Table 9–1) or patients with refractory angina, hemodynamic instability, or electrical instability (eg, ventricular arrhythmias) (see Figure 9–3).[4,5,9] Several clinical trials support an "invasive" interventional strategy with early angiography and PCI or CABG versus an ischemia-guided approach, whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing.[4,21] An early invasive approach results in a long-term reduction in the rates of CV death or MI, with the largest absolute effect seen in higher-risk patients.[4] Several studies have also shown less angina, fewer hospitalizations, and improved quality of life with an invasive strategy.

All patients with ACS undergoing PCI should receive dual antiplatelet therapy (DAPT) with ASA and a $P2Y_{12}$ inhibitor antiplatelet (either clopidogrel, prasugrel, or ticagrelor) for at least 3 to 12 months following PCI regardless of stent type (Table 9–3).[3,4,22,23] A shorter duration of DAPT is suggested for patients at high risk of major bleeding, including patients requiring concomitant oral anticoagulation (eg, stroke prevention in atrial fibrillation), while a longer duration can be considered in patients who have tolerated DAPT without bleeding and are at higher risk of recurrent ischemic events (eg, second MI, DM, or multivessel CAD). After initial DAPT with aspirin and a $P2Y_{12}$ inhibitor, single antiplatelet therapy with either low-dose aspirin or a $P2Y_{12}$ inhibitor should be continued indefinitely. Clopidogrel is the preferred $P2Y_{12}$ inhibitor in patients with a high risk of bleeding as large comparative randomized trials demonstrated lower risk of major bleeding with clopidogrel compared to either prasugrel or ticagrelor.[4] The risk of ischemic events appears to be lower with prasugrel compared to ticagrelor with a similar risk of major bleeding.[24]

Ischemia-Guided Therapy ("Medical Management") for ACS

For patients with NSTE-ACS, an initial conservative ischemia-guided strategy is recommended for patients with a low-risk score, normal ECGs, and negative troponin who are without recurrence of chest discomfort (see Figure 9–3).[4] An ischemia-guided strategy may also be preferred in patients with extensive comorbidities in which the cumulative risks of comorbidities plus revascularization would outweigh the potential benefits of revascularization.

Stress testing (see Figure 9–1) is indicated in patients with NSTE-ACS when an initial ischemia-guided strategy is selected. It is also reasonable for STEMI patients who may be candidates for revascularization but did not undergo coronary angiography.[3,4] Following the stress test, patients experiencing recurrent ischemia or symptoms despite optimal medical treatment or who are considered high risk (see Table 9–1) should undergo left heart catheterization with coronary angiography and revascularization as indicated.[3,4] Patients with NSTE-ACS at low risk for recurrent CHD events following stress testing should be given low-dose ASA indefinitely and either clopidogrel or ticagrelor for up to 12 months following hospital discharge in addition to other secondary preventive pharmacotherapy described later in this chapter.[4] Patients with STEMI at low risk for recurrent CHD events should receive low-dose ASA indefinitely and clopidogrel for at least 14 days and up to 12 months in addition to other secondary preventive pharmacotherapy (see Figure 9–2).[3]

Early Pharmacologic Therapy for ACS

Pharmacotherapy for early treatment of ACS is outlined in Figures 9–2 and 9–3 and Table 9–3.[3-5] KEY CONCEPT According to ACC/ACCF/AHA STEMI and NSTE-ACS practice guidelines, pharmacotherapy that all patients should receive within the first day of hospitalization, and preferably in the ED, are intranasal oxygen (if oxygen saturation is low), sublingual (SL) nitroglycerin (NTG), ASA, a $P2Y_{12}$ inhibitor (agent and timing of administration dependent on reperfusion strategy), and anticoagulation (agent dependent on reperfusion strategy). Intravenous (IV) NTG may be given in select patients with either acute HF, severe hypertension, or who are still experiencing pain despite SL NTG. It is reasonable to administer morphine to patients with refractory angina as an analgesic and a venodilator. Oral β-blockers should be initiated within the first day in patients without cardiogenic shock or other contraindications.[3,4] ACE inhibitors (or ARB in ACE inhibitor-intolerant patients) should be initiated in select patients during hospitalization with ACS.[3] High-intensity statin therapy should be initiated or continued during hospitalization in all patients without contraindications. Dosing and contraindications for SL and IV NTG, ASA, clopidogrel, β-blockers, ACE inhibitors, statins, anticoagulants, and fibrinolytics are listed in Table 9–3.

▶ *Morphine*

While morphine is an effective analgesic and may reduce preload in patients presenting with ACS, administration has been found to delay the absorption of $P2Y_{12}$ inhibitors and their active metabolites resulting in a delay and attenuation of their antiplatelet effects.[25-27] The use of morphine has been associated with increased risk of recurrent in-hospital MI in some ACS studies

Table 9–3

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction (STEMI) and Non–ST-Segment Elevation Acute Coronary Syndrome (NSTE-ACS)[3,4,20]

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
Antiplatelets			
Aspirin	STEMI, class I recommendation for all patients. NSTE-ACS, class I recommendation for all patients.	Hypersensitivity, active bleeding, severe bleeding risk.	162–325 mg orally once on hospital day 1. 81–325 mg orally once daily starting hospital day 2 and continued indefinitely in all patients. Aspirin dose of 81 mg is preferred. Limit dose to < 100 mg if using ticagrelor.
Clopidogrel	NSTE-ACS, class I recommendation added to aspirin. STEMI, class I recommendation added to aspirin. PCI in STEMI and NSTE-ACS, class I recommendation. In patients with aspirin allergy, class I recommendation.	Hypersensitivity, active bleeding, severe bleeding risk.	NSTE-ACS: 300- to 600-mg oral loading dose on hospital day 1 followed by a maintenance dose of 75 mg once daily starting on hospital day 2. STEMI: 300-mg oral loading dose followed by 75 mg orally daily in patients receiving a fibrinolytic or who do not receive reperfusion therapy; avoid loading dose in patients ≥ 75 years. 600-mg (class I recommendation) loading dose before or when PCI performed (unless within 24 hours of fibrinolytic therapy, a dose of 300 mg should be given). Discontinue at least 5 days before CABG surgery if bleeding risk outweighs benefit (class I recommendation). Administer indefinitely in patients with aspirin allergy (class I recommendation). Continue for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent. In patients with NSTE-ACS treated medically, administer for up to 12 months (class I recommendation). In patients receiving a fibrinolytic or who do not receive reperfusion therapy, administer for at least 14 days (class I recommendation) and ideally up to 12 months. Genetic testing might be considered to identify patients at high risk of poor response (class IIb recommendation). In these patients, an alternative $P2Y_{12}$ inhibitor might be considered (class IIb recommendation). The routine use of genetic testing is not recommended (class III recommendation).
Prasugrel	PCI in STE and NSTE-ACS, added to aspirin, class I recommendation. Class IIa as preference over clopidogrel for those not at high risk of bleeding and do not have a history of stroke/TIA.	Active bleeding, prior stroke or TIA. Not recommended in patients not receiving PCI.	Initiate in patients with known coronary artery anatomy only (so as to avoid use in patients needing CABG surgery; class I recommendation). Give no later than 1 hour after PCI. Patients who have history of prior stroke/TIA, are 75 years of age or more, or weigh < 60 kg (132 lb) have higher risk of bleeding, and there is no added benefit compared with clopidogrel. 60-mg oral loading dose followed by 10 mg once daily for patients weighing 60 kg (132 lb) or more. Consider 5 mg once daily in patients weighing < 60 kg (132 lb) (based on limited data). Discontinue at least 7 days prior to CABG surgery if bleeding risk outweighs benefit (class I recommendation). Continue for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent.

Anticoagulants			
Unfractionated heparin	STEMI, class I recommendation in patients undergoing PCI and for those patients treated with fibrinolytics. NSTE-ACS, class I recommendation in combination with antiplatelet therapy for ischemia-guided or early invasive approach PCI, class I recommendation (NSTE-ACS and STEMI).	Active bleeding, history of heparin-induced thrombocytopenia, severe bleeding risk, recent stroke.	STEMI with fibrinolytics: initial 60-units/kg IV bolus (maximum 4000 units) followed by a constant IV infusion at 12 units/kg/hour (maximum 1000 units/hour). Titrate to therapeutic aPTT. STEMI primary PCI: administer 50- to 70 units/kg IV bolus if a GPI planned; 70–100 units/kg IV bolus if no GPI planned and supplement with IV bolus doses to maintain target ACT. NSTE-ACS: administer 60 units/kg IV bolus (maximum 4000 units) followed by a constant IV infusion at 12 units/kg/hour (maximum 1000 units/hour). Titrated to maintain an aPTT of 1.5–2.0 times control (~ 50–70 seconds) for STEMI with fibrinolytics and for NSTE-ACS. Titrated to ACT of 250–350 seconds for primary PCI without a GPI and 200–250 seconds in patients given a concomitant GPI. The first aPTT should be measured at 4–6 hours for NSTE-ACS and STEMI in patients not treated with fibrinolytics or undergoing primary PCI. The first aPTT should be measured at 3 hours in patients with STEMI who are treated with fibrinolytics. Continue for 48 hours or until revascularization.
Enoxaparin	STEMI class I recommendation in patients receiving fibrinolytics. NSTE-ACS, class I recommendation in combination with aspirin for ischemia-guided or early invasive strategy. For PCI, class I recommendation as an alternative to UFH in patients with NSTE-ACS.	Active bleeding, history of heparin-induced thrombocytopenia, severe bleeding risk, recent stroke, avoid enoxaparin if CrCl < 15 mL/min (0.25 mL/s), avoid if CABG surgery planned.	NSTE-ACS: Enoxaparin 1 mg/kg SC every 12 hours for patients (CrCl ≥ 30 mL/min [0.50 mL/s]). Enoxaparin 1 mg/kg SC every 24 hours (CrCl 15–29 mL/min [0.25–0.49 mL/s]). For all patients undergoing PCI following initiation of SC enoxaparin for NSTE-ACS or STEMI, a supplemental 0.3 mg/kg IV dose of enoxaparin should be administered at the time of PCI if the last dose of SC enoxaparin was given 8–12 hours prior to PCI or received < 2 therapeutic SC doses. STEMI with fibrinolytics: • Age < 75 years: Administer enoxaparin 30 mg IV bolus followed in 15 minutes by 1 mg/kg SC every 12 hours (maximum of 100 mg for first two doses). • Age ≥ 75 years: Administer enoxaparin 0.75 mg/kg SC every 12 hours (maximum of 75 mg for first two doses). • Continue throughout hospitalization, up to 8 days, or until revascularization. Continue for duration of hospitalization for NSTE-ACS or until revascularization. Discontinue at least 12–24 hours before CABG surgery.
Bivalirudin	NSTE-ACS class I recommendation for invasive strategy. PCI in STEMI (class I recommendation).	Active bleeding, severe bleeding risk.	NSTE-ACS planned early invasive strategy: Administer 0.1 mg/kg IV bolus followed by 0.25-mg/kg/hour infusion. PCI in NSTE-ACS: Administer a second bolus of 0.5 mg/kg IV and increase infusion rate to 1.75 mg/kg/hour if already receiving bivalirudin PCI in NSTE-ACS and STEMI: Administer 0.75-mg/kg IV bolus followed by 1.75 mg/kg/hour infusion if not already receiving bivalirudin If prior UFH given, discontinue UFH and wait 30 minutes before initiating bivalirudin. CrCl < 30 mL/min (0.50 mL/s): Adjust dose of infusion to 1 mg/kg/hour Hemodialysis: Adjust dose of infusion to 0.25 mg/kg/hour Lower bleeding rates are mitigated when administered with a GPI. Clopidogrel should be administered at least 6 hours before if a GPI is not used. Discontinue at least 3 hours prior to CABG surgery.

(*Continued*)

Table 9–3

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction (STEMI) and Non–ST-Segment Elevation Acute Coronary Syndrome (NSTE-ACS)[3,4,20] (*Continued*)

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy
Fondaparinux	STEMI class I recommendation receiving fibrinolytics. NSTE-ACS class I recommendation for ischemia-guided or early invasive strategy. Class III as sole agent in PCI.	Active bleeding, severe bleeding risk, SCr ≥ 3.0 mg/dL (265 μmol/L) or CrCl < 30 mL/min (0.50 mL/s).	STEMI: 2.5-mg IV bolus followed by 2.5-mg SC once daily starting on hospital day 2. NSTE-ACS: 2.5-mg SC once daily. Continue throughout hospitalization, up to 8 days, or until revascularization. For PCI, give additional doses of either UFH or bivalirudin as recommended above. Discontinue at least 24 hours prior to CABG surgery.
Fibrinolytic therapy	STEMI, class I recommendation for patients presenting within 12 hours following the onset of symptoms, class IIa in patients presenting between 12 and 24 hours following the onset of symptoms with continuing signs of ischemia. NSTE-ACS, class III recommendation.	Any prior ICH, known structural cerebrovascular lesions such as an arterial venous malformation, known intracranial malignant neoplasm, ischemic stroke within 3 months, active bleeding (excluding menses) or known bleeding diathesis, significant closed head or facial trauma within 3 months, severe uncontrolled HTN unresponsive to treatment.	Alteplase: 15-mg IV bolus followed by 0.75 mg/kg IV over 30 minutes (maximum 50 mg) followed by 0.5 mg/kg (max 35 mg) over 60 minutes (maximum total dose 100 mg). Reteplase: 10 units IVP over 2 minutes × 2 doses, 30 minutes apart. Tenecteplase: Single bolus administered over 5 seconds • < 60 kg: 30-mg IV bolus • 60–69 kg: 35-mg IV bolus • 70–79 kg: 40-mg IV bolus • 80–89 kg: 45-mg IV bolus • > 90 kg: 50-mg IV bolus • Consider reducing the dose by 50% in patients ≥ 75 years to reduce the risk of ICH
Nitroglycerin	STEMI and NSTE-ACS, class I recommendation in patients with ongoing ischemic discomfort, control of HTN, or management of HF.	Hypotension, sildenafil, avanafil, tadalafil, or vardenafil are all contraindicated with nitrates.	0.4-mg SL, repeated every 5 minutes × 3 doses then assess need for IV infusion. 5- to 10-mcg/min IV infusion titrated up to 75–100 mcg/min until relief of symptoms or limiting side effects (headache) with a systolic BP < 90 mm Hg or > 30% below starting mean arterial pressure levels if significant HTN is present. Topical patches or oral nitrates are acceptable alternatives for patients without ongoing or refractory symptoms. Discontinue IV infusion after 24–48 hours.
β-Blockers[c]	STEMI and NSTE-ACS, class I recommendation for oral β-blockers in all patients without contraindications in the first 24 hours, class IIa for IV β-blockers in STEMI patients with HTN or those with ongoing ischemia. Class III for IV β-blockers in patients with risk factors for shock.	PR ECG interval > 0.24 seconds, second-degree or third-degree atrioventricular heart block without a pacemaker, heart rate < 60 beats/min, systolic BP < 90 mm Hg, shock, left ventricular failure with decompensated HF, severe reactive airway disease.	Metoprolol 5-mg slow IV push (over 1–2 minutes), repeated every 5 minutes for a total of 15 mg followed in 1–2 hours by 25–50 mg orally every 6-12 hours; if a very conservative regimen is desired, initial doses can be reduced to 1–2 mg. Atenolol 5-mg IV dose followed in 5 minutes by a second 5-mg IV dose for a total of 10 mg followed in 1–2 hours by 50–100 mg orally once daily. Alternatively, initial IV therapy can be omitted and treatment started with oral dosing. For dosing of carvedilol, metoprolol succinate, and bisoprolol in patients with systolic HF, please refer to Chapter 7. Continue oral β-blocker for 3 years and possibly indefinitely.

Calcium channel blockers	NSTE-ACS class I recommendation for patients with ongoing ischemia or vasospasm who are already taking adequate doses of nitrates and β-blockers or in patients with contraindications or intolerance to β-blockers (diltiazem or verapamil preferred during initial presentation if EF > 40% [0.40]). NSTE-ACS, class IIb recommendation for diltiazem for patients with AMI.	Pulmonary edema, evidence of left ventricular dysfunction, systolic BP < 100 mm Hg, PR ECG segment to > 0.24 seconds second- or third-degree atrioventricular heart block for verapamil or diltiazem, pulse rate < 60 beats/min for diltiazem or verapamil.	Diltiazem 120–360 mg sustained release orally once daily. Verapamil 180–480 mg sustained release orally once daily. Amlodipine 5–10 mg orally once daily. Continue as indicated to manage angina, HTN, or arrhythmias.		
ACE inhibitors	NSTE-ACS and STEMI, class I recommendation for patients with HF, left ventricular dysfunction and EF < 40% (0.40), DM, HTN, or stable CKD in the absence of contraindications. Consider in all patients with CAD (class I recommendation, class IIb in low-risk patients). Indicated indefinitely for all patients with EF < 40% (0.40) (class I recommendation).	Systolic BP < 100 mm Hg, history of intolerance to an ACE inhibitor, bilateral renal artery stenosis, serum potassium > 5.5 mEq/L (mmol/L), acute renal failure, pregnancy.	**Drug**	**Initial Dose (mg)**	**Target Dose (mg)**
			Captopril	6.25–12.5	25–50 orally three times daily
			Enalapril	2.5–5.0	10 twice daily orally
			Lisinopril	2.5–5.0	10–20 once daily orally
			Ramipril	2.5	5 twice daily or 10 once daily orally
			Trandolapril	1.0	4 once daily orally
			Continue indefinitely.		
Angiotensin receptor blockers	NSTEMI and STEMI, class I recommendation in patients with HF or left ventricular EF < 40% (0.40) and intolerant of an ACE inhibitor, class IIa recommendation in patients with clinical signs of HF or EF < 40% (0.40) and no documentation of ACE inhibitor intolerance. Class I in other ACE inhibitor–intolerant patients with HTN.	Systolic BP < 100 mm Hg, bilateral renal artery stenosis, serum potassium > 5.5 mEq/L (mmol/L), acute renal failure, pregnancy.	**Drug**	**Initial Dose (mg)**	**Target Dose (mg)**
			Candesartan	4–8	32 once daily orally
			Valsartan	20	160 twice daily orally
			Losartan	12.5–25	150 daily
			Continue indefinitely.		
Aldosterone antagonists	NSTEMI and STEMI class I recommendation in patients with EF ≤ 40% (0.40) and either DM or HF who are already receiving an ACE inhibitor and β-blocker.	Hypotension, hyperkalemia, serum potassium > 5.0 mEq/L (mmol/L), SCr ≥ 2.5 mg/dL (221 μmol/L) for men and ≥ 2.0 mg/dL (177 μmol/L) for women and/or CrCl ≤ 30 mL/min (0.5 mL/s). Concomitant strong CYP3A inhibitors with eplerenone.	**Drug**	**Initial Dose (mg)**	**Target Dose (mg)**
			Eplerenone	25	50 once daily orally
			Spironolactone	12.5	25–50 once daily orally
			Continue indefinitely.		

(*Continued*)

Table 9–3

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction (STEMI) and Non–ST-Segment Elevation Acute Coronary Syndrome (NSTE-ACS)[3,4,20] (*Continued*)

Drug	Clinical Condition and Guideline Recommendations[a]	Contraindications[b]	Dose and Duration of Therapy	
Morphine sulfate	STEMI and NSTE-ACS class IIb recommendation for patients whose chest pain persists despite treatment with maximally tolerated anti-anginal drugs.	Hypotension, respiratory depression, confusion, obtundation.	1- to 5-mg IV bolus dose. May be repeated every 5–30 minutes as needed to relieve symptoms and maintain patient comfort.	
Statins	NSTE-ACS and STEMI class I recommendation to initiate or continue high-intensity statin therapy during early hospital care. For patients > 75 years of age, it is reasonable to initiate moderate- or high-intensity statin therapy.	Caution with use of fibrate and statin-specific drug interactions. Contraindicated in active liver disease.	**Dose Adjustment for CKD** Atorvastatin 40–80 mg daily. Rosuvastatin 20–40 mg daily. Continue indefinitely.	No adjustment needed. Reduce initial dose to 5 mg in CrCl < 50 mL/min (0.50 mL/s); max dose 10 mg daily.

[a] Class I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective. Class II recommendations are those conditions for which there is conflicting evidence and/or divergence of opinion about the usefulness/efficacy of a procedure or treatment. For class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion. Class III recommendations are those where the procedure or treatment is not useful and may be harmful.

[b] Allergy or prior intolerance is a contraindication for all categories of drugs listed in this chart.

[c] Choice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as metoprolol, or the ultra short-acting agent esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (eg, 2.5-mg IV metoprolol, 12.5-mg oral metoprolol, or 25-mcg/kg/min esmolol as initial doses) rather than complete avoidance of β-blocker therapy.

ACE, angiotensin-converting enzyme; ACT, activated clotting time; AMI, acute myocardial infarction; aPTT, activated partial thromboplastin time; BP, blood pressure; CABG, coronary artery bypass graft; CAD, coronary artery disease; CKD, chronic kidney disease; CrCl, creatinine clearance; CYP, cytochrome P450; DAPT, dual antiplatelet therapy; DM, diabetes mellitus; ECG, electrocardiogram; EF, ejection fraction; GPI, glycoprotein IIb/IIIa inhibitor; HF, heart failure; HTN, hypertension; ICH, intracranial hemorrhage; IV, intravenous; IVP, intravenous push; PCI, percutaneous coronary intervention; SC, subcutaneous; SCr, serum creatinine; SL, sublingual; TIA, transient ischemic attack; UFH, unfractionated heparin.

Modified with permission from Rogers KC, de Denus S, Finks SW, Spinler SA. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:173–176.

Patient Encounter 2, Part 1

A 55-year-old, 81 kg (178 lb) man presents to the ED by ambulance complaining of chest pressure and nausea for 4 hours after awakening from sleep. His symptoms were not relieved with two antacid tablets. Local paramedics were called who gave the patient a total of three 0.4 mg sublingual nitroglycerin tablets over three successive doses and 325 mg ASA by mouth without relief of chest discomfort. The patient is transferred to the hospital where an early invasive strategy is chosen.

PMH: Dyslipidemia and HTN for 5 years

FH: Father died after MI at age 50; mother and brother alive with HTN and dyslipidemia

SH: Nonsmoker

Allergies: NKDA

Meds: Atorvastatin 80 mg by mouth once daily at bedtime; aspirin 81 mg by mouth daily; amlodipine 10 mg by mouth once daily

ROS: Chest pressure and nausea

PE:

HEENT: Normocephalic atraumatic

CV: Regular rate and rhythm; S_1, S_2, no S_3, no S_4; no murmurs or rubs

VS: BP 150/88 mm Hg; HR 86 beats/min; T 37°C (98.6°F)

Lungs: Clear to auscultation and percussion

Abd: Nontender, nondistended

GI: Normal bowel sounds

GU: Stool guaiac negative

Exts: No bruits, no peripheral edema, pulses 2+, femoral pulses present, good range of motion

Neuro: Alert and oriented × 3, cranial nerves intact

Labs: Sodium 140 mEq/L (mmol/L), potassium 3.7 mEq/L (mmol/L), chloride 101 mEq/L (mmol/L), bicarbonate 24 mEq/L (mmol/L), SCr 0.8 mg/dL (71 μmol/L), glucose 88 mg/dL (4.9 mmol/L), WBC $4.9 \times 10^3/\text{mm}^3$ (4.9×10^9/L), hemoglobin 13.9 g/dL (139 g/L or 8.6 mmol/L), hematocrit 44% (0.44), platelets $220 \times 10^3/\text{mm}^3$ (220×10^9/L), hs-cTnI < 2 ng/L (99th percentile 5 ng/L), oxygen saturation 97% (0.97) on room air, BNP 550 pg/mL (ng/L; 159 pmol/L)

ECG: Normal sinus rhythm, PR 0.16 seconds, QRS 0.08 seconds, QTc 0.38 seconds, 1-mm ST-segment depression in inferior leads

CXR: Normal

Echo: Inferior wall dyskinesis, LVEF 55% (0.55)

What type of ACS is this?

What information is suggestive of acute MI?

but not all. Some clinicians advocate repeating the loading dose of the $P2Y_{12}$ inhibitor 6 to 8 hours after the last dose of opiate.

▶ Nitrates

Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilation may lower blood pressure (BP), thus reducing myocardial oxygen demand. Arterial vasodilation also relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. Randomized clinical trials failed to show a mortality benefit for IV nitrate therapy followed by oral nitrate therapy in acute MI.[4]

In patients presenting with ACS, one SL NTG tablet should be administered every 5 minutes for up to three doses to relieve myocardial ischemia, unless contraindicated. IV NTG may be initiated in patients who have persistent ischemia, acute HF, or uncontrolled hypertension in the absence of contraindications.[3,4] IV NTG is typically continued until revascularization is performed or for approximately 24 hours following ischemia relief.

The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated in patients who have received oral phosphodiesterase-5 inhibitors.[4]

▶ Aspirin

ASA is the preferred antiplatelet agent in the treatment of ACS.[3,4] The antiplatelet effects of ASA are mediated by inhibiting the synthesis of TXA_2 through an irreversible inhibition of platelet cyclooxygenase-1.

In patients receiving fibrinolytics, ASA reduces mortality, and its effects are additive to fibrinolysis alone.[28] In patients undergoing PCI, ASA prevents acute thrombotic occlusion during the procedure. Additionally, in patients undergoing PCI, ASA, in addition to a $P2Y_{12}$ inhibitor, reduces the risk of stent thrombosis. ASA reduces the risk of death or MI by approximately 50% compared with no antiplatelet therapy in patients with NSTE-ACS.[28] Therefore, ASA remains the cornerstone of early treatment for all ACSs.

In patients experiencing an ACS, an initial dose of at least 162 mg nonenteric-coated ASA is recommended to achieve a rapid platelet inhibition. Current guidelines for STEMI and NSTE-ACS recommend an initial ASA dose of 162 to 325 mg (see Table 9–3).[3,4] This first dose can be chewed to achieve high blood concentrations and platelet inhibition rapidly. Current data suggest that although an initial dose of 162 to 325 mg is required, long-term therapy with doses of 75 to 150 mg daily are as effective as higher doses. Therefore, a daily maintenance dose of 81 mg is recommended as part of DAPT.[29] In patients receiving ticagrelor, the maximum recommended maintenance dose of ASA is 100 mg daily. Higher doses were associated with increased ischemic events in a large clinical trial and is a boxed warning in the product label.[4] The duration of DAPT was discussed previously in this chapter. The duration of single antiplatelet therapy with either ASA or a $P2Y_{12}$ inhibitor should be continued indefinitely following either STEMI or NSTE-ACS.[3,4,30]

The most frequent side effects of ASA are dyspepsia and nausea. Patients should be counseled about the risk of bleeding, especially gastrointestinal (GI) bleeding (see Table 9–3).[28] Nonsteroidal anti-inflammatory agents (NSAIDs) other than ASA as well as cyclooxygenase-2 (COX-2) selective anti-inflammatory agents are contraindicated and should be discontinued at the time of ACS secondary to increased risk of death, reinfarction, HF, and myocardial rupture.[3,4]

▶ Platelet P2Y$_{12}$ Inhibitors

Figures 9–2 and 9–3 and Table 9–4 outline the role of antiplatelets in ACS. Clopidogrel, prasugrel, ticagrelor, and cangrelor block the P2Y$_{12}$ receptor, a subtype of ADP receptor, on platelets which prevents the binding of ADP to the receptor and subsequent expression of platelet GP IIb/IIIa receptors and reduces platelet activation and aggregation. Both clopidogrel and prasugrel are thienopyridines and prodrugs that are converted to an active metabolite by a variety of cytochrome P-450 (CYP) isoenzymes, the most critical appearing to be CYP2C19 for clopidogrel (Table 9–4).[28] Both of these agents bind irreversibly to P2Y$_{12}$ receptors. Ticagrelor, which is not a thienopyridine, is a reversible, noncompetitive P2Y$_{12}$ receptor inhibitor. Ticagrelor's parent compound has antiplatelet effects and is also metabolized primarily by CYP3A4 to an active metabolite producing additional antiplatelet effects. Both prasugrel and ticagrelor are more potent ADP inhibitors than clopidogrel. Clopidogrel, ticagrelor, and prasugrel are administered orally with a loading dose followed by a maintenance dose. Cangrelor is the only intravenous P2Y$_{12}$ inhibitor approved as an adjunct to PCI in patients who did not receive prior oral P2Y$_{12}$ inhibitors or planned GP IIb/IIIa inhibitors (GPIs) to reduce the risk of periprocedural MI, revascularization, and stent thrombosis. Currently, there are no US guideline recommendations describing the role of cangrelor in ACS.

Prasugrel has the fewest significant drug–drug interactions of the oral agents. Moderate and strong inhibitors of CYP2C19 reduce the production of clopidogrel's active metabolite and consequently its antiplatelet effect, whereas strong inhibitors of CYP3A increase ticagrelor's exposure. Cangrelor is an active drug that undergoes rapid dephosphorylation in the circulation and has no drug–drug interactions involving the CYP system. A more detailed discussion of the drug interactions with clopidogrel and proton pump inhibitors (PPIs) may be found in Chapter 8, "Stable Ischemic Heart Disease."

Genetic variations in the gene coding for *CYP2C19* significantly modulate the antiplatelet effects of clopidogrel. Specifically, carriers of reduced-function allele (ie, *2 or *3) are not able to convert clopidogrel to its active metabolite to the extent of carriers of the wild-type allele. This results in decreased antiplatelet effects which could translate into higher rates of CV events, especially stent thrombosis and periprocedural MI.[28,31] As the efficacy of prasugrel and ticagrelor is not associated with *CYP2C19* genotype, these agents may be considered preferred agents in carriers of *CYP2C19* reduced-function alleles.[28,32] Nevertheless, due to the absence of a large randomized trial demonstrating the benefit of such genotype-based approach, the most recent clinical practice guidelines of the ACC/AHA/SCAI have not endorsed routine genotyping to guide the prescription of P2Y$_{12}$ inhibitors.[3,4] Most recently, the largest clinical trial comparing pharmacogenetic-guided therapy with ticagrelor for carriers and clopidogrel for noncarriers failed to show a benefit in the primary composite ischemic endpoint.[33] Administration of a P2Y$_{12}$ inhibitor, in addition to low-dose ASA, is recommended for all patients with ACS.[3,4,30] For patients with STEMI undergoing primary PCI, clopidogrel, prasugrel, ticagrelor, or cangrelor in addition to ASA, should be administered to prevent subacute stent thrombosis and long-term CV events (see Table 9–3 and Figure 9–2).[3-5,30] The more potent P2Y$_{12}$ inhbitors, ticagrelor or prasugrel, may be preferred in this setting.

In patients with STEMI receiving fibrinolytics, either clopidogrel or ticagrelor may be used.[3,24,34] Early therapy with clopidogrel 75 mg once daily administered during hospitalization and up to 28 days (mean: 14 days) reduced mortality and reinfarction without increasing the risk of major bleeding.[28] In adult patients 75 years or younger receiving fibrinolytics, a 300-mg loading dose of clopidogrel followed by 75 mg daily is recommended; in those older than 75 years, the loading dose should be omitted.[3] Clopidogrel should be continued for at least 14 days (and up to 1 year in the absence of bleeding) for patients presenting with STEMI who undergo reperfusion therapy with fibrinolysis.[3,34]

A large randomized trial demonstrated noninferiority of ticagrel to clopidogrel in patients with STEMI receiving fibrinolytics.[34] Most patients in the study received an initial clopidogrel loading dose and then were randomized to standard maintenance doses of either ticagrelor or clopidogrel which were continued for 12 months. Although prasugrel is recommended in the setting of STEMI and primary PCI, no studies have evaluated its use in conjunction with fibrinolytics.

In patients with NSTE-ACS who receive initial ischemia-guided therapy, ticagrelor is preferred over clopidogrel in patients not at high risk of bleeding.[4,30] In a large randomized clinical trial, ticagrelor compared with clopidogrel significantly reduced the rate of vascular death at 1 year by 22% (4% vs 5.1%), MI (5.8% vs 6.9%), and stent thrombosis (1.3% vs 1.9%).[35] There was no difference in the rate of total stroke. Although no increase in study-defined major bleeding was noted with ticagrelor, the frequency of non-CABG major bleeding was increased compared with clopidogrel (4.5% vs 3.8%). Therefore, ticagrelor is more efficacious than clopidogrel but also associated with an increased risk of bleeding. In addition, prasugrel has been compared to clopidogrel in patients with NSTE-ACS not undergoing planned revascularization.[36] There was no difference in ischemic or bleeding outcomes with prasugrel. Current guidelines recommend either clopidogrel or ticagrelor in these patients.[4]

A large randomized double-blind study demonstrated that prasugrel compared to clopidogrel for patients undergoing PCI significantly reduced the risk of CV death or MI by 19% (9.9% vs 12.1%), as well as MI and stent thrombosis, but increased the risk of major bleeding (not ICH) by 32% (2.4% vs 1.8%).[37] Patients with a history of prior stroke or transient ischemic attack (TIA) had an increased risk of ICH and net harm from prasugrel; therefore, prior stroke or TIA are contraindications to prasugrel. Patients 75 years and older as well as those weighing less than 60 kg (132 lb) are at increased risk of bleeding with prasugrel compared with clopidogrel and received no net clinical benefit from prasugrel.

Prasugrel demonstrated reduced ischemic events and similar major bleeding as ticagrelor in a large clinical trial in patients with either NSTE-ACS or STEMI where an initial strategy of PCI was planned.[24] However, the trial was open-label and had a large percentage of patient drop-outs. Therefore, whether or not prasugrel is preferred over ticagrelor is still a matter of debate.

Cangrelor is only administered intravenously as an adjunct agent during PCI; an oral P2Y$_{12}$ agent must be initiated after PCI if cangrelor is used. Specific dosing and contraindications of the P2Y$_{12}$ inhibitors are described in Tables 9–3 and 9–4.[3,4,22]

Although a variety of blood tests can assess functional platelet aggregation inhibition to P2Y$_{12}$ inhibitors, especially clopidogrel, there is no one gold standard test. Moreover, their benefit to personalize antiplatelet regimens has not been demonstrated. Therefore, the most recent practice guidelines do not recommend routine platelet aggregation testing to determine P2Y$_{12}$ inhibitor strategy.[3-5]

Table 9–4

Clinical Considerations When Choosing a P2Y$_{12}$ Receptor Inhibitor[3-5,20]

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Pharmacologic class	Thienopyridine	Thienopyridine	Cyclopentyl triazolopyrimidine	ATP analog
ADP receptor binding	Irreversible	Irreversible	Reversible	Reversible
Pharmacokinetics	Prodrug Metabolism: Hepatic Converted twice to active metabolite primarily through CYP 2C19; 3A4, 1A2, 2B6 Half-life 6 hours No dose adjustment necessary in CKD	Prodrug Metabolism: Hepatic Converted to active metabolite through CYP 3A4 and 2B6; 2C19, 2C9 Half-life 7 hours No dose adjustment necessary in CKD	Active drug Metabolism: Hepatic Converted to active metabolite through CYP 3A4/5; 2C9 Half-life 7–9 hours No dose adjustment necessary in CKD	Active drug Metabolism: Rapidly dephosphorylzed to inactive metabolite by ATPases in vascular endothelium Half-life 3–6 minutes No dose adjustment necessary in CKD
Dosing	300 mg loading dose with fibrinolytics; 600 mg loading dose for all other patients; 75 mg daily	60 mg loading dose; 10 mg daily < 60 kg (< 132 lb): consider 5 mg daily	180 mg loading dose; 90 mg twice daily. After 12 months, can use 60 mg twice daily in patients at low risk for bleeding	30 mcg/kg bolus; 4 mcg/kg/min IV infusion continued for at least 2 hours or the duration of PCI, whichever is longer
Onset of loading dose effect	Peak platelet inhibition occurs within 2–4 hours after 600 mg load and 6–8 hours after oral 300 mg load; 3–5 days after 75 mg dose	Peak platelet inhibition reached within 60 minutes after oral 60 mg load; 3 days after 10 mg dose	Peak platelet inhibition within 60 minutes after oral 180 mg load; 2–3 days after 90 mg dose	Peak platelet inhibition within 2 minutes after 30 mcg/kg bolus
Duration of effect	3–5 days	7–10 days	3–5 days	1–2 hours
Drug and disease considerations	Genetic polymorphisms may influence efficacy Enhanced bleeding with NSAIDs; avoid use Enhanced bleeding with parenteral anticoagulants, DOACs and warfarin; monitor carefully for bleeding; target INR to 2.0–2.5 for most indications Avoid use with moderate or strong CYP2C19 inhibitors (omeprazole, esomeprazole, chloramphenicol, cimetidine, efavirenz, etravirine felbamate, fluoxetine, fluconazole, fluvoxamine, isoniazid, oxcarbazepine, ketoconazole, voriconazole); select alternative noninteracting P2Y$_{12}$ inhibitor or alternative noninteracting drug	Enhanced bleeding with parenteral anticoagulants, warfarin, DOACs, and NSAIDs, avoid use	Enhanced bleeding with parenteral anticoagulants, DOACs, warfarin, and NSAIDs Use aspirin doses < 100 mg daily Avoid use with strong CYP3A inhibitors (atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ketoconazole, ritonavir, saquinavir, telithromycin, voriconazole) Avoid use with potent CYP3A inducers (carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin) Avoid simvastatin and lovastatin doses > 40 mg daily (ticagrelor inhibits CYP3A4 and increases statin concentration) Monitor digoxin serum concentrations with any change in ticagrelor dose (ticagrelor inhibits P-glycoprotein) Unique side effects including dyspnea and bradycardia	Do not administer clopidogrel or prasugrel prior to the discontinuation of cangrelor infusion Ticagrelor may be given at any time during cangrelor infusion or immediately after the discontinuation of cangrelor infusion
Contraindications	Any active pathological bleeding	Any active pathological bleeding; any history of TIA/stroke	Any active pathological bleeding; ICH or severe hepatic disease	Significant active bleeding or hypersensitivity
Surgery hold time	5 days for elective surgery; 24 hours for urgent	7 days	5 days for elective surgery; 24 hours for urgent	1 hour
NSTE-ACS indication	May be used regardless of treatment strategy; additional non-ACS indications	Reasonable over clopidogrel in patients treated with PCI who are not at high risk for bleeding and who have no history of stroke/TIA	Reasonable over clopidogrel for NSTE-ACS patients treated with invasive or ischemia-guided approach	No US guideline recommendation; may be considered in P2Y$_{12}$ inhibitor–naïve patients undergoing PCI

(Continued)

Table 9–4

Clinical Considerations When Choosing a $P2Y_{12}$ Receptor Inhibitor[3-5,20] (*Continued*)

	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
STEMI indication	Preferred when fibrinolytics used	Superior to clopidogrel in STEMI or in other high-risk patients like DM; not studied in patients receiving fibrinolytic therapy	Superior to clopidogrel; not studied in patients receiving fibrinolytic therapy	No US guideline recommendation; may be considered in $P2Y_{12}$ inhibitor–naïve patients undergoing PCI
Risk benefit considerations	Gold standard for reducing CV death and stent thrombosis compared to placebo Consider alternative if documented clopidogrel ineffectiveness (ie, poor metabolism, stent thrombosis during clopidogrel therapy)	Superior to clopidogrel with a significant increase in bleeding risk (driven mainly by reductions in MI and stent thrombosis); no clinical benefit when age ≥ 75 years or weight < 60 kg (132 lb); net harm in patients with history of TIA or stroke	Superior to clopidogrel with modest increase in major non–CABG-related bleeding; associated with an all-cause mortality reduction; consider compliance with twice daily dosing	Demonstrated better efficacy than post-PCI clopidogrel with minor increases in bleeding Has potential use as a bridge to CABG surgery in high-risk patients

ACS, acute coronary syndrome; ADP, adenosine diphosphate; ATP, adenosine triphosphate; CABG, coronary artery bypass graft; CKD, chronic kidney disease; CV, cardiovascular; CYP, cytochrome P-450; DM, diabetes mellitus; DOAC, direct oral anticoagulant; ICH, intracranial hemorrhage; INR, international normalized ratio; IV, intravenous; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; NSTE-ACS, non–ST-segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; TIA, transient ischemic attack.

From Rogers KC, de Denus S, Finks SW, Spinler SA. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:179–180, with permission.

Bleeding should be carefully monitored when using $P2Y_{12}$ inhibitors. If it is recommended that a $P2Y_{12}$ inhibitor be discontinued prior to elective surgery, clopidogrel and ticagrelor should be withheld preferably for 5 days, prasugrel at least 7 days, and cangrelor for 1 hour to reduce the risk of postoperative bleeding, unless the need for revascularization outweighs the bleeding risk. If urgent CABG is necessary, discontinue clopidogrel and ticagrelor up to 24 hours before CABG to reduce the risk of major bleeding.[4,5] Rarely, thrombotic thrombocytopenic purpura (TTP) has been reported with clopidogrel.[38] In addition, the use of ticagrelor is associated with dyspnea and, rarely, ventricular pauses and bradyarrhythmias. Small nonclinically significant increases in SCr and serum uric acid have also been reported with ticagrelor.[35]

▶ *Glycoprotein IIb/IIIa Receptor Inhibitors*

GP IIb/IIIa receptor inhibitors block the final common pathway of platelet aggregation, namely cross-linking of platelets by fibrinogen bridges between the GP IIb and IIIa receptors on the platelet surface. In patients with STEMI undergoing primary PCI who are treated with unfractionated heparin (UFH), eptifibatide or tirofiban may be administered on an individual basis.[3,5] Investigations of GPIs precede the widespread use of oral DAPT and thus their benefit in modern settings is not as clear. Their use appears most appropriate and beneficial in patients who are not adequately treated with a $P2Y_{12}$ inhibitor or in those with a large thrombus burden. Routine use of a GPI is not recommended in patients who have received fibrinolytics or bivalirudin secondary to increased bleeding risk. For patients treated with bivalirudin as the anticoagulant, GPIs should only be used in select cases as clinically indicated. These agents should not be administered for medical management of patients with STEMI who will not be undergoing PCI.[3]

The role of GPIs in NSTE-ACS has diminished since $P2Y_{12}$ inhibitors are used earlier in therapy, and bivalirudin is commonly selected as the anticoagulant in patients receiving an early intervention approach. Current evidence indicates no benefit of routine use of GPIs in patients treated with an ischemia-guided approach because the bleeding risk exceeds the benefit.[4] Nevertheless, in select patients treated with an ischemia-guided approach who experience recurrent ischemia (chest discomfort and ECG changes), HF, or arrhythmias after initial medical therapy necessitating a change in strategy to angiography and revascularization, a GPI may be added to ASA prior to the angiogram, particularly if the patient is (1) not adequately pretreated with clopidogrel or ticagrelor and (2) not treated with bivalirudin.

In patients who undergo an early invasive strategy and are adequately pretreated with clopidogrel or ticagrelor, routine upstream (prior to coronary angiography) administration of a GPI is not recommended, although eptifibatide or tirofiban may be considered in select high-risk patients (troponin positive). Clinical trials have shown that eptifibatide (added to ASA and clopidogrel) prior to angiography and PCI (ie, "upstream" use) in NSTE-ACS does not reduce ischemic events and increases bleeding risk.[4,39] In patients undergoing PCI, a GPI (double-bolus eptifibatide 180 mcg/kg or high-dose bolus tirofiban 25 mcg/kg) should be used in patients presenting with high-risk features who are not adequately pretreated with clopidogrel or ticagrelor (and who are not treated with bivalirudin as the anticoagulant), and may be considered in select individuals adequately pretreated with clopidogrel.[4]

Dosing and contraindications for GPIs are described in Table 9–3. Bleeding is the most significant adverse effect associated with administration of GPIs; therefore, they should not be administered to patients with a prior history of hemorrhagic stroke or recent ischemic stroke. The risk of bleeding is increased in patients with CKD. Eptifibatide is contraindicated in patients dependent on dialysis and requires a 50% reduced infusion rate in patients with CrCl less than 50 mL/min (0.83 mL/s).[3] The rate of tirofiban infusion should also be halved in patients with CrCl less than or equal to 60 mL/min (1.0 mL/s).[3]

▶ *Anticoagulants*

All patients should receive an anticoagulant in addition to DAPT regardless of ACS type or initial treatment strategy.[3,4] Options for anticoagulant therapy are outlined in Figures 9–2 and 9–3. For patients with STEMI undergoing primary PCI, either UFH or bivalirudin is preferred.[3] Bivalirudin monotherapy reduces CV and overall mortality while minimizing bleeding compared to UFH plus a GPI. However, direct head-to-head comparisons of monotherapy with UFH and bivalirudin have not shown this bleeding advantage.[40] Anticoagulant therapy is generally discontinued after primary PCI unless a compelling reason to continue exists. When fibrinolytic therapy is utilized in STEMI, anticoagulation with either UFH, enoxaparin, or fondaparinux are administered concomitantly. In this case, anticoagulant therapy should be maintained for a minimum of 48 hours (for UFH) and preferably for the duration of the hospitalization (with enoxaparin and fondaparinux) up to 8 days after fibrinolysis or until reperfusion is performed to support patency and prevent reocclusion of the affected artery.[3] Enoxaparin dosing is adjusted for body weight and renal function, and when administered in combination with fibrinolysis, it has special dosing requirements for older patients and those weighing more than 100 kg (220 lb) (see Table 9–3).

The choice of anticoagulant for a patient with NSTE-ACS is guided by risk stratification and initial treatment strategy, either an early invasive approach with coronary angiography and PCI or an ischemia-guided strategy with angiography in select patients guided by relief of symptoms and stress testing (see Figure 9–3). For patients treated by an early invasive strategy, UFH, enoxaparin, fondaparinux, or bivalirudin are options.[4] However, due to an increased risk of catheter-related thrombosis, fondaparinux is not indicated as an anticoagulant for use during PCI. Additional heparin must be administered during PCI if fondaparinux was initially chosen for anticoagulation. Clinical trials with bivalirudin have demonstrated similar efficacy in preventing CV ischemic events with a lower bleeding rate compared to UFH or enoxaparin plus a GPI in moderate- and high-risk patients with NSTE-ACS undergoing an early invasive strategy.[28] Use of enoxaparin during PCI is considered reasonable in patients treated with upstream subcutaneous enoxaparin. Unless there is an indication for chronic oral anticoagulation (eg, stroke prevention in atrial fibrillation), therapeutic anticoagulation is not continued following PCI. Venous thromboembolism prophylaxis anticoagulation is then started and continued for the duration of hospitalization.[4] Dosing considerations for initial treatment and during PCI are outlined in Table 9–3.

In NSTE-ACS patients in whom an initial ischemia-guided strategy is planned, enoxaparin, UFH, or low-dose fondaparinux is recommended.[4] Bivalirudin has not been studied as initial therapy in this setting. When added to ASA, UFH and low-molecular-weight heparins (LMWHs) reduce the frequency of death or MI in patients presenting with NSTE-ACS compared with control/placebo in patients primarily managed with an ischemia-guided strategy.[4,28] Compared with enoxaparin, fondaparinux showed similar ischemic outcomes with a lower bleeding rate in patients with NSTE-ACS primarily managed with an ischemia-guided strategy and may be preferred in patients at high risk for bleeding.[28] However, if fondaparinux is chosen for a patient who subsequently undergoes angiography and PCI, it should be administered in combination with UFH to avoid catheter thrombosis.[4] Guideline-recommended dosing and contraindications are described in Table 9–3.

UFH is preferred following angiography in patients proceeding to CABG during the same hospitalization because it has a short duration of action following discontinuation. Because enoxaparin is eliminated renally and patients with renal insufficiency generally have been excluded from clinical trials, UFH should be considered for patients with CrCl rates of less than 30 mL/min (0.50 mL/s) (where CrCl is estimated using total patient body weight in the Cockroft–Gault equation).[4] Although recommendations for dosing adjustment of enoxaparin in patients with CrCl between 10 and 30 mL/min (0.17 and 0.50 mL/s) are listed in the product manufacturer's label, the safety and efficacy of enoxaparin in this patient population remain vastly understudied. Administration of enoxaparin should be avoided in dialysis patients with ACS. While the duration of bivalirudin infusion is generally short (several hours only), few patients with significant renal impairment have been included in clinical trials. Dose adjustments for bivalirudin in patients with CrCl less than 30 mL/min (0.50 mL/s) or on hemodialysis are recommended. Patients with SCr greater than 3.0 mg/dL (265 μmol/L) were excluded from ACS trials with fondaparinux. Fondaparinux is contraindicated in patients with CrCl less than 30 mL/min (0.50 mL/s).[4]

UFH is monitored and the dose adjusted to a target aPTT or antifactor Xa (anti-Xa) levels, whereas the dose of enoxaparin is based on actual body weight without routine monitoring of anti-Xa levels. No routine monitoring of coagulation is recommended for enoxaparin, bivalirudin, or fondaparinux. Some experts recommend anti-Xa monitoring for LMWHs (eg, enoxaparin, fondaparinux) in patients with renal impairment during prolonged courses of administration of more than several days.

Besides bleeding, the most serious adverse effect of UFH and enoxaparin is **heparin-induced thrombocytopenia**; however, the frequency is rare.[28] Bivalirudin would be the preferred anticoagulant for patients with a history of heparin-induced thrombocytopenia undergoing PCI.[5]

▶ *β-Blockers*

Oral β-blockers should be administered early in the care of patients with an ACS and continued for at least 3 years in patients with normal LVF.[3,4] In ACS, the benefit of β-blockers results mainly from the competitive blockade of β_1-adrenergic receptors located on the myocardium. β_1-Blockade produces a reduction in heart rate, myocardial contractility, and BP, decreasing myocardial oxygen demand. In addition, the reduction in heart rate increases diastolic time, thus improving ventricular filling and coronary artery perfusion. As a result of these effects, β-blockers reduce the risk for recurrent ischemia, infarct size, risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.[3,4]

The role of early β-blocker therapy in reducing MI mortality was established in the 1970s and 1980s before routine use of early reperfusion therapy. Data in the reperfusion era are derived mainly from a large clinical trial that suggests IV initiation followed by oral β-blockers early in the course of MI is associated with a lower risk of reinfarction or ventricular fibrillation. However, there may be an early risk of cardiogenic shock in patients presenting with advanced age (> 70 years), heart rate greater than 100 beats/min, systolic BP less than 120 mm Hg, or late presentation.[3,4] Therefore, initiation of β-blockers (oral preferred) should be limited to patients who are hemodynamically stable, not at increased risk for cardiogenic shock, and without signs or symptoms of acute HF. Careful assessment for any contraindications to β-blockers should be performed following initiation and prior to any dose titration. The most serious side effects of β-blocker administration early in ACS are hypotension, acute HF, bradycardia, and heart block.[3,4]

Patients already taking β-blockers can continue taking them. Patients with contraindications to their use in the first 24 hours of presentation should be reevaluated and treated with β-blockers at a later time if they become eligible. In patients presenting with acute HF, use of β-blockers should be delayed until they are stabilized. Initiation of β-blockers may be attempted before hospital discharge in most patients following resolution of acute HF. Patients with HF secondary to reduced LVF should receive one of three β-blockers: bisoprolol, sustained-release metoprolol succinate, or carvedilol.[3,4]

▶ *Additional Therapies*

Oral ACE inhibitors have been shown to decrease nonfatal and fatal major CV events.[3,4] The benefit of ACE inhibitors in patients with MI most likely comes from their ability to prevent cardiac remodeling and ultimately development of HF. The largest reduction in mortality is observed in patients with left ventricular dysfunction (low LVEF) or HF symptoms. Early initiation (within 24 hours) of an oral ACE inhibitor is recommended as benefit can be seen as early as 24 hours post-MI, especially in patients with high-risk features such as HF, low LVEF, or STEMI in the anterior location.[3,4] However, these agents should be used cautiously in the first 24 hours to avoid renal dysfunction or hypotension. The use of IV ACE inhibitors is not recommended because mortality may be increased. Administration of ACE inhibitors should be continued indefinitely in those patients without contraindications with LVEF less than 40% (0.40) and in those with HTN, stable CKD, or DM.[3,4]

To accurately assess baseline low-density lipoprotein (LDL), it is recommended to obtain a lipid panel within 24 hours, or as soon as possible, in patients presenting with an ACS.[3,4] The administration of high-intensity statins prior to PCI may reduce the risk of periprocedural MI, and hence statins should be initiated as early as possible in ACS.[5] Additionally, statins reduce the risk of CV death, recurrent MI, stroke, and the need for revascularization when initiated early in the treatment of ACS.[3,4,41] Although the primary effect of statins is to decrease LDL cholesterol, statins are believed to produce many non–lipid-lowering or "pleiotropic" effects such as anti-inflammatory and antithrombotic properties. Based on current evidence, the most recent guidelines for the management of blood cholesterol in adults recommend that patients who experience an ACS should receive high-intensity statin therapy (atorvastatin 40–80 mg daily; rosuvastatin 20–40 mg daily) if they are less than or equal to 75 years of age or those greater than 75 if considered at very high risk. For patients greater than 75, either moderate-to high-intensity statins are recommended. Moderate-intensity statins (eg, atorvastatin 10–20 mg; pravastatin 40–80 mg; rosuvastatin 5–10 mg; simvastatin 20–40 mg) would be appropriate for any patient who is not a candidate for high-intensity statins because of contraindications, at risk for statin intolerance, or have a history of statin-associated adverse drug reactions. High- and moderate-intensity statins are defined as daily statin doses required to reduce LDL cholesterol greater than or equal to 50% and 30% to 49%, respectively.[41] Thus, in the absence of contraindications and depending on age, moderate- to high-intensity statin therapy should be initiated early during hospitalization to all patients experiencing ACS.[3,4]

Patient Encounter 2, Part 2

Is reperfusion therapy with fibrinolysis indicated at this time for this patient?

What adjunctive pharmacotherapy should be administered to this patient in the ED?

▶ *Calcium Channel Blockers*

Calcium channel blockers in the setting of ACS are used for relief of continued ischemia despite β-blocker and nitrate therapy, vasospastic angina, additional need for BP lowering (ie, amlodipine), or in patients with contraindications to β-blockers. Data suggest little benefit on clinical outcomes beyond symptom relief for calcium channel blockers in the setting of ACS especially in patients with reduced LVEF.[3,4] Therefore, calcium channel blockers should be avoided in the acute management of ACS unless there is a clear symptomatic need or contraindication to β-blockers. Agent selection is based on presenting heart rate and left ventricular dysfunction (diltiazem and verapamil are contraindicated in patients with bradycardia, heart block, or reduced LVEF). Immediate-release nifedipine should be avoided because it has demonstrated reflex sympathetic activation, tachycardia, and worsened myocardial ischemia.[3,4] Dosing and contraindications are described in Table 9–3.

Secondary Prevention Following MI

The long-term goals following ACS are to (a) control modifiable CHD risk factors; (b) prevent the development of HF; (c) prevent new or recurrent MI and stroke; (d) prevent death, including sudden cardiac death; and (e) prevent stent thrombosis following PCI. Pharmacotherapy, which has been proven to decrease mortality, HF, reinfarction, stroke, and stent thrombosis should be initiated prior to hospital discharge for secondary prevention. **KEY CONCEPT** Secondary prevention therapies following MI include long-term treatment with ASA, and/or a $P2Y_{12}$ inhibitor, β-blocker, an ACE inhibitor, and a statin for secondary prevention of death, stroke, or recurrent infarction.[4] A $P2Y_{12}$ inhibitor should be continued for at least 12 months for patients undergoing PCI and for patients with NSTE-ACS receiving an ischemia-guided treatment strategy.[3-5,30] Clopidogrel should be continued for at least 14 days and ideally up to 1 year in patients with STEMI receiving thrombolytics. Other $P2Y_{12}$ inhibitors have not been studied in combination with thrombolytics; however, prasugrel may be an alternative to clopidogrel in patients who undergo delayed PCI after thrombolytics.[3] An ACE inhibitor or ARB and an aldosterone antagonist should be given to select patients. Dosing and contraindications of medication therapy are described in detail in Table 9–3. For all patients with ACS, treatment and control of modifiable risk factors such as HTN, dyslipidemia, obesity, smoking, and DM are essential.[3,4] Patients should receive proper counseling and education, both verbal and written, regarding these treatments and recommendations prior to discharge. At follow-up appointments, medication reconciliation and dose optimization improve drug adherence.[42] Use of ICDs for the prevention of sudden cardiac death following MI in patients with reduced LVF and nonsustained ventricular arrhythmias is discussed in more detail in Chapter 10, "Arrhythmias."

▶ *Aspirin*

ASA decreases the risk of death, recurrent infarction, and stroke following MI. All patients should receive daily low-dose ASA as part of DAPT.[3,4,30] The risk of major bleeding from chronic ASA therapy is approximately 2% and is dose related. Higher doses of ASA, 160 to 325 mg, are not more effective than ASA doses of 75 to 81 mg but have higher rates of bleeding. Therefore, the guidelines recommend 81 mg daily as a preferred strategy in ACS patients with or without PCI.[3,4,30]

▶ *P2Y$_{12}$ Inhibitors*

For patients with either STEMI or NSTE-ACS, clopidogrel decreases the risk of CV events and stent thrombosis compared with placebo. Compared with clopidogrel, either prasugrel or ticagrelor lowers the risk of CV death, MI, or stroke by an additional 20% to 30% depending on the patient population studied. The frequency of stent thrombosis following PCI is also lower with prasugrel or ticagrelor compared with clopidogrel. However, the rate of bleeding not related to CABG surgery is higher with both prasugrel and ticagrelor compared with clopidogrel.[35,37]

The ACC/AHA Dual Antiplatelet Therapy Focused Update recommends continuation of a P2Y$_{12}$ inhibitor for at least 12 months following PCI for ACS.[30] However, more recent data suggest that major bleeding is reduced and anti-ischemic efficacy preserved with a shorter (3–6 months) duration of DAPT.[23] Continuation of P2Y$_{12}$ inhibitors longer than 12 months may be considered in patients who have not experienced any bleeding episodes and are not at high risk for bleeding.[30] Single antiplatelet therapy with either low-dose ASA or a P2Y$_{12}$ inhibitor should be continued indefinitely. For patients with STEMI receiving fibrinolytics, clopidogrel should be continued for at least 14 days and ideally up to 1 year.[3] Ticagrelor should be continued for up to 1 year.[34] For NSTE-ACS patients who do not receive a coronary stent, clopidogrel or ticagrelor should be continued up to 1 year.[4,30]

Bleeding is an inherent risk with long-term DAPT. In fact, oral antiplatelet agents are the third leading cause of adverse drug reaction–associated hospital admissions after ED visits among seniors.[43] Therefore, patients should be counseled on the risks and sites of potential bleeding and should be told to seek medical care immediately if significant bleeding is noticed. Some patients who are at increased risk of GI bleeding (eg, patients taking concomitant oral anticoagulants) may benefit from the addition of a PPI.[30,44,45]

Evidence for duration of DAPT is evolving in the setting of ACS with or without PCI. Clinical trials are investigating a shorter duration of DAPT with different strategies of stopping aspirin and continuing a P2Y$_{12}$ inhibitor to reduce risk of bleeding in patients.

▶ *β-Blockers, Nitrates, and Calcium Channel Blockers*

Current treatment guidelines recommend that following an ACS, patients with normal LVF should receive a β-blocker for at least 3 years, indefinitely for those with reduced LVF, and may be considered longer if needed for the treatment of HTN or angina.[3,4,46] Overwhelming data support the use of β-blockers in patients with a previous MI to improve long-term survival. Currently, there are no data to support the superiority of one β-blocker over another in the absence of HF with reduced LVF.

Although β-blockers should be initially avoided in patients with decompensated HF from left ventricular systolic dysfunction complicating an acute MI, clinical trial data suggest it is safe to initiate β-blockers prior to hospital discharge in these patients once HF symptoms have resolved.[3,4] In patients who cannot tolerate or have a contraindication to a β-blocker, a calcium channel blocker can be used to prevent anginal symptoms but nondihydropyridines should not be used in patients with reduced LVF.[3,4]

Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI and is not indicated in ACS patients who have undergone revascularization, unless the patient has stable ischemic heart disease, refractory angina, coronary vasospasm, or significant coronary stenoses that were not revascularized. All patients should be prescribed short-acting SL NTG tablets or spray to relieve any anginal symptoms when necessary and instructed on its use.[3,4] If ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact emergency medical services. Nitrates should not be administered to patients with hypotension or who have recently received a phosphodiesterase inhibitor (see Table 9–3).[3,4]

▶ *ACE Inhibitors and ARBs*

ACE inhibitors reduce mortality, decrease reinfarction, and prevent the development of HF with recent ACS, especially in those with reduced LVF.[3,4] Additional trials suggest that most patients with CAD, not just ACS or HF patients, benefit from ACE inhibitors. Therefore, ACE inhibitors should be considered in all patients (eg, those with HTN, DM, or stable CKD) following an ACS in the absence of a contraindication.

Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients who cannot tolerate an ACE inhibitor may be prescribed an ARB. Other, less common but more serious adverse effects of ACE inhibitors and ARBs include acute renal failure, hyperkalemia, and angioedema.[3]

▶ *Aldosterone Antagonists*

Aldosterone plays an important role in HF and in MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, HTN, left ventricular hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Aldosterone antagonists have been shown to attenuate these adverse effects and reduce mortality in patients who are already receiving an ACE inhibitor (or ARB) and β-blocker and have an LVEF less than or equal to 40% (0.40) and either HF symptoms or DM.[3,4]

Eplerenone and spironolactone are aldosterone antagonists that block the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities. In a large clinical trial, eplerenone significantly reduced mortality as well as hospitalization for HF in post-MI patients with an LVEF less than 40% (0.40) and symptoms of HF at any time during hospitalization.[47]

The risk of hyperkalemia increases with the use of aldosterone antagonists when added to an ACE inhibitor or ARB. Therefore, patients with serum potassium concentrations greater than 5.0 mmol/L (mEq/L) should not receive these agents. Specific contraindications for spironolactone include SCr greater than or equal to 2.5 mg/dL (221 μmol/L) for men or 2.0 mg/dL (177 μmol/L) for women, or CrCl less than or equal to 30 mL/min (0.50 mL/s). Contraindications for eplerenone include SCr greater than or equal to 2.0 mg/dL (177 μmol/L) for men or 1.8 mg/dL (159 μmol/L) for women, or CrCl less than or equal to 50 mL/min (0.83 mL/s). Currently, there are no data to support that eplerenone is superior or preferred to spironolactone but it may be an option in patients who experience adverse effects including gynecomastia, breast pain, or impotence while receiving spironolactone.

▶ *Lipid-Lowering Agents*

Following MI, statins reduce total mortality, CV mortality, need for revascularization, and stroke. According to practice guidelines, all patients who have experienced ACS should receive high-intensity statin therapy provided that no contraindications exist.[4,41] Indeed, results from landmark clinical trials have unequivocally demonstrated the value of statins in secondary prevention. High-intensity statin therapy, which typically lowers LDL cholesterol by 50% or greater, is preferred because of the greatest reduction in outcomes. The current evidence indicates that higher-intensity statin therapy, such as atorvastatin 40 to 80 mg daily and rosuvastatin 10 to 20 mg daily, produces a greater reduction in CV events such as MI, ischemic stroke, and revascularization than less intensive statin regimens (such as simvastatin 20–40 mg daily). Moderate-intensity statin therapy is recommended for those who are 75 years or older if high-intensity therapy is not tolerated, or in those who have a high risk for statin-associated adverse effects such as those with drug–drug interactions.

In patients for whom a 50% reduction of LDL cholesterol is not achieved by statin therapy alone (or in whom LDL cholesterol remains ≥ 70 mg/dL [1.81 mmol/L]), nonstatin therapy may be added to the statin for therapy intensification.[41] The addition of either ezetimibe or a proprotein convertase subtilisin/kexin type (PCSK9) inhibitor to statin therapy is recommended in very high-risk patients with clinical atherosclerotic cardiovascular disease (ASCVD) after considering desired LDL reduction, potential for additional CV risk reduction, adverse events or drug–drug interactions, and patient preference.[41] Based on randomized data, ezetimibe added to statin therapy after ACS produced a modest benefit (~10% reduction) on CV outcomes.[41] Both evolocumab and alirocumab (PCSK9 inhibitors) have also demonstrated improved CV outcomes in patients with ASCVD added to maximal statin therapy with or without ezetimibe and is a reasonable alternative.[41]

▶ *Other Modifiable Risk Factors*

Smoking cessation, managing HTN, weight loss, exercise, and glucose control for patients with DM, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events.[4] Referral to a comprehensive CV risk reduction program for cardiac rehabilitation is recommended.[3] HTN should be strictly controlled according to published guidelines.[46] Patients who are overweight, hypertensive, or who require cholesterol lowering should be educated on the importance of regular exercise, healthy eating habits, and reaching and maintaining an ideal weight.

Patient Encounter 2, Part 3

The patient undergoes coronary angiography and is found to have a 95% stenosis in his right coronary artery. PCI is performed and a drug-eluting stent is placed without complications.

What additional pharmacotherapy should be initiated on the first day of this patient's hospitalization following successful reperfusion with PCI?

Identify the long-term treatment goals for this patient.

Create a care plan for this patient for hospital discharge that includes pharmacotherapy, desired treatment outcomes, and monitoring for efficacy and adverse effects.

Because patients with DM have up to a fourfold increased mortality risk compared with patients without DM, the importance of blood glucose control, as well as other CHD risk factor modifications, cannot be overstated.[4] Sodium-glucose cotransporter 2 (SGLT2) inhibitors (depending on renal function) and glucagon-like peptide-1 receptor agonists (GLP-1RA) are recommended first- or second-line agents (to metformin) for managing both hyperglycemia and CV risk reduction in patients with type 2 DM.[48,49] Proposed CV risk reduction mechanisms with SGLT2 inhibitors include weight loss, blood pressure lowering, improved endothelial function, and reductions in preload and afterload, in addition to glycemic control. In clinical trials, dapagliflozin, empagliflozin, and canagliflozin have all demonstrated reduction in adverse cardiac events (composite of CV death, nonfatal MI or stroke) as well as hospitalizations for HF in patients with ASCVD. GLP1-RAs, specifically dulaglutide, liraglutide, injectable semaglutide, also have CV benefits such as weight loss, anti-inflammatory and natriuretic effects with observed reductions in blood pressure. Only liraglutide has shown reductions in cardiovascular outcomes or all-cause mortality.[50] Selection of specific agents and monitoring for adverse effects is discussed in Chapter 44 "Diabetes Mellitus."

Finally, influenza vaccination is recommended in all patients with CVD. Additionally, vaccination with the 23-valent pneumococcal polysaccharide vaccine (PCV) is recommended in those 65 years and older, as well as all high-risk individuals presenting with CVD.[4] The use of PCV-13 is reserved for patients with certain risk factors, and its use should be determined after discussion with the patient.

In patients who require treatment for musculoskeletal pain, a stepped-care approach should be taken in the selection of treatment. Acetaminophen, tramadol, and nonacetylated salicylates are preferred. Use of small doses of narcotics for short periods can be added if the aforementioned are not adequate to relieve the patient.[4] If these agents are insufficient, NSAIDs can be considered and should be used at the lowest effective dose and for the shortest possible time. Existing evidence suggests that naproxen may have the lowest risk to induce CV ischemic events, but the quality of the evidence available limits the definitiveness of assessment of its safety, particularly when it is used for long term. Importantly, all NSAIDs increase the risk of HF. If NSAIDs are used in combination with antiplatelets or anticoagulants, a PPI should be added to reduce risk of GI bleeding.[45]

OUTCOME EVALUATION

- **KEY CONCEPT** To determine the efficacy of nonpharmacologic and pharmacotherapy for both STEMI and NSTE-ACS, monitor patients for (a) relief of ischemic discomfort; (b) return of ECG changes to baseline; and (c) absence or resolution of HF signs and symptoms.
- Monitoring parameters for recognition and prevention of adverse effects from ACS pharmacotherapy are described in Table 9–5. In general, the most common adverse reactions from ACS therapies are hypotension and bleeding. To treat bleeding and hypotension, discontinue the offending agent(s) until symptoms resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.
- Because poor medication adherence of secondary prevention medications following MI leads to worsened CV outcomes, patients should receive medication

Table 9–5

Therapeutic Drug Monitoring of Pharmacotherapy for Acute Coronary Syndromes

Drug	Adverse Effects	Monitoring
Aspirin	Dyspepsia, bleeding, gastritis	Clinical signs of bleeding[a]; GI upset; baseline and every 6 months: Hgb, HCT, platelet count
Clopidogrel and prasugrel	Bleeding, diarrhea, rash, TTP (rare)	Clinical signs of bleeding[a]; baseline and every 6 months: Hgb, HCT, platelet count
Ticagrelor	Bleeding, dyspnea, diarrhea, rash, elevated SCr, elevated serum uric acid	Clinical signs of bleeding[a]; baseline and every 6 months: Hgb, HCT, platelet count
Unfractionated heparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline aPTT, INR, Hgb, HCT, and platelet count; ACT during cardiac catheterization; aPTT every 6 hours until target then every 24 hours; daily Hgb, HCT, and platelet count
Enoxaparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, Hgb, HCT, and platelet count; daily SCr, Hgb, HCT, and platelet count
Fondaparinux	Bleeding	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, Hgb, HCT, and platelet count; daily SCr, Hgb, HCT, and platelet count
Bivalirudin	Bleeding	Clinical signs of bleeding[a]; baseline SCr, aPTT, INR, Hgb, HCT, and platelet count
Fibrinolytics	Bleeding, especially ICH	Clinical signs of bleeding[a]; baseline aPTT, INR, Hgb, HCT, and platelet count; mental status every 2 hours for signs of ICH; daily Hgb, HCT, and platelet count
GPIs	Bleeding, acute profound thrombocytopenia	Clinical signs of bleeding[a]; baseline SCr (for eptifibatide and tirofiban), Hgb, HCT, and platelet count; platelet count at 4 hours after initiation; daily Hgb, HCT, and platelet count (and SCr for eptifibatide and tirofiban)
IV nitrates	Hypotension, flushing, headache, tachycardia	BP and HR every 2 hours
β-Blockers	Hypotension, bradycardia, heart block, bronchospasm, HF, fatigue, depression, sexual dysfunction	BP, RR, HR, 12-lead ECG, and clinical signs of HF every 5 minutes with bolus IV dosing; BP, RR, HR, and clinical signs of HF every shift with oral therapy, then BP and HR every 6 months following hospital discharge
Diltiazem and verapamil	Hypotension, bradycardia, heart block, HF, constipation, gingival hyperplasia	BP and HR every shift with oral therapy, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
Amlodipine	Hypotension, dose-dependent peripheral edema, gingival hyperplasia	BP every shift with oral therapy, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
ACE inhibitors and ARBs	Hypotension, cough (with ACE inhibitors), hyperkalemia, prerenal azotemia, acute renal failure, angioedema (ACE inhibitors more so than ARBs)	BP every 4 hours × 3 for first dose, then every shift with oral therapy, then once every 6 months following hospital discharge; baseline SCr and potassium; daily SCr and potassium while hospitalized, then every 6 months (or 1–2 weeks after each outpatient dose titration); closer monitoring required in patients receiving spironolactone or eplerenone or if renal insufficiency; counsel patient on symptoms of angioedema including throat, tongue, and facial swelling
Aldosterone antagonists	Hypotension, hyperkalemia, increased SCr	BP and HR every shift with oral therapy, then once every 6 months; SCr and serum potassium concentration at baseline then at 48 hours, at 7 days, monthly for 3 months, then every 3 months thereafter
Morphine	Hypotension, respiratory depression	BP and RR 5 minutes after each bolus dose and resolution of pain
Statins	GI upset, myopathy, hepatotoxicity	Liver function tests at baseline. Lipid panel for adherence. Only repeat liver function tests if patients present with sign/symptoms of liver failure. Check a CK if muscle symptoms; counsel patient on myalgia; consider CK at baseline if adding a fibrate or niacin

[a] Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.

ACE, angiotensin-converting enzyme; ACT, activated clotting time; aPTT, activated partial thromboplastin time; ARB, angiotensin receptor blocker; BP, blood pressure; CK, creatine kinase; ECG, electrocardiogram; GI, gastrointestinal; GPI, glycoprotein IIb/IIIa inhibitor; HCT, hematocrit; HF, heart failure; Hgb, hemoglobin; HR, heart rate; ICH, intracranial hemorrhage; INR, international normalized ratio; IV, intravenous; RR, respiratory rate; SCr, serum creatinine; TTP, thrombotic thrombocytopenic purpura.

Modified with permission from Rogers KC, de Denus S, Finks SW, Spinler SA. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:188.

counseling (including counseling prior to hospital discharge) and be monitored for medication persistence.[3,4,42] Counseling should include assessment of health literacy level, assessment of barriers to adherence, assessment of access to medications, written and verbal instructions about the purpose of each medication, changes to previous medication regimen, optimal time to take each medication, new allergies or medication intolerances, need for timely prescription fill after discharge, anticipated duration of therapy, consequences of nonadherence, common and/or serious adverse reactions that may develop, drug–drug and drug–food interactions, and an assessment of instruction understanding.

Patient Care Process

Collect Information:

- Perform a medication history for use of prescriptions, over-the-counter medications, and dietary supplements. Identify allergies to medications and other substances.
- Review the medical history and physical assessment findings for possible causes and risk factors for ACS including other symptoms and what may have relieved the patient's angina.
- Review results of the ECG which should be performed and interpreted within 10 minutes.
- Review relevant laboratory tests (eg, serial cardiac troponin levels, renal function, lipids, CBC) (Figure 9–1 and Clinical Presentation and Diagnosis textbox).
- Speak with the patient to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Risk-stratify the NSTE-ACS patient (Table 9–1).
- For patients already receiving pharmacotherapy for ACS, assess efficacy and safety including any significant drug interactions.
- Document existing contraindications and adverse events to medications in the medical record.
- Assess refill history to determine medication adherence and to identify any barriers to adherence.
- Review relevant laboratory tests.

Develop a Care Plan:

- Use risk stratification to select antithrombotic therapies for patients with NSTE-ACS and STEMI (Figures 9–2 and 9–3).
- Initiate secondary prevention therapies as appropriate before discharge.
- Ensure all patients without contraindications receive oral β-blockers, preferably within the first 24 hours of admission. Patients with initial contraindications in the first 24 hours should be reevaluated prior to discharge.
- Ensure all patients receive aspirin and statins at discharge and continue indefinitely as long as no contraindication exists.
- Initiate prescription of PPI therapy as appropriate for those at increased risk of bleeding or those requiring triple therapy with aspirin, a $P2Y_{12}$ receptor inhibitor, and an oral anticoagulant.
- Determine appropriate vaccinations prior to discharge.

Implement the Care Plan:

- Verify orders for anti-ischemic, antiplatelet, and analgesic medications where appropriate early in care and prior to discharge.
- Initiate appropriate antithrombotic medications based on ACS type and treatment strategy (Figures 9–2 and 9–3).
- Appropriately adjust all medications based on renal function, as well as baseline coagulation tests for antithrombotics (Table 9–3).
- Monitor for signs and symptoms of bleeding.
- Educate patient on discharge prescriptions. Discuss the importance of DAPT (especially in the patient receiving a stent), which should be given for 12 months after ACS regardless of stenting.
- Ensure patients receive a prescription for SL NTG at the time of discharge with instructions for use.
- Discontinue NSAIDs and select COX-2 inhibitor agents taken prior to ACS.
- Educate patient regarding appropriate secondary prevention therapies including lifestyle management with easily understandable and culturally sensitive verbal and written instructions.

Follow-up: Monitor and Evaluate:

- Follow-up within 2 weeks to assess angina symptoms and interventional success.
- Ensure appropriate use of evidence-based pharmacotherapy.
- Determine presence of any adverse events or drug interactions.
- Discuss and review adherence to medication/treatment plan.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. Shannon Finks, an author of this chapter in previous editions of this book.

Abbreviations Introduced in This Chapter

ACC	American College of Cardiology
ACCF	American College of Cardiology Foundation
ACE	Angiotensin-converting enzyme
ACS	Acute coronary syndrome
ACT	Activated clotting time
ADP	Adenosine diphosphate
AHA	American Heart Association
AMI	Acute myocardial infarction
aPTT	Activated partial thromboplastin time
ARB	Angiotensin receptor blocker
ASA	Aspirin
ASCVD	Atherosclerotic cardiovascular disease
ATP	Adenosine triphosphate
BNP	B-type natriuretic peptide
BP	Blood pressure
CABG	Coronary artery bypass graft (surgery)
CAD	Coronary artery disease
CBC	Complete blood count
CHD	Coronary heart disease
CKD	Chronic kidney disease
CK	Creatine kinase
COX-2	Cyclooxygenase-2
CrCl	Creatinine clearance
CV	Cardiovascular
CVD	Cardiovascular disease
CYP	Cytochrome P-450
DAPT	Dual antiplatelet therapy
DBP	Diastolic blood pressure
DM	Diabetes mellitus
DOAC	Direct oral anticoagulant

ECG	Electrocardiogram
ED	Emergency department
EF	Ejection fraction
GI	Gastrointestinal
GLP-1RA	Glucagon-like peptide-1 receptor agonist
GP	Glycoprotein
GPI	Glycoprotein IIb/IIIa inhibitor
GRACE	Global Registry of Acute Coronary Events
HCT	Hematocrit
HEART	History, Electrocardiogram (ECG), Age, Risk factors, and Troponin
HF	Heart failure
Hgb	Hemoglobin
HMG CoA	3-Hydroxy-3-methylglutaryl coenzyme A
HR	Heart rate
HTN	Hypertension
hs-cTnI	High-sensitivity cardiac troponin I
hs-cTnT	High-sensitivity cardiac troponin T
ICD	Implantable cardioverter-defibrillator
ICH	Intracranial hemorrhage
INR	International normalized ratio
IV	Intravenous
IVP	Intravenous push
LDL	Low-density lipoprotein
LMWH	Low-molecular-weight heparin
LVEF	Left ventricular ejection fraction
LVF	Left ventricular function
MI	Myocardial infarction
NSAID	Nonsteroidal anti-inflammatory drug
NSTE	Non–ST-segment elevation
NSTEMI	Non–ST-elevation myocardial infarction
NTG	Nitroglycerin
PCI	Percutaneous coronary intervention
PCSK9	Proprotein convertase subtilisin/kexin type 9
PCV	Pneumococcal polysaccharide vaccine
PPI	Proton pump inhibitor
RR	Respiratory rate
SBP	Systolic blood pressure
SC	Subcutaneous
SCAI	Society for Cardiovascular Angiography and Interventions
SCr	Serum creatinine
SGLT2	Sodium-glucose cotransporter 2
SL	Sublingual
STE	ST-segment elevation
STEMI	ST-segment elevation myocardial infarction
TIA	Transient ischemic attack
TIMI	Thrombolysis in myocardial infarction
TTP	Thrombotic thrombocytopenic purpura
TXA_2	Thromboxane A_2
UA	Unstable angina
UFH	Unfractionated heparin

10 Arrhythmias

Robert B. Parker and James C. Coons

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the phases of the cardiac action potential, cardiac myocyte ion currents corresponding to each phase, and the relationship between the cardiac action potential and the electrocardiogram (ECG).
2. Describe the modified Vaughan Williams classification of antiarrhythmic drugs and compare and contrast the effects of these drugs on cardiac electrophysiology.
3. Determine risk factors for and mechanisms, etiologies, symptoms, and goals of therapy of (a) sinus bradycardia, (b) atrioventricular (AV) block, (c) atrial fibrillation (AF), (d) paroxysmal supraventricular tachycardia (PSVT), (e) premature ventricular complexes (PVCs), (f) ventricular tachycardia (VT, including torsades de pointes [TdP]), and (g) ventricular fibrillation (VF).
4. Compare and contrast mechanisms of action of drugs used for ventricular rate control, conversion to sinus rhythm, and maintenance of sinus rhythm in patients with AF.
5. Compare and contrast the advantages and disadvantages of warfarin and the direct oral anticoagulants (DOACs) for prevention of stroke and systemic embolism in patients with AF.
6. Discuss nonpharmacologic methods for termination of PSVT and compare and contrast mechanisms of action of drugs used for acute termination of PSVT, as well as treatment options for long-term prevention of PSVT recurrence.
7. Describe the role of drug therapy for management of asymptomatic and symptomatic PVCs.
8. Compare and contrast mechanisms of action of drugs used for treatment of acute episodes of VT and describe options and indications for nonpharmacologic treatment of VT and VF.
9. Design individualized drug therapy treatment plans for patients with (a) sinus bradycardia, (b) AV block, (c) AF, (d) PSVT, (e) PVCs, (f) VT (including TdP), and (g) VF.

NORMAL AND ABNORMAL CARDIAC CONDUCTION AND ELECTROPHYSIOLOGY

The two primary functions of the heart are mechanical and electrical activity. Mechanical activity refers to atrial and ventricular contraction, the mechanism by which blood is delivered to tissues. Deoxygenated blood returns to the heart via the venous circulation and enters the right atrium. Right atrial contraction delivers blood to the right ventricle through the tricuspid valve. Right ventricular contraction pumps blood through the pulmonic valve and pulmonary arteries to the lungs, where it is oxygenated. The oxygenated blood then flows through the pulmonary veins into the left atrium. Left atrial contraction pumps blood through the mitral valve into the left ventricle (LV), contraction of which delivers blood through the aortic valve and to the body's tissues.

The heart's mechanical activity stems from its electrical activity. The heart possesses an intrinsic electrical conduction system (Figure 10–1). Normal function of the heart's electrical conduction system is required for normal myocardial contraction. Atrial depolarization causes atrial contraction, and ventricular depolarization produces ventricular contraction. Perturbation of the heart's electrical conduction system may result in dysfunctional atrial and/or ventricular contraction and reduce cardiac output.

Cardiac Conduction System

The sinoatrial (SA) node (frequently referred to as the sinus node), located in the upper portion of the right atrium, normally serves as the heart's pacemaker and generates the electrical impulses that

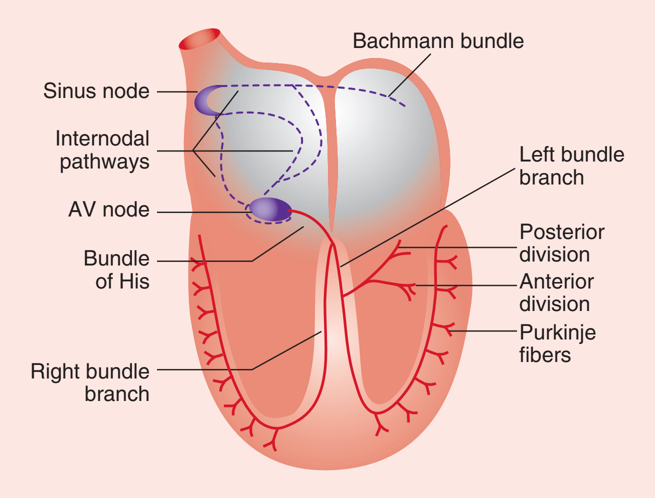

FIGURE 10–1. The cardiac conduction system. (AV, atrioventricular.)

result in atrial and ventricular depolarization (see Figure 10–1). The sinus node serves as the heart's dominant pacemaker because it has the greatest degree of automaticity, defined as the ability of a cardiac fiber or tissue to initiate depolarizations spontaneously. In adults at rest, normal intrinsic depolarization rate of the sinus node is 60 to 100 per minute. Other cardiac fibers also possess automaticity, but normally the intrinsic depolarization rates are slower than that of the sinus node. For example, normal depolarization rate of the atrioventricular (AV) node and ventricular tissue is 40 to 60 per minute and 30 to 40 per minute, respectively. As a result of greater automaticity, the sinus node normally serves as the heart's pacemaker. However, if the sinus node fails to depolarize faster than the AV node, the AV node may take over as the pacemaker. If both the sinus and AV nodes fail to depolarize faster than 30 to 40 per minute, ventricular tissue may take over.

Following initiation of the electrical impulse from the sinus node, the impulse travels through internodal pathways of the specialized atrial conduction system and the Bachmann bundle. Upon excitation via the internodal pathways and the Bachmann bundle, atrial depolarization spreads as a wave through atrial tissues, conceptually similar to throwing a pebble into water. As the impulse is conducted across the atria, each depolarized cell depolarizes the surrounding connected cells, until both atria have been completely depolarized. Atrial contraction follows normal atrial depolarization.

Following atrial depolarization, impulses are conducted through the AV node, located in the lower right atrium (Figure 10–1). The impulse then enters the bundle of His and is conducted through the ventricular conduction system, consisting of the left and right bundle branches. The LV requires a larger conduction system than the right ventricle due to its larger mass; therefore, the left bundle branch bifurcates into the left anterior and posterior divisions (also known as "fascicles"). The bundle branches further divide into the Purkinje fibers through which impulse conduction results in ventricular depolarization, initiating ventricular contraction.

Ventricular Action Potential

Ventricular action potential is depicted in Figure 10–2. Ventricular myocyte resting membrane potential is −70 to −90 mV, due to the function of the sodium–potassium adenosine triphosphatase (ATPase) pump, which maintains relatively high extracellular sodium concentrations and low extracellular potassium concentrations. During each action potential cycle, the membrane potential slowly increases due to a slow influx of sodium into the cell, raising the threshold to −60 to −80 mV. When the membrane potential reaches this threshold, the fast sodium channels open and sodium ions rapidly enter the cell. This rapid influx of positive ions creates a vertical upstroke of the action potential, which reaches 20 to 30 mV. This is phase 0, representing ventricular depolarization. At this point, the fast sodium channels become inactivated, and ventricular repolarization begins, consisting of phases 1 through 3. Phase 1 repolarization occurs primarily as a result of an efflux of potassium ions. During phase 2, potassium ions continue to exit the cell, but the membrane potential is balanced by an influx of calcium and sodium ions, transported through slow calcium and slow sodium channels, resulting in a plateau. During phase 3, the efflux of potassium ions greatly exceeds calcium and sodium influx, resulting in the major component of ventricular repolarization. During phase 4, sodium ions gradually enter the cell, increasing the threshold again to −60 to −80 mV and initiating another action potential. Understanding the ion fluxes responsible for the action potential facilitates understanding of the effects of specific drugs. Drugs that primarily inhibit ion flux through sodium channels influence phase 0 (ventricular depolarization), whereas drugs that primarily inhibit

ion flux through potassium channels influence the repolarization phases, particularly phase 3.

Electrocardiogram

The electrocardiogram (ECG) is a noninvasive means of measuring the heart's electrical activity. The relationship between the ventricular action potential and the ECG is depicted in Figure 10–2. The P wave on the ECG represents atrial depolarization (not depicted in Figure 10–2, which shows only the ventricular action potential). Phase 0 of the action potential corresponds to the QRS complex and represents ventricular depolarization. Atrial repolarization is not visible on the ECG because it occurs during ventricular depolarization and is obscured by the QRS complex. The T wave on the ECG corresponds to phase 3 ventricular repolarization.

Several ECG intervals and durations are measured routinely. The PR interval is the time from the start of the P wave to the beginning of the QRS complex and represents conduction through the AV node. The normal PR interval in adults is 0.12 to 0.2 seconds (120–200 ms). The QRS duration represents the time required for ventricular depolarization, which is normally 0.08 to 0.12 seconds (80–120 ms) in adults. The QT interval is the time from the start of the QRS complex to the end of the T wave and is an indicator of ventricular repolarization time. The normal QT interval in adults is 0.32 to 0.4 seconds (320–400 ms). The QT interval varies with heart rate—the faster the heart rate, the shorter the QT interval, and vice versa. A number of formulas are used to correct the QT interval for heart rate (QTc). Normal QTc interval in adults is 0.36 to 0.47 seconds (360–470 ms) in men and 0.36 to 0.48 seconds (360–480 ms) in women.[1]

Refractory Periods

After an impulse is initiated and conducted, there is a period during which cells and fibers cannot be depolarized again, termed the absolute refractory period (Figure 10–2), and corresponds to phases 1, 2, and approximately the first one-third of phase 3 repolarization. The absolute refractory period corresponds to the period from the Q wave to approximately the first half of the T wave on the ECG (Figure 10–2). During this period, electrical impulses cannot be conducted because the tissue is absolutely refractory to conduction. However, there is a period following the absolute refractory period during which a premature electrical stimulus can be conducted and is often conducted abnormally, which is called the relative refractory period, corresponding to the latter two-thirds of phase 3 repolarization on the action potential and to the latter half of the T wave on the ECG. If a premature electrical stimulus is initiated during the relative refractory period (sometimes referred to as the "vulnerable period"), it can be conducted abnormally, potentially resulting in an arrhythmia.

Mechanisms of Cardiac Arrhythmias

KEY CONCEPT Cardiac arrhythmias are caused by (a) abnormal impulse initiation, (b) abnormal impulse conduction, or (c) both.

▶ *Abnormal Impulse Initiation*

Abnormal initiation of electrical impulses occurs due to abnormal automaticity. Increased automaticity is associated with an increased slope of phase 4 depolarization whereas decreased automaticity is linked to a decrease in phase 4 depolarization slope. A decrease in sinus node automaticity results in a reduced rate of impulse generation and a slow heart rate (sinus bradycardia). Conversely, an increase in sinus node automaticity results in an increased rate of impulse generation and a rapid heart rate (sinus tachycardia). If other cardiac fibers become abnormally automatic, such that the rate of spontaneous impulse initiation exceeds that of the sinus node, or premature impulses are generated, other tachyarrhythmias may occur. Many cardiac fibers possess the capability for automaticity, including atrial tissue, the AV node, the Purkinje fibers, and ventricular muscle. Also, tissue in the pulmonary veins in the left atrium can initiate and conduct electrical impulses. Abnormal atrial automaticity may result in premature atrial depolarizations or may precipitate atrial tachycardia or atrial fibrillation (AF); abnormal AV nodal automaticity may result in "junctional tachycardia" (so named because the AV node is also sometimes referred to as the AV junction). Abnormal automaticity originating from the pulmonary veins is a precipitant of AF. In addition, abnormal automaticity in the ventricles may result in premature ventricular complexes (PVCs) or may precipitate ventricular tachycardia (VT) or ventricular fibrillation (VF).

Cardiac fiber automaticity is controlled in part by sympathetic and parasympathetic nervous system activity. Enhanced sympathetic nervous system activity increases automaticity of the sinus node or other automatic cardiac fibers. Enhanced parasympathetic nervous system activity suppresses automaticity, while parasympathetic nervous system activity inhibition increases automaticity. Other factors may increase automaticity of extrasinus node tissues, including hypoxia, atrial or ventricular stretch (such as following long-standing hypertension or during and after development of heart failure [HF]), electrolyte abnormalities such as hypokalemia or hypomagnesemia, and certain drugs including digoxin and adrenergic agonists.

▶ *Abnormal Impulse Conduction*

The mechanism of abnormal impulse conduction is termed **reentry**. Reentry is often triggered as a result of an abnormal premature electrical impulse (abnormal automaticity); therefore, in these situations, the arrhythmia mechanism is both abnormal impulse formation (automaticity) and abnormal impulse conduction (reentry). For reentry to occur, three conditions must be present: (a) at least two pathways down which an electrical impulse may travel; (b) a "unidirectional block" in one of the conduction pathways ("unidirectional block" reflects prolonged refractoriness in this pathway, or increased "dispersion of refractoriness," defined as substantial variation in refractory periods between cardiac fibers); and (c) slowed impulse conduction velocity down the other conduction pathway.

The reentry process is depicted in Figure 10–3.[2] Normally, when a premature impulse is initiated, it cannot be conducted in either direction down either pathway because the tissue is in its absolute refractory period from the previous impulse. A premature impulse may be conducted down both pathways if it is only slightly premature and arrives after the tissue is no longer refractory. However, when refractoriness is prolonged down one of the pathways, a precisely timed premature beat can conduct down one pathway but cannot be conducted in either direction in the pathway with prolonged refractoriness because the tissue is still in its absolute refractory period.[2] Refractoriness may be prolonged more in one pathway than in the other due to increased dispersion of repolarization. When the third condition for reentry is present, the impulse traveling forward down the other pathway still cannot be conducted. However, because the impulse in one pathway is traveling more slowly than normal, by the time it circles around and travels upward along the other pathway, sufficient time has passed so the pathway is no longer in its absolute

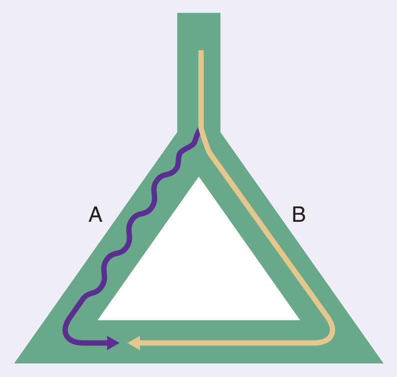

FIGURE 10–3. The process of initiation of reentry. There are two pathways for impulse conduction: slowed impulse conduction down pathway A and a longer refractory period in pathway B. A precisely timed premature impulse initiates reentry; the premature impulse cannot be conducted down pathway B because the tissue is still in the absolute refractory period from the previous, normal impulse. However, because of dispersion of refractoriness (ie, different refractory periods down the two pathways), the impulse can be conducted down pathway A. Because conduction down pathway A is slowed by the time the impulse reaches pathway B in a retrograde direction, the impulse can be conducted retrogradely up the pathway since the pathway is now beyond its refractory period from the previous impulse. This creates reentry, in which the impulse continuously and repeatedly travels in a circular fashion around the loop.

refractory period, and now the impulse may travel upward in that pathway. In other words, the electrical impulse "reenters" a previously stimulated pathway in the reverse (retrograde) direction. This results in circular movement of electrical impulses; as the impulse travels in this circular fashion, it depolarizes each cell around it, and if the impulse is traveling at a rate faster than the intrinsic rate of the sinus node, a tachycardia occurs. Reentry may occur in numerous tissues, including the atria, the AV node, and the ventricles.

Prolonged refractoriness and/or slowed impulse conduction velocity may be present in cardiac tissues for a variety of reasons. Myocardial ischemia may alter ventricular refractory periods or impulse conduction velocity, facilitating reentry. In patients with past myocardial infarction (MI), the infarcted myocardium is dead and cannot conduct impulses. However, there is typically a border zone of tissue that is damaged and in which refractory periods and conduction velocity are aberrant, facilitating ventricular reentry. In patients with left atrial or LV hypertrophy as a result of hypertension, refractory periods and conduction velocity are often perturbed. In patients with HF with reduced ejection fraction (HFrEF), ventricular refractoriness and conduction velocity are often altered due to LV hypertrophy, collagen deposition, and other anatomical and structural changes. Antiarrhythmic drugs, or other drugs affecting cardiac electrophysiology, can also alter the balance between conduction velocity and refractory periods and precipitate reentrant arrhythmias.

Vaughan Williams Classification of Antiarrhythmic Drugs

The Vaughan Williams classification of antiarrhythmic drugs is the most commonly used method for categorizing antiarrhythmic drugs (Table 10–1).[3,4] This classification is primarily based on the effects of these drugs on sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}) channels and the resultant effects on conduction velocity, repolarization/refractoriness, and automaticity. Class I drugs all block the fast Na+ channel during phase 0 depolarization resulting in decreases in ventricular automaticity and conduction velocity. However, due to differences in potency of the drugs to reduce conduction velocity, the class I drugs are subdivided into classes IA, IB, and IC. The class IC drugs are the most potent Na^+ channel blockers and markedly slow ventricular conduction but have minimal effects on refractory periods. The class IA drugs have intermediate potency and also block K^+ channels to prolong the refractory period. Class IB drugs have the lowest potency for the Na^+ channel with minimal effects on conduction velocity at normal heart rates. Class II drugs are the β-adrenergic receptor inhibitors (β-blockers). Class III drugs primarily block K^+ channels during phase 3 repolarization resulting in prolonged ventricular repolarization and refractoriness. The class IV drugs are the nondihydropyridine calcium channel blockers (CCBs) diltiazem and verapamil that predominantly block the slow Ca^{2+} channel in the sinus and AV nodes.

The Vaughan Williams classification of antiarrhythmic drugs has notable limitations. The classification is based on the effects of drugs on laboratory preparations of normal, rather than diseased, myocardium. In addition, many of the drugs affect multiple ion channels (eg, Na^+ and K^+) and may be placed into more than one class. For example, the class IA drugs, in addition to blocking Na+ channels, also block K+ channels and prolong repolarization/refractoriness, either via the parent drug or an active metabolite. The class III agent sotalol is also a β-blocker and therefore could fit into class II. Amiodarone inhibits Na^+, K^+, and Ca^{2+} channels and is also a noncompetitive inhibitor of β-receptors and therefore may be placed into any of the four classes. Thus, drugs within each class cannot be considered interchangeable. Despite these limitations, the Vaughan Williams classification continues to be widely used because of its simplicity.

CARDIAC ARRHYTHMIAS

Arrhythmias are classified into two broad categories: supraventricular (those occurring above the ventricles) and ventricular (those occurring in the ventricles). Names of specific arrhythmias are generally composed of two words, the first of which indicates location of the electrophysiological abnormality resulting in the arrhythmia (sinus node, AV node, atrial, or ventricular), and the second describes the arrhythmia as abnormally slow (bradycardia) or fast (tachycardia) or type of arrhythmia (block, fibrillation, or flutter).

SUPRAVENTRICULAR ARRHYTHMIAS

Sinus Bradycardia

Sinus bradycardia is defined by a sinus rate less than 60 beats/min.[5]

▸ *Epidemiology and Etiology*

Many individuals, particularly those who engage in regular vigorous exercise, have resting heart rates less than 60 beats/min. For those individuals, sinus bradycardia is normal and healthy, and does not require evaluation or treatment. However, some people develop symptomatic sinus node dysfunction. In the absence of correctable underlying causes, idiopathic sinus node dysfunction is referred to as sick sinus syndrome. Incidence of sick sinus syndrome is about 0.8 per 1000 person-years of follow-up, increases with advancing age, and is higher in White versus Black individuals.[6] Sinus node dysfunction accounts for roughly 50% of pacemaker implantations in the United States[6] and may also

Table 10–1

Vaughan Williams Classification of Antiarrhythmic Agents[a,3,4]

Class	Drug	Conduction Velocity[b]	Repolarization/Refractoriness[b]	Automaticity[b]	Ion Channel Block
IA	Quinidine Procainamide Disopyramide	↓	↑	↓	Na^+/K^+
IB	Lidocaine Mexiletine	0/↓	↓/0	↓	Na^+
IC	Flecainide Propafenone	↓↓	0	↓	Na^+
II	β-Blockers[c] Acebutolol Atenolol Betaxolol Bisoprolol Carteolol Carvedilol[d] Esmolol Labetalol[d] Metoprolol Nadolol Nebivolol Penbutolol Pindolol Propranolol Timolol	0	0	0	N/A
III	Amiodarone[e] Dofetilide Dronedarone[e] Ibutilide Sotalol	0	↑	0	K^+
IV	CCBs[c] Diltiazem Verapamil	0	0	0	Ca^{+2}

[a] Adenosine and digoxin are agents used for management of arrhythmias that do not fit into the Vaughan Williams classification.

[b] In ventricular tissue only; effects may differ in atria, sinus node, or atrioventricular node.

[c] Slow conduction, prolong refractory period, and reduce automaticity in sinoatrial node and atrioventricular node tissue but generally not in the ventricles.

[d] Combined α- and β-blocker.

[e] Amiodarone and dronedarone also slow conduction velocity and inhibit automaticity. Amiodarone also blocks Na^+ and Ca^{+2} channels and β-receptors.

Ca, calcium; CCB, calcium channel blocker; K, potassium; Na, sodium; ↑, increase/prolong; ↓, decrease; 0, no effect; 0/↓, does not change or may decrease: ↓/0, decreases or does not change.

Clinical Presentation and Diagnosis of Sinus Bradycardia

Symptoms

- Many patients are asymptomatic, particularly those with resting heart rates less than 60 beats/min as a result of physical fitness due to regular exercise
- Susceptible patients may develop symptoms, depending on degree of heart rate lowering
- Symptoms include dizziness, fatigue, light-headedness, syncope, chest pain (in patients with underlying coronary artery disease [CAD]), and shortness of breath and other symptoms of HF (in patients with underlying LV dysfunction)

Diagnosis

- Cannot be made on the basis of symptoms alone because the symptoms of all bradyarrhythmias are similar
- History of present illness, presenting symptoms, and 12-lead ECG showing sinus bradycardia
- Assess possible correctable etiologies, including myocardial ischemia, serum potassium concentration (for hyperkalemia), and thyroid function tests (for hypothyroidism)
- Determine whether patient is taking any drugs known to cause sinus bradycardia and discontinue if possible

manifest as the bradycardia-tachycardia syndrome (also known as tachy-brady syndrome), characterized by alternating periods of supraventricular tachyarrhythmias and bradycardia.[5]

Sick sinus syndrome leading to sinus bradycardia may be caused by degenerative changes in the sinus node that occur with advancing age. However, there are other possible etiologies of sinus bradycardia including drugs (Table 10–2).[5]

▶ *Pathophysiology*

Sick sinus syndrome leading to sinus bradycardia is due to replacement of normal sinus node tissue with fibrotic tissue.[5]

▶ *Treatment*

Desired Outcomes Desired treatment outcomes are to restore normal heart rate and alleviate patient symptoms.

Pharmacologic Therapy KEY CONCEPT Treatment of sinus bradycardia is only necessary in symptomatic patients. Any medication(s) that may cause symptomatic sinus bradycardia should be discontinued whenever possible. If the patient remains in sinus bradycardia after drug discontinuation and after five half-lives of the drug(s) have elapsed, then drug(s) can usually be excluded as the etiology. In certain circumstances, however, discontinuation may be undesirable, even if the drug causes symptomatic sinus bradycardia. For example, if the patient has a history of MI or HFrEF, discontinuation of a β-blocker may be necessary in the short term but undesirable long term because β-blockers reduce mortality and prolong life in patients with these diseases, and benefits of therapy outweigh risks associated with sinus bradycardia. In this situation, clinicians and patients may elect to implant a permanent pacemaker to allow continuation of β-blocker therapy.

  Propafenone
  Propofol
  Remifentanil
  Sotalol
  Succinylcholine
  Thalidomide
  Verapamil

KEY CONCEPT Acute treatment of the symptomatic and/or hemodynamically unstable patient with sinus bradycardia includes administration of the anticholinergic drug atropine, given in doses of 0.5 mg intravenous (IV) every 3 to 5 minutes to a maximum recommended total dose of 3 mg.[5] Atropine is used to achieve acute symptom control while awaiting placement of a transcutaneous or transvenous pacemaker. Where necessary, transcutaneous pacing can be initiated during atropine administration. Atropine should be used cautiously in patients with myocardial ischemia or MI because increasing heart rate and myocardial oxygen demand may aggravate ischemia or extend the infarct. Atropine should not be used in patients post-heart transplant.[5]

In patients with hemodynamically unstable sinus bradycardia unresponsive to atropine, transcutaneous pacing may be initiated. In patients with hemodynamically unstable or severely symptomatic sinus bradycardia unresponsive to atropine and in whom temporary or transvenous pacing is not available or is ineffective, or while awaiting pacemaker placement, dopamine (5–20 mcg/kg/min starting at 5 mcg/kg/min and increasing the dose by 5 mcg/kg/min every 2 minutes based on response), epinephrine (2–10 mcg/min or 0.1–0.5 mcg/kg/min, titrate to response), or isoproterenol (20–60 mcg IV bolus followed by doses of 10–20 mcg or continuous infusion of 1–20 mcg/min, titrate to heart rate response) may be administered to increase heart rate.[5]

In patients with sinus bradycardia due to underlying correctable disorders such as electrolyte abnormalities or hypothyroidism, management consists of correcting those disorders.

Nonpharmacologic Therapy Long-term management of patients with sick sinus syndrome requires implantation of a permanent pacemaker.[5]

▶ *Outcome Evaluation*

- Monitor heart rate, goal is symptom alleviation.
- Monitor for adverse effects of medications such as atropine (dry mouth, mydriasis, urinary retention, and tachycardia).

AV Block

AV block occurs when conduction of electrical impulses through the AV node is impaired to varying degrees. AV block is classified into three categories. First-degree (1°) AV block is prolongation of the PR interval to greater than 0.2 seconds. Here, all impulses initiated by the sinus node are conducted through the AV node, but more slowly than normal, resulting in PR interval prolongation.[5,7] Second-degree (2°) AV block is subdivided into two types: Mobitz type I (also known as Wenckebach) and Mobitz type II. Mobitz type I is due to progressive lengthening of the PR interval until a P wave is not followed by a QRS complex (dropped beat). In contrast, Mobitz type II is not associated with a progressive lengthening of the PR interval prior to or after the nonconducted P wave. In both types, some of the sinus node impulses are not conducted through the AV node. This often occurs in a regular pattern; for example, there may be absence of AV nodal conduction of every third or fourth impulse. Mobitz type II has a higher risk for progression to third-degree (3°) AV block. During 3° AV block, also called "complete heart block," impulses generated by the sinus node are not conducted through the AV node. This results in AV dissociation, during

Table 10–3

Etiologies of Atrioventricular (AV) Block[5,7]

Idiopathic degeneration of the AV node
Myocardial ischemia or infarction
Neurocardiac syncope
Carotid sinus hypersensitivity
Electrolyte abnormalities: hypokalemia or hyperkalemia
Hypothyroidism
Hypothermia
Infectious diseases: Chagas disease, endocarditis, Lyme disease
Amyloidosis
Sarcoidosis
Systemic lupus erythematosus
Scleroderma
Obstructive sleep apnea
Myocarditis
Drugs:

  Fingolimod
  Flecainide
  Hydroxychloroquine
  Paclitaxel
  Propafenone
  Propofol
  Sotalol
  Thioridazine
  Tricyclic antidepressants
  Verapamil

which the atria continue to depolarize normally as a result of normal impulses initiated by the sinus node; however, the ventricles initiate their own depolarizations because no sinus node-generated impulses are conducted to the ventricles. Therefore, on the ECG, there is no relationship (dissociation) between the P waves and the QRS complexes.

▶ *Epidemiology and Etiology*

Overall incidence of AV block is unknown. AV block may occur as a result of age-related AV node degeneration. There are many other possible etiologies of AV block including drugs (Table 10–3).[5,7]

▶ *Pathophysiology*

1° AV block is due to inhibition of conduction within the upper portion of the node.[5,7] Mobitz type I 2° AV block results from inhibition of conduction further down within the node.[5,7] Mobitz type II 2° AV block is caused by inhibition of conduction within or below the level of the bundle of His.[5,7] 3° AV block may be a result of inhibition of conduction either within the AV node or within the bundle of His or the His-Purkinje system.[5,7]

▶ *Treatment*

Desired Outcomes Desired treatment outcomes are to restore normal sinus rhythm and alleviate patient symptoms.

Pharmacologic Therapy **KEY CONCEPT** Treatment of 1° AV block is rarely necessary because symptoms rarely occur. However, ECGs of patients with 1° AV block should be monitored to assess the possibility of progression to 2° or 3° block, which requires treatment because bradycardia often results in symptoms. If the patient is taking any medication(s) that may cause AV block, the drug(s) should be discontinued whenever possible. If the patient's rhythm still exhibits AV block after discontinuing the medication(s) and after five half-lives of the drug(s) have elapsed, then drug(s) can usually be excluded as the etiology. However, in certain circumstances, discontinuation of a medication that is inducing AV block may be undesirable. For example, if the patient has a history of MI or HFrEF, discontinuation of a β-blocker is undesirable, as the benefits of therapy outweigh risks associated with AV block. Here, permanent pacemaker placement to enable the patient to continue β-blocker therapy is often considered.

Clinical Presentation and Diagnosis of AV Block

Symptoms

- 1° AV block is rarely symptomatic because it rarely results in bradycardia
- 2° AV block may cause bradycardia because not all impulses generated by the sinus node are conducted through the AV node to the ventricles
- In 3° AV block, heart rate is often 30 to 40 beats/min, resulting in symptoms
- Symptoms vary from asymptomatic to dizziness, fatigue, light-headedness, syncope, chest pain (in patients with underlying CAD), and shortness of breath and other symptoms of HF (in patients with underlying HF).

Diagnosis

- Made on the basis of patient presentation, including history of present illness and presenting symptoms, as well as a 12-lead ECG that reveals AV block
- Assess potentially correctable etiologies, including myocardial ischemia, serum potassium concentration (for hyperkalemia), and thyroid function tests (for hypothyroidism)
- Determine whether the patient is taking any drugs known to cause AV block and discontinue if possible

KEY CONCEPT Acute treatment of patients with 2° or 3° AV block consists primarily of administration of atropine, given in the same doses as recommended for management of sinus bradycardia. In patients with hemodynamically unstable or severely symptomatic AV block unresponsive to atropine and in whom temporary or transvenous pacing is not available or is ineffective, epinephrine (2–10 mcg/min, titrate to response) and/or dopamine (5–20 mcg/kg/min) may be administered.[5]

In patients with 2° or 3° AV block due to underlying correctable disorders (such as electrolyte abnormalities or hypothyroidism), management consists of correcting those disorders.

Nonpharmacologic Therapy Long-term treatment of most patients with 2° or 3° AV block due to nonreversible causes requires permanent pacemaker implantation.[5]

▶ *Outcome Evaluation*

- Monitor for AV block termination and restoration of normal sinus rhythm, heart rate, and symptom alleviation.
- If atropine is administered, monitor for adverse effects, including dry mouth, mydriasis, urinary retention, and tachycardia.

Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia encountered in clinical practice. Understanding AF is important because it is associated with substantial morbidity and mortality, and because many strategies for drug therapy are available. Some drugs used to treat AF have a narrow therapeutic index and numerous adverse effects.

▶ *Epidemiology and Etiology*

Approximately 5.2 million Americans have AF, and as many as 8.8 million in the European Union.[6] Prevalence and incidence of AF increase with advancing age; roughly 8% of patients between 80 and 89 years old have AF. AF occurs more commonly in men than women.

Etiologies of AF are presented in Table 10–4.[8-10] The common feature of most etiologies is left atrial hypertrophy development. Hypertension may be the most important risk factor for AF development. However, AF also occurs commonly in patients with CAD. HF is increasingly recognized as a cause; approximately 25% to 30% of patients with New York Heart Association (NYHA) class III HF and as many as 50% of patients with NYHA class IV HF have AF.[11] AF is responsible for more than 467,000 annual hospitalizations in the United States.[10]

Drug-induced AF is relatively uncommon but is reported (Table 10–4).[8,12-14] Use of some bisphosphonate drugs is associated with new-onset AF, but this potential relationship requires further study.[12] Recent evidence suggests that both acute and chronic alcohol ingestion are associated with an increased risk of AF and that alcohol abstinence reduces AF recurrences.[13,14]

▶ *Pathophysiology*

AF may be caused by both abnormal impulse formation and abnormal impulse conduction. Traditionally, AF was believed to be initiated by premature impulses initiated in the atria. However, in most patients AF is triggered by electrical impulses generated within the pulmonary veins.[15] These impulses initiate the reentry process within the atria, and AF is believed to be sustained by multiple reentrant wavelets operating simultaneously within the atria. In some patients, the increased automaticity in the pulmonary veins may be the sole mechanism of AF. However, the concept of multiple simultaneous reentrant wavelets remains the predominant hypothesis regarding the mechanism of AF.[9,10]

AF leads to electrical remodeling of the atria. Episodes that are of longer duration and occur with increasing frequency result in progressive shortening of atrial refractory periods, further potentiating atrial reentry.[9] Therefore, it is often said that "atrial fibrillation begets atrial fibrillation"; that is, AF causes atrial electrophysiological alterations that further promote AF.[9,10] AF is associated with chaotic, disorganized atrial electrical activity, resulting in no atrial contraction.

AF occurs due to structural and/or electrophysiological abnormalities that promote abnormal atrial and/or pulmonary vein automaticity and/or atrial reentry.[9,10] Atrial structural abnormalities include fibrosis, dilation, ischemia, infiltration, and hypertrophy.[9,10] Other contributing factors include inflammation, oxidative stress, activation of the renin-angiotensin-aldosterone system, autonomic nervous system activation, and genetic variants in myocardial ion channels and those leading to cardiomyopathy.[9,10] A substantial amount of the atrial electrical activity occurring during AF is conducted through the AV node into the ventricles, resulting in ventricular rates ranging from 100 to 200 beats/min.

Table 10–4

Etiologies of and Risk Factors for Atrial Fibrillation (AF)[8-10]

- Older age
- Hypertension
- Myocardial infarction
- Heart failure
- Diabetes mellitus
- Hyperthyroidism
- Rheumatic heart disease
- Diseases of the heart valves:
  - Mitral stenosis or regurgitation
  - Mitral valve prolapse
- Obesity
- Smoking
- Obstructive sleep apnea
- Critical Illness
- Pericarditis
- Amyloidosis
- Myocarditis
- Pulmonary embolism
- Idiopathic
- Family history
- Genetic predisposition
- Thoracic surgery:
  - Coronary artery bypass graft surgery
  - Pulmonary resection
  - Thoracoabdominal esophagectomy
- Drugs:
  - Adenosine
  - Albuterol
  - Alcohol
  - Alendronate
  - Dobutamine
  - Dopamine
  - Doxorubicin
  - Enoximone
  - Epinephrine
  - Fingolimod
  - Interleukin-2
  - Ivabradine
  - Methylprednisolone
  - Milrinone
  - Mitoxantrone
  - Morphine
  - Paclitaxel
  - Propafenone
  - Theophylline
  - Verapamil
  - Zoledronic acid

Patient Encounter Part 1

A 67-year-old man presents to the emergency department (ED) complaining of his heart racing, shortness of breath, and fatigue. He states that this started a few hours ago and occurred at rest. He also complains of occasional light-headedness. His pulse is irregular, with a rate of 150 beats/min.

What information suggests AF?

What additional information do you need to develop a treatment plan?

Clinical Presentation and Diagnosis of AF

Symptoms

- Approximately 20% to 30% of patients with AF remain asymptomatic
- Symptoms include fatigue, palpitations, dizziness, lightheadedness, dyspnea, chest pain (if underlying CAD is present), near-syncope, and syncope. Patients commonly complain of palpitations; often the complaint is "I can feel my heart beating fast" or "I can feel my heart fluttering" or "It feels like my heart is going to beat out of my chest"
- Other symptoms depend on the degree of cardiac output reduction, which in turn depends on ventricular rate and the degree to which **stroke volume** is reduced by the rapidly beating heart
- In some patients, the first symptom of AF is stroke

Diagnosis

- Symptoms of all tachyarrhythmias depend on heart rate and can be similar, therefore diagnosis depends on presence of AF on the ECG
- Characterized on ECG by an absence of P waves (an undulating baseline that represents chaotic atrial electrical activity) and an irregularly irregular rhythm (meaning the intervals between the R waves are irregular with no pattern to the irregularity)
- Sometimes first diagnosed in patients presenting with ischemic stroke

AF is categorized into several classifications.[10] *Paroxysmal AF* terminates spontaneously or with interventions within 7 days of onset.[10] Episodes begin suddenly and spontaneously, last minutes to hours, or sometimes as long as several days, and terminate spontaneously. The frequency of recurrence in patients with paroxysmal AF is variable. *Persistent AF* is defined as continued AF of duration longer than 7 days.[10] *Long-standing persistent AF* is defined as continuous AF lasting longer than 12 months.[10] The term *permanent AF* is used when patient and clinician jointly decide to terminate further attempts to restore and/or maintain sinus rhythm.[10] Acceptance of AF represents a specific therapeutic viewpoint from the patient and clinician rather than a pathophysiological characteristic of AF and may change as symptoms, efficacy of treatments, and patient and clinician preferences develop and evolve.[10]

AF is associated with substantial morbidity and mortality, including risk of ischemic stroke of approximately 5% per year.[10] Stroke risk is increased two- to sevenfold in patients with AF compared to patients without this arrhythmia.[6] AF is the cause of roughly one of every six strokes. During AF, atrial contraction is absent. Because atrial contraction is responsible for approximately 30% of LV filling, blood that is not ejected from the left atrium to the LV pools in the atrium, particularly in the left atrial appendage. Blood pooling facilitates thrombus formation, which subsequently may travel across the mitral valve into the LV and be ejected during ventricular contraction. The thrombus then may travel through a carotid artery into the brain, resulting in an ischemic stroke. Patients with AF are also at increased risk for systemic thromboembolism. Note that risk of thromboembolism is more complex than simply blood stasis in the left atrium and likely involves many factors including inflammation, endothelial dysfunction, atrial myopathy, and many others.[9]

AF is associated with a threefold increase in risk of HF as a result of tachycardia-induced cardiomyopathy.[10] AF increases risk of dementia and mortality approximately twofold compared to patients without AF[10]; cause of death is likely stroke or HF.

▶ *Treatment*

Desired Outcomes KEY CONCEPT The goals of individualized therapy for AF are (a) ventricular rate control; (b) termination of AF and restoration of sinus rhythm (commonly referred to as "cardioversion" or "conversion to sinus rhythm"); (c) maintenance of sinus rhythm, or reduction in the frequency of episodes of paroxysmal AF; and/or (d) prevention of stroke and systemic embolism. These goals of therapy do not necessarily apply to all patients; the specific goal(s) depend on the patient's AF classification (Table 10–5).

Hemodynamically Unstable AF For patients with hemodynamically unstable AF, emergent conversion to sinus rhythm is necessary using **direct current cardioversion** (DCC). Hemodynamic instability is defined as the presence of any of the following: (a) acutely altered mental status; (b) hypotension (systolic blood pressure < 90 mm Hg) or other signs of shock; (c) ischemic chest discomfort; and/or (d) acute HF.[16]

DCC is the process of administering a synchronized electrical shock to the chest. The purpose of DCC is to simultaneously depolarize all of the myocardial cells, resulting in interruption and termination of the multiple reentrant circuits and restoration of normal sinus rhythm. The recommended initial energy level for conversion of AF to sinus rhythm is 120 to 200 Joules (J) for biphasic shocks or 200 J for monophasic shocks. If the DCC attempt is unsuccessful, DCC energy should be increased in a stepwise fashion.[11] Shock delivery is synchronized to the ECG by the cardioverter machine, such that the electrical charge is not delivered during the latter portion of the T wave (ie, the relative refractory period) to avoid delivering an electrical impulse

Table 10–5

Treatment Goals According to Atrial Fibrillation (AF) Classification

Paroxysmal AF	Persistent AF	Long-Standing Persistent AF	Permanent AF
Ventricular rate control Prevention of stroke and systemic embolism Maintenance of sinus rhythm *if ventricular rate control is not sufficient to control symptoms*	Ventricular rate control Prevention of stroke and systemic embolism Conversion to sinus rhythm	Ventricular rate control Prevention of stroke and systemic embolism Conversion to sinus rhythm	Ventricular rate control Prevention of stroke and systemic embolism

that may be conducted abnormally, which may result in a life-threatening ventricular arrhythmia ("R-on-T phenomenon").

The remainder of this section is devoted to pharmacologic management of hemodynamically stable AF.

Ventricular Rate Control Ventricular rate control can be achieved by inhibiting the proportion of electrical impulses conducted from the atria to the ventricles through the AV node. Drugs that are effective for ventricular rate control inhibit AV node impulse conduction: β-blockers, diltiazem, verapamil, digoxin, and amiodarone (Tables 10–6[10] and 10–7).

In patients who present to the ED with an episode of symptomatic persistent AF or paroxysmal AF for which intervention is desired, ventricular rate control is usually initially achieved using IV drugs. A decision algorithm for selecting a specific drug for ventricular rate control is presented in Figure 10–4.[10] In general, an IV CCB or β-blocker is preferred for ventricular rate control in patients with normal LV function because ventricular rate control can often be achieved within minutes. In patients with acute decompensated HF (ADHF) or HFrEF, IV diltiazem and verapamil should be avoided, as these drugs have negative inotropic effects and may exacerbate HFrEF.[10] An IV β-blocker may be administered in these patients, but only following stabilization of ADHF, due to potential for exacerbation. Amiodarone or digoxin may be considered as alternatives for rate control in patients with AF associated with severe LV dysfunction and HF or hemodynamic instability. However, caution is warranted with amiodarone due to the potential for chemical cardioversion. Therefore, patients must either be anticoagulated or evaluated by echocardiography to rule out thrombus prior to amiodarone use.[17]

For patients requiring long-term rate control with oral medications, the treatment algorithm is the same (Figure 10–4). Although digoxin is effective for rate control in patients at rest,

Table 10–6

Drugs for Ventricular Rate Control in Atrial Fibrillation (AF)[10]

Drug	Mechanism of Action	Intravenous Administration	Usual Oral Maintenance Dose	Drug Interactions
Amiodarone	β-Blocker CCB	300 mg over 1 hour, then 10–50 mg/hour over 24 hours via continuous infusion	100–200 mg once daily	Inhibits clearance of warfarin, some statins, and other drugs. Increases digoxin bioavailability and reduces clearance
β-Blockers[a]	Inhibit AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	Esmolol 500 mcg/kg over 1 minute, then 50–300 mcg/kg/min continuous infusion Propranolol 1 mg over 1 minute, up to 3 doses at 2-minute intervals Metoprolol tartrate 2.5–5 mg over 2 minutes; up to 3 doses	Atenolol 25–100 mg once daily Bisoprolol 2.5–10 mg once daily Carvedilol 3.125–25 mg twice daily Metoprolol tartrate 25–100 mg twice daily Metoprolol XL (succinate) 50–400 mg once daily Nadolol 10–240 mg once daily Propranolol 10–40 mg three or four times daily	
Diltiazem	Inhibits AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	0.25 mg/kg bolus over 2 minutes, then 5–15 mg/hour continuous infusion	120–360 mg once daily (extended release)	Increases carbamazepine, cyclosporine, midazolam, triazolam, theophylline, atorvastatin, lovastatin, simvastatin concentrations Cimetidine, ranitidine, diazepam, grapefruit juice may increase serum diltiazem concentrations Dantrolene (combination may lead to ventricular arrhythmias)
Verapamil	Inhibits AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	0.075–0.15 mg/kg bolus over 2 minutes. If no response after 30 minutes, may give an additional 10 mg, then 0.005 mg/kg/min continuous infusion	180–480 mg daily (extended release)	Increases digoxin, carbamazepine, cyclosporine, theophylline, atorvastatin, lovastatin, simvastatin concentrations Dantrolene (combination may lead to ventricular arrhythmias)
Digoxin	Inhibits AV nodal conduction by (a) vagal stimulation, (b) directly slowing AV nodal conduction, and (c) prolonging AV nodal refractoriness	0.25 mg every 2 hours, up to 1.5 mg over 24 hours	0.125–0.25 mg once daily	Amiodarone, verapamil inhibit digoxin elimination and increase bioavailability

[a] In patients with acute decompensated heart failure, therapy with intravenous β-blockers should be initiated only after the patient has been stabilized. Diltiazem and verapamil should be avoided in these patients.

AV, atrioventricular; CCB, calcium channel blocker.

Table 10–7

Adverse Effects of Drugs Used to Treat Arrhythmias

Drug	Adverse Effects
Adenosine	Chest pain, flushing, dyspnea, transient sinus bradycardia/AV block
Amiodarone	IV: Hypotension, sinus bradycardia, phlebitis, QT interval prolongation, torsades de pointes Oral: Blue–gray skin discoloration, photosensitivity, corneal microdeposits, pulmonary fibrosis, hepatotoxicity, sinus bradycardia, hypo- or hyperthyroidism, peripheral neuropathy, weakness, AV block
Atenolol	Hypotension, bradycardia, AV block, HF exacerbation[a]
Atropine	Tachycardia, urinary retention, blurred vision, dry mouth, mydriasis
Bisoprolol	Hypotension, bradycardia, AV block, HF exacerbation[a]
Carvedilol	Hypotension, bradycardia, AV block, HF exacerbation[a]
Digoxin	Nausea, vomiting, anorexia, visual changes such as green–yellow halos around objects, AV block, ventricular arrhythmias
Diltiazem	Hypotension, sinus bradycardia, HF exacerbation, AV block
Dofetilide	Torsades de pointes
Dronedarone	Diarrhea, asthenia, nausea and vomiting, abdominal pain, bradycardia, GI distress, hepatotoxicity
Esmolol	Hypotension, sinus bradycardia, AV block, bronchospasm, HF exacerbation
Flecainide	Dizziness, blurred vision, HF exacerbation, torsades de pointes, life-threatening ventricular tachycardia (in patients with underlying CAD)
Ibutilide	Torsades de pointes
Lidocaine	Slurred speech, diminished consciousness, seizures, bradycardia
Metoprolol	Hypotension, sinus bradycardia, AV block, fatigue, bronchospasm, HF exacerbation[a]
Mexiletine	Nausea, vomiting, GI distress, tremor, dizziness, fatigue, seizures (if dose too high)
Nadolol	Hypotension, bradycardia, AV block, HF exacerbation[a]
Procainamide	Hypotension, HF exacerbation, QT interval prolongation, torsades de pointes
Propafenone	Dizziness, blurred vision, life-threatening ventricular tachycardia (in patients with underlying CAD)
Propranolol	Hypotension, sinus bradycardia, AV block, bronchospasm, HF exacerbation[a]
Sotalol	Sinus bradycardia, AV block, fatigue, torsades de pointes
Verapamil	Hypotension, HF exacerbation, bradycardia, AV block, constipation (oral)

[a] Associated with intravenous administration (metoprolol, propranolol), inappropriately high oral doses at initiation of therapy, or overly aggressive and rapid dose titration.

AV, atrioventricular; CAD, coronary artery disease; GI, gastrointestinal; HF, heart failure; IV, intravenous.

it is less effective than CCBs or β-blockers in patients undergoing physical activity, including activities of daily living. This is likely because activation of the sympathetic nervous system during exercise and activity overwhelms the stimulating effect of digoxin on the parasympathetic nervous system. Digoxin may be associated with increased mortality risk in patients with AF, and this risk may be associated with higher digoxin plasma concentrations.[18,19] Overall, in patients with normal LV function, CCBs or β-blockers are preferred for long-term ventricular rate control. Diltiazem may be preferable to verapamil in older patients due to a lower incidence of constipation. However, in patients with HFrEF, oral diltiazem and verapamil are contraindicated due to their negative inotropic activity and propensity to exacerbate HFrEF. Therefore, the options in this population are β-blockers or digoxin. Most patients with HFrEF should receive an oral β-blocker to reduce mortality risk. In patients with HFrEF who develop rapid AF while receiving therapy with β-blockers, digoxin can be administered for ventricular rate control. The combination of digoxin and β-blockers is effective for ventricular rate control, likely as a result of β-blocker–induced attenuation of the inhibitory effects on the sympathetic nervous system.[20]

Conversion to Sinus Rhythm Antiarrhythmic drug therapy or elective DCC can be used to terminate AF in hemodynamically stable patients. Drugs effective for conversion to sinus rhythm are presented in Table 10–8.[10] These agents slow atrial conduction velocity and/or prolong refractoriness, interrupting reentrant

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension × 30 years; MI 2 years ago; HFrEF × 1 year (left ventricular ejection fraction [LVEF] 35% [0.35])

Meds: Aspirin 81 mg once daily; atorvastatin 40 mg orally once daily; sacubitril/valsartan 49 mg/51 mg orally twice daily; carvedilol 12.5 mg orally twice daily; bumetanide 2 mg orally once daily; eplerenone 25 mg orally once daily.

PE:

Ht 5 ft 11 in (180 cm), Wt 98 kg (216 lb), BP 115/78 mm Hg, P 150 beats/min, RR 20 breaths/min; remainder of physical examination noncontributory

Labs: All within normal limits. Serum creatinine 1.1 mg/dL (97 μmol/L)

CXR: Mild pulmonary edema

ECG: Atrial fibrillation

What is your assessment of the patient's condition?

What are your treatment goals?

What pharmacologic or nonpharmacologic alternatives are available for each treatment goal?

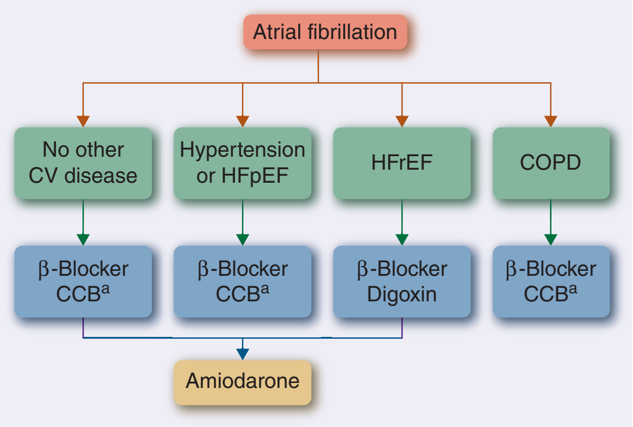

FIGURE 10–4. Decision algorithm for selecting drug therapy for ventricular rate control. In boxes where multiple medications are listed, drugs are listed alphabetically, not in order of preference. [a]When administered intravenously, diltiazem is generally preferred over verapamil because of a lower risk of severe hypotension. (CCB, calcium channel blocker [diltiazem or verapamil]; COPD, chronic obstructive pulmonary disease; CV, cardiovascular; HFpEF, heart failure with preserved ejection fraction; HFrEF, heart failure with reduced ejection fraction.) (Adapted with permission from January CT, Wann LS, Alpert JS, et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation. J Am Coll Cardiol. 2014;64:e1–e76).

circuits and restoring sinus rhythm. DCC is generally more effective than drug therapy for converting AF to sinus rhythm. However, patients undergoing elective DCC must be sedated and/or anesthetized to avoid the discomfort associated with delivery of electrical shock to the chest. Therefore, it is important that patients undergoing elective DCC not eat within approximately 8 to 12 hours of the procedure to avoid aspiration of stomach contents and resulting aspiration pneumonitis during the period of sedation/anesthesia.

A decision strategy for conversion of AF to sinus rhythm is presented in Figure 10–5.[10] The cardioversion decision strategy primarily depends on AF duration. If the AF episode began within 48 hours, conversion to sinus rhythm is safe and may be attempted with elective DCC or drug therapy. However, if the duration of the AF episode is 48 hours or longer, or if there is uncertainty regarding duration, two strategies for conversion may be considered. A thrombus may form in the left atrium during AF episodes of 48 hours or longer; if an atrial thrombus is present, conversion to sinus rhythm, whether with DCC or drugs, can dislodge the atrial thrombus, leading to embolization and a stroke. Therefore, in patients experiencing an AF episode of 48 hours or longer, conversion to sinus rhythm should be deferred unless it is known that an atrial thrombus is not present. One option in patients with AF of duration 48 hours or longer, or of unknown duration, is to anticoagulate with warfarin (maintaining an international normalized ratio [INR] of 2–3) or a direct oral anticoagulant (DOAC; dabigatran, rivaroxaban, apixaban, or edoxaban) for 3 weeks, after which cardioversion may be performed. Patients should subsequently be anticoagulated for a minimum of 4 weeks following restoration of sinus rhythm. An alternative approach is to perform a transesophageal echocardiogram (TEE) to determine

Table 10–8

Drugs for Conversion of Atrial Fibrillation (AF) to Normal Sinus Rhythm[10]

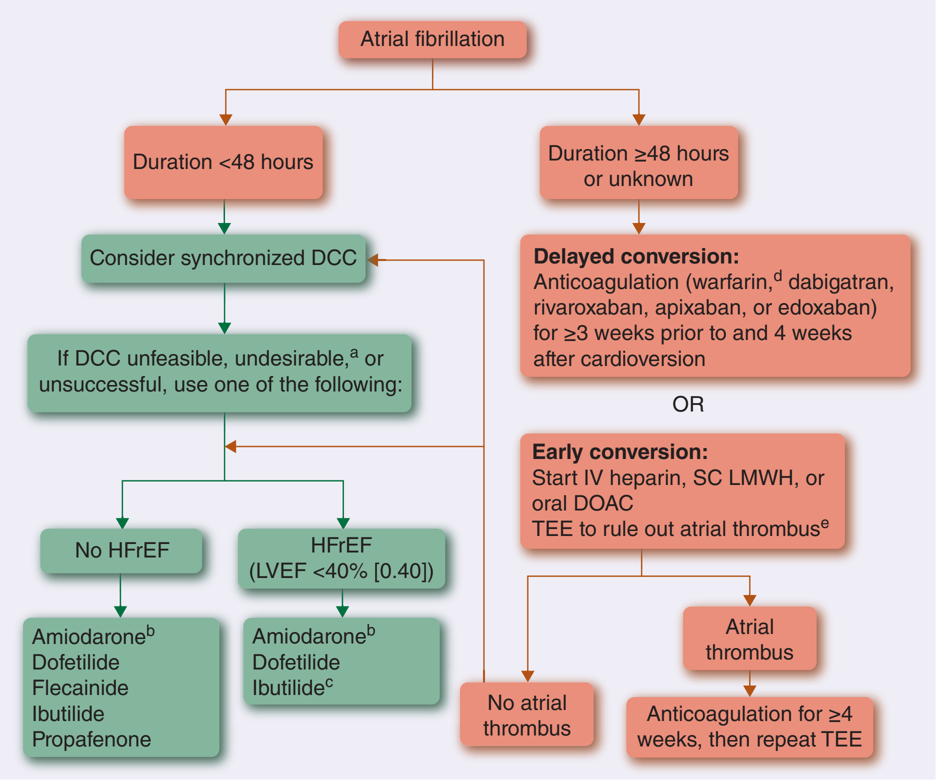
Treatment	IV Administration	Oral Administration	Drug Interactions
Amiodarone	150 mg over 10 minutes, then 1 mg/min for 6 hours, then 0.5 mg/min for 18 hours or change to oral dosing	600–800 mg daily in divided doses up to a total load of 10 g, then maintenance dose of 200 mg daily	Inhibits clearance of warfarin, some statins, and other drugs. Increases digoxin bioavailability and reduces clearance
Dofetilide	Not available IV	CrCl (mL/min)[a,b]: > 60 mL/min: 500 mcg twice daily 40–60 mL/min: 250 mcg twice daily 20–40 mL/min: 125 mcg twice daily < 20 mL/min: Not recommended	Cimetidine, hydrochlorothiazide, ketoconazole, dolutegravir, megestrol, prochlorperazine, promethazine, trimethoprim, verapamil (all inhibit dofetilide elimination, most by inhibition of renal cation transport)
Flecainide	Not available IV in the United States	200–300 mg × one dose[c]	Quinidine, fluoxetine, tricyclic antidepressants increase flecainide concentrations
Ibutilide	1 mg IV over 10 minutes, followed by a second 1 mg IV dose if necessary. If weight < 60 kg (132 lb), dose should be 0.01 mg/kg	Not available orally	—
Propafenone	Not available IV	450–600 mg × one dose[c]	Quinidine, fluoxetine, tricyclic antidepressants increase propafenone concentrations Increases serum digoxin concentrations Inhibits CYP2C9, inhibits warfarin metabolism

[a] Creatinine clearance of > 60, 40–60, 20–40, and < 20 mL/min corresponds to > 1, 0.67–1, 0.33–0.67, and < 0.33 mL/s, respectively.

[b] Dofetilide therapy must be initiated in hospital, due to risk of QT interval prolongation that may lead to torsades de pointes.

[c] It is recommended that a β-blocker or nondihydropyridine calcium channel blocker be administered ≥ 30 minutes prior to administering flecainide or propafenone to avoid accelerated atrioventricular (AV) node conduction and increased heart rate.

CrCl, creatinine clearance; CYP, cytochrome P450; IV, intravenous.



Atrial fibrillation
Duration <48 hours
Duration ≥48 hours or unknown
Consider synchronized DCC
Delayed conversion: Anticoagulation (warfarin,d dabigatran, rivaroxaban, apixaban, or edoxaban) for ≥3 weeks prior to and 4 weeks after cardioversion
If DCC unfeasible, undesirable,a or unsuccessful, use one of the following:
OR
Early conversion: Start IV heparin, SC LMWH, or oral DOAC TEE to rule out atrial thrombuse
No HFrEF
HFrEF (LVEF <40% [0.40])
Amiodaroneb Dofetilide Flecainide Ibutilide Propafenone
Amiodaroneb Dofetilide Ibutilidec
Atrial thrombus
No atrial thrombus
Anticoagulation for ≥4 weeks, then repeat TEE

FIGURE 10–5. Decision algorithm for conversion of hemodynamically stable atrial fibrillation to normal sinus rhythm. [a]Patients should not be sedated for synchronized DCC if they have eaten a meal within 12 hours, due to risk of aspiration. [b]Drugs are listed in alphabetical order, not order of preference. [c]Ibutilide can be administered to patients with LVEF 30%–40% (0.30–0.40) but should be avoided in patients with LVEF < 30% (0.30) due to risk of ventricular proarrhythmia. [d]International normalized ratio (INR) of 2–3. [e]Anticoagulation must be achieved prior to TEE and maintained for more than or equal to 4 weeks after TEE. (DCC, direct current cardioversion; DOAC, direct oral anticoagulant; HFrEF, heart failure with reduced ejection fraction; IV, intravenous; LVEF, left ventricular ejection fraction; LMWH, low-molecular-weight heparin; SC, subcutaneous; TEE, transesophageal echocardiogram.)

whether an atrial thrombus is present; if no thrombus is present, DCC or pharmacologic cardioversion may be performed. If this strategy is selected, hospitalized patients should undergo anticoagulation with IV unfractionated heparin, with the dose targeted to an activated partial thromboplastin time (aPTT) of 60 seconds (range: 50–70 seconds), low-molecular-weight heparin, or oral anticoagulation therapy with warfarin (target INR range: 2–3) or a DOAC during hospitalization prior to the TEE and cardioversion procedure. If a thrombus is not present during TEE and cardioversion is successful, patients should remain on oral anticoagulation therapy for at least 4 weeks. If a thrombus is observed during TEE, then cardioversion should be postponed and anticoagulation continued indefinitely. Another TEE should be performed prior to a subsequent cardioversion attempt.[10]

Conversion of hemodynamically stable AF to sinus rhythm may be performed in patients with a symptomatic episode of persistent or paroxysmal AF. For patients in permanent AF, a joint decision has been made by the patient and clinician to forego further attempts to restore and/or maintain sinus rhythm, therefore conversion to sinus rhythm is not attempted.[10]

Maintenance of Sinus Rhythm/Reduction in the Frequency of Episodes of Paroxysmal AF Many patients experience AF recurrences after cardioversion, thus permanent maintenance of sinus rhythm after cardioversion is an unrealistic goal. Similarly, in patients with paroxysmal AF, complete maintenance of sinus rhythm without recurrent AF episodes is often not achievable. A more realistic goal for these patients is not permanent maintenance of sinus rhythm, but rather reduction in frequency or duration of episodes of paroxysmal AF. Maintenance of sinus rhythm is more likely to be successful in patients with AF duration of less than 6 months.

Numerous studies compared whether drug therapy for maintenance of sinus rhythm is preferred to ventricular rate control.[21-24] In these studies, patients were assigned randomly to receive drug therapy either for rate control or rhythm control (Table 10–9). No significant differences in mortality were found between the two strategies.[21-24] However, patients assigned to the rhythm control strategy were more likely to be hospitalized[21,22,24] and to experience adverse effects associated with drug therapy.[23,24]

KEY CONCEPT Therefore, drug therapy to maintain sinus rhythm or reduce the frequency of AF episodes should be initiated only in patients with paroxysmal AF who continue to experience symptoms despite maximum tolerated doses of drugs for ventricular rate control. A decision strategy for maintenance therapy of sinus rhythm is presented in Figure 10–6.[10] Therapy with dofetilide or sotalol should be initiated in the hospital with patients undergoing continuous ECG monitoring due to the risk of torsades de pointes (TdP). Drug therapy for maintenance of sinus rhythm and/or reduction in the frequency of episodes of paroxysmal AF should not be initiated in patients with underlying correctable causes of AF, such as hyperthyroidism; rather, the underlying cause should be corrected. Drug therapy for maintenance of sinus rhythm should be discontinued when AF becomes designated as permanent.

Table 10–9

Drugs for Maintenance of Sinus Rhythm/Reduction in the Frequency of Episodes of Atrial Fibrillation[10]

Drug	Dose
Amiodarone	400–600 mg orally in 2–3 divided doses for 2–4 weeks; maintenance dose 100–200 mg orally once daily
Dofetilide[a]	As described in Table 10–8
Dronedarone	400 mg orally every 12 hours with food
Flecainide	50–200 mg orally every 12 hours
Propafenone	Immediate release: 150–300 mg orally every 8 hours Extended release: 225–425 mg orally every 12 hours
Sotalol[a]	Initial dose, CrCl[b] > 60 mL/min: 80 mg orally twice daily Initial dose, CrCl[b] 40–60 mL/min: 80 mg orally once daily CrCl[b] < 40 mL/min: Contraindicated Maintenance dose: If 80-mg doses are tolerated and QTc interval remains < 500 ms after 3 days, patients can be discharged. Alternatively, dose can be increased to 120 mg orally once or twice daily as appropriate during hospitalization and patient followed for 3 days on this dose IV available as substitute for oral sotalol Note: 75 mg IV over 5 hours twice daily equivalent to 80 mg orally twice daily; 112.5 mg IV over 5 hours twice daily equivalent to 120 mg orally twice daily; 150 mg IV over 5 hours twice daily equivalent to 160 mg orally twice daily

[a] Dofetilide and sotalol therapy must be initiated in the hospital due to the risk of QT interval prolongation that may lead to torsades de pointes.

[b] CrCl of > 60, 40–60, and < 40 mL/min corresponds to > 1, 0.67–1, and < 0.67 mL/s, respectively.

CrCl, creatinine clearance; IV, intravenous; ms, milliseconds; QTc, corrected QT interval.

Catheter ablation is a nonpharmacologic treatment for rhythm control in patients with paroxysmal AF. During this procedure, a catheter is introduced transvenously and directed to the left atrium under fluoroscopic guidance. Energy is delivered through the catheter to ablate, or destroy, reentrant circuits in the pulmonary veins responsible for propagating AF. The most common energy source for catheter ablation is radiofrequency energy, though cryoablation is sometimes used as an alternative. Catheter ablation is often reserved for patients in whom symptomatic AF is refractory to, or the patient is intolerant of, at least one antiarrhythmic agent. However, some patients prefer catheter ablation to avoid antiarrhythmic drug adverse effects. Compared to antiarrhythmic drugs, catheter ablation does not reduce the risk of death, disabling stroke, serious bleeding, or cardiac arrest but does reduce AF recurrence.[25,26]

Prevention of Stroke and Systemic Embolism Most patients with paroxysmal, persistent, or permanent AF should receive therapy for prevention of stroke and systemic embolism unless compelling contraindications exist. The CHA_2DS_2-VASc score

FIGURE 10–6. Decision algorithm for maintenance of sinus rhythm/reduction in the frequency of episodes of atrial fibrillation (AF) for patients with symptomatic paroxysmal or persistent AF despite rate control therapy. In boxes where multiple medications are listed, drugs are listed alphabetically, not in order of preference. [a]Not recommended in patients with severe left ventricular hypertrophy. [b]Should be used cautiously in patients at risk for torsades de pointes. [c]Catheter ablation is only recommended as first-line therapy in patients with paroxysmal AF and is recommended depending on patient preference when performed at experienced centers. (CAD, coronary artery disease; HF, heart failure.) (Adapted with permission from January CT, Wann LS, Alpert JS, et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation. J Am Coll Cardiol. 2014;64:e1–e76.)

is used to assess stroke risk in patients with atrial fibrillation.[10,17] Oral anticoagulation is recommended in men and women with CHA_2DS_2-VASc scores greater than or equal to 2 or 3, respectively. A decision strategy for assigning patients to receive anticoagulation for prevention of stroke or systemic embolism in AF is presented in Table 10–10.[17]

The landscape of anticoagulation for stroke prevention in AF has changed with the availability of the DOACs. Dabigatran, approved by the Food and Drug Administration (FDA) in 2010, is a direct thrombin inhibitor for reducing the risk of stroke and systemic embolism in patients with nonvalvular AF. Dabigatran is associated with lower rates of stroke and systemic embolism than warfarin in patients with AF, with a similar incidence of major bleeding.[27] Dabigatran should not be used in patients with end-stage kidney disease (creatinine clearance [CrCl] under 15 mL/min [0.25 mL/s]) or advanced liver disease (impaired baseline clotting function). The recommended dabigatran dose is 150 mg twice daily except for patients with severe kidney disease (CrCl: 15–30 mL/min [0.25–0.50 mL/s]), for whom the recommended dose is 75 mg twice daily.

Advantages of dabigatran include INR monitoring is not required and the drug's onset of action is rapid, eliminating the need for bridging with unfractionated or low-molecular-weight heparins. In addition, there is a lower likelihood of drug interactions with dabigatran than with warfarin. However, dabigatran is a P-glycoprotein (P-gp) substrate, and therefore concomitant administration with P-gp inhibitors such as amiodarone, dronedarone, and verapamil may result in increases in plasma dabigatran concentrations.[28] Adjustments in the dose of dabigatran, or avoidance altogether, are recommended with specific decrements of CrCl in the presence of these P-gp inhibitors. Similarly, concomitant administration of dabigatran with combined P-gp and strong cytochrome P450 (CYP) 3A inducers (eg, phenytoin, carbamazepine, primidone, rifampin, phenobarbital, St. John's wort) should be avoided based on reduction in plasma dabigatran concentrations.[28] In patients with life-threatening or uncontrolled bleeding on dabigatran, a humanized monoclonal antibody fragment (idarucizumab) is FDA approved to rapidly reverse its anticoagulant effects.[29] Finally, while none of the DOACs are recommended for administration to patients with AF that has occurred as a result of valvular heart disease (defined as AF with moderate-to-severe mitral stenosis or a mechanical heart valve),[17] dabigatran is specifically contraindicated in patients with mechanical heart valves due to higher rates of stroke, MI, and thrombus formation on the mechanical valve compared with warfarin.

Rivaroxaban, an oral factor Xa inhibitor, was FDA approved in 2011 for reducing the risk of stroke and systemic embolism in patients with nonvalvular AF. Rivaroxaban was noninferior to warfarin for preventing stroke or systemic embolism in patients with AF and had a lower risk of intracranial and fatal bleeding.[30] Rivaroxaban is contraindicated in patients with end-stage renal disease (CrCl < 15 mL/min [0.25 mL/s]). The recommended rivaroxaban dose is 20 mg once daily

Table 10–10

American Heart Association/American College of Cardiology/Heart Rhythm Society Recommendations for Prevention of Stroke and Systemic Embolism in Patients with Nonvalvular Atrial Fibrillation (AF)[a,17]

CHA_2DS_2-VASc Score	Recommended Stroke Prevention Strategy
0 in men or 1 in women	May omit anticoagulation
1 in men or 2 in women	Oral anticoagulation may be considered
≥ 2 in men or ≥ 3 in women	Oral anticoagulation recommended. Options include: Warfarin (INR: 2–3) Dabigatran Rivaroxaban Apixaban Edoxaban DOACs (dabigatran, rivaroxaban, apixaban, and edoxaban) are recommended over warfarin in DOAC-eligible patients with AF (except with moderate-to-severe mitral stenosis or a mechanical heart valve) Warfarin or apixaban are reasonable in patients with end-stage CKD (CrCl < 15 mL/min [0.25 mL/s]) or who are on dialysis

CHA_2DS_2-VASc score calculated as follows:[10]

	Score	CHA_2DS_2-VASc score	Adjusted stroke rate (% per year)
Congestive heart failure	1 point	0	0
Hypertension	1 point	1	1.3
Age ≥ 75 years	2 points	2	2.2
Diabetes mellitus	1 point	3	3.2
History of **s**troke, TIA, or thromboembolism	2 points	4	4.0
Vascular disease (prior MI, PAD, or aortic plaque)	1 point	5	6.7
Age 65–74 years	1 point	6	9.8
Female **s**ex	1 point	7	9.6
Maximum score	9 points	8	6.7
		9	15.2

[a] Patients with AF who have mechanical heart valves should receive warfarin titrated to an INR of 2–3 or 2.5–3.5 depending on the type and location of the prosthetic heart valve.

CKD, chronic kidney disease; CrCl, creatinine clearance; DOAC, direct oral anticoagulant; INR, international normalized ratio; MI, myocardial infarction; PAD, peripheral arterial disease; TIA, transient ischemic attack.

with the evening meal. For patients with CrCl 15 to 50 mL/min (0.25–0.83 mL/s), the dose should be reduced to 15 mg once daily with the evening meal. Similar to dabigatran, rivaroxaban should be avoided in patients receiving combined P-gp and strong CYP3A inducers. Rivaroxaban should also be avoided if the CrCl is less than 80 mL/min (1.33 mL/s) in patients receiving concomitant dronedarone, amiodarone, verapamil, or diltiazem.[28] In patients with life-threatening or uncontrolled bleeding, a modified recombinant inactive form of human factor Xa (andexanet alfa) is FDA approved to rapidly reverse rivaroxaban's anticoagulant effects.[31]

Apixaban, an oral factor Xa inhibitor, was FDA approved in 2012 for reducing the risk of stroke and systemic embolism in patients with nonvalvular AF. Apixaban is superior to warfarin for preventing stroke or systemic embolism in patients with AF, with lower bleeding risk.[32] The recommended dose of apixaban is 5 mg orally twice daily. Apixaban dose should be reduced to 2.5 mg orally twice daily when any two of the following characteristics are present: serum creatinine greater than 1.5 mg/dL (133 μmol/L), 80 years of age or older, and body weight less than or equal to 60 kg (132 lb). Apixaban should not be administered to patients with severe liver disease. While patients with CrCl less than 25 mL/min (0.42 mL/s) were excluded from the landmark AF trial, an observational study found a lower risk of major bleeding with apixaban versus warfarin in patients with end-stage renal disease on dialysis.[33] Consequently, the current AF guidelines recommend either apixaban or warfarin as reasonable options for patients with end-stage chronic kidney disease (CKD; CrCl < 15 mL/min [0.25 mL/s] or on dialysis).[17] Similar to rivaroxaban, apixaban should be avoided in patients receiving combined P-gp and strong CYP3A inducers.[28] Andexanet alfa is also FDA approved to treat life-threatening or uncontrolled bleeding in patients receiving apixaban.[31]

Edoxaban, another oral factor Xa inhibitor, was FDA approved in 2015 for reduction in risk of stroke and systemic embolism in patients with nonvalvular AF. Edoxaban is noninferior to warfarin for preventing stroke or systemic embolism in these patients, with a lower bleeding risk.[34] The recommended edoxaban dose is 60 mg orally once daily in patients with CrCl 50 to 95 mL/min (0.83–1.58 mL/s). In patients with kidney disease (CrCl 15–50 mL/min [0.25–0.83 mL/s]), the dose should be reduced to 30 mg orally once daily. There are no data or dosage recommendations for patients with CrCl less than 15 mL/min (0.25 mL/s). Edoxaban should not be used in patients with CrCl greater than 95 mL/min (1.58 mL/s), as these patients have an increased risk of ischemic stroke with edoxaban 60 mg once daily compared to warfarin-treated patients. The most likely reason for this finding is increased renal edoxaban clearance leading to reduced anticoagulant effect in patients with CrCl greater than 95 mL/min (1.58 mL/s). Like other factor Xa inhibitors, edoxaban should be avoided in patients receiving combined P-gp and strong CYP3A inducers. The edoxaban dose should also be decreased by 50% in patients receiving concomitant dronedarone.[28]

For patients not DOAC eligible (eg, patients with moderate-to-severe mitral stenosis, mechanical heart valve, or with end-stage CKD not otherwise suitable for apixaban), warfarin adjusted to an INR of 2 to 3 (target 2.5) is recommended.[17] A standard empirical dosing approach can be used, such as initiating warfarin at 5 mg once daily, and titrating based on daily INR measurements until a stable therapeutic INR is achieved. Another approach is to use a clinical dosing algorithm, such as those available at warfarindosing.org, to determine the initial warfarin dose[35]; dose titration based on daily INR measurements is still required if this approach is employed. In some situations, pharmacogenomic data may be available to help guide initial warfarin dosing. These tests assess single-nucleotide polymorphisms for the gene that encodes *CYP2C9*, the primary hepatic enzyme responsible for warfarin metabolism, and the gene *VKORC1*, which encodes vitamin K epoxide reductase complex subunit 1, the enzyme that is inhibited by warfarin as its mechanism of anticoagulation.[35] Patients with specific polymorphisms of one or both of these genes may require adjustment of the initial warfarin dose to achieve adequate anticoagulation or avoid over-anticoagulation and toxicity; guidelines for pharmacogenetics-guided warfarin dosing have been published.[35] Genetic testing to guide the initiation of warfarin therapy is not yet standard practice, and some question the efficacy and cost-effectiveness of routine genetic testing with warfarin therapy. Clinical trials evaluating anticoagulation control with pharmacogenomic guidance versus standard dosing have led to mixed results.[35] The role of routine genetic testing in selecting initial warfarin doses continues to evolve. However, in patients for whom *VKORC1* and/or *CYP2C9* genotype information is available, the pharmacogenetics-guided warfarin dosing guidelines are useful for guiding initial warfarin dose selection.[35]

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the patient's acute AF episode and for long-term management of his AF.

Your plan should include (a) a statement of the drug-related needs and/or problems, (b) the goals of therapy, (c) a patient-specific detailed therapeutic plan, and (d) a follow-up plan to determine whether the goals have been achieved and adverse effects avoided.

▶ *Outcome Evaluation*

- Monitor the patient to determine whether the ventricular rate control goal is met. A target heart rate less than 80 beats/min is recommended for symptomatic patients and those with HFrEF. A target heart rate of less than 110 beats/min may be reasonable for asymptomatic patients with preserved LV systolic function.[10]
- Monitor ECG to assess continued presence of AF and determine whether conversion to sinus rhythm has occurred.
- In patients receiving warfarin, monitor INR approximately monthly to make sure it is therapeutic (target: 2.5; range: 2–3).
- Monitor for adverse effects of specific drug therapy (see Table 10–7). Monitor patients receiving oral anticoagulation for signs and symptoms of bruising or bleeding.

Paroxysmal Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (PSVT) refers to a number of arrhythmias that originate above the ventricles and require atrial or AV nodal tissue for initiation and maintenance.[36] The most common form of PSVT is AV nodal reentrant tachycardia caused by a reentrant circuit that involves the AV node or tissue adjacent to the AV node. Other types of PSVT include the relatively uncommon Wolff-Parkinson-White syndrome, which is caused by reentry through an accessory extra-AV nodal pathway. For the purposes of this section, the term *PSVT* refers to AV nodal reentrant tachycardia.

Clinical Presentation and Diagnosis of PSVT

Symptoms

- Symptoms include palpitations, "neck-pounding," dizziness, light-headedness, shortness of breath, polyuria, chest pain (if underlying CAD is present), near-syncope, and syncope. Patients commonly complain of palpitations; often the complaint is "I can feel my heart beating fast" or "I can feel my heart fluttering" or "It feels like my heart is going to beat out of my chest"
- Other symptoms depend on the degree to which cardiac output is diminished, which in turn depends on heart rate and extent to which stroke volume is reduced by the rapidly beating heart

Diagnosis

- Because the symptoms of all tachyarrhythmias depend primarily on heart rate and are therefore similar, diagnosis depends on the presence of PSVT on the ECG, characterized by narrow QRS complexes (< 0.12 seconds). P waves are usually visible but may be difficult to discern if the heart rate is extremely rapid
- PSVT is a regular rhythm and occurs at rates of 100 to 250 beats/min

▶ *Epidemiology and Etiology*

Approximately 570,000 persons in the United States have PSVT, with an estimated prevalence of 2.29 per 1000 individuals.[6,36] The incidence of PSVT is 35 per 100,000 person-years,[6] and there are roughly 89,000 new cases annually.[36] The average age of onset of PSVT is 57 years. PSVT occurs more commonly in women than men, and individuals older than 65 years have five times the risk of developing PSVT compared to younger people.[6,36] Although PSVT can occur in patients experiencing myocardial ischemia or MI, it sometimes occurs in individuals with no history of cardiac disease.

▶ *Pathophysiology*

PSVT is caused by reentry that includes the AV node as a part of the reentrant circuit. Typically, electrical impulses travel forward (antegrade, from atria to ventricles) down the AV node and then travel back up the AV node (retrograde, from ventricles to atria) in a repetitive circuit. In some patients, the retrograde conduction pathway of the reentrant circuit may exist in extra-AV nodal tissue adjacent to the AV node. One of these pathways usually conducts impulses rapidly while the other usually conducts impulses slowly. Most commonly, during PSVT the impulse conducts antegrade through the slow pathway and retrograde through the faster pathway; in approximately 5% to 10% of patients the reentrant circuit is reversed.[36]

▶ *Treatment*

Desired Outcomes The desired outcomes for treatment are to terminate the arrhythmia, restore sinus rhythm, and prevent recurrence. Drug therapy is used to terminate the arrhythmia and restore sinus rhythm; nonpharmacologic measures are generally preferred to prevent recurrence, though some patients prefer drug therapy.

Termination of PSVT KEY CONCEPT The primary method to terminate PSVT is inhibition of impulse conduction and/or prolongation of the refractory period within the AV node. Because PSVT is propagated via a reentrant circuit involving the AV node, inhibition of conduction within the AV node interrupts and terminates the reentrant circuit.

KEY CONCEPT Prior to initiation of drug therapy to terminate PSVT, some simple nonpharmacologic methods known as vagal maneuvers may be attempted.[16,36] Vagal maneuvers stimulate the activity of the parasympathetic nervous system, which inhibits AV nodal conduction, facilitating arrhythmia termination. Vagal maneuvers alone may terminate PSVT in up to 28% of cases.[36] The simplest vagal maneuver to perform is cough, which stimulates the vagus nerve. Instructing the patient to cough two or three times may successfully terminate PSVT. Carotid sinus massage is another useful vagal maneuver; one of the carotid sinuses, located in the neck in the vicinity of the carotid arteries, may be gently massaged for 5 to 10 seconds, stimulating vagal activity. Carotid sinus massage should not be performed in patients with a history of stroke or transient ischemic attack or in those in whom carotid bruits are heard on auscultation. The Valsalva maneuver, during which patients bear down against a closed glottis for 10 to 30 seconds, may also be attempted. The Valsalva maneuver is more effective than carotid sinus massage.[36] If one vagal maneuver is unsuccessful, switching to another maneuver may successfully terminate PSVT.[36]

If vagal maneuvers are unsuccessful, IV drug therapy should be initiated.[16,36] Drugs used for termination of hemodynamically stable PSVT are presented in Table 10–11.[16,36] A decision strategy for pharmacologic termination of PSVT is presented in Figure 10–7.[36]

KEY CONCEPT Adenosine is the drug of choice for pharmacologic termination of PSVT and is successful in 95% of patients. Adenosine inhibits conduction transiently and is associated with adverse effects (Table 10–7) including flushing, transient sinus bradycardia or AV block, and bronchospasm in susceptible patients. Adenosine may also cause chest pain that mimics myocardial ischemia but is not actually associated with ischemia. The adenosine half-life is approximately 10 seconds; therefore, in most patients, adverse effects are of short duration.

If adenosine does not terminate PSVT, subsequent choices of therapy depend on whether the patient is hemodynamically stable or not. If the patient is hemodynamically unstable, synchronized DCC should be administered, using an initial energy level of 50 to 100 J; if the initial DCC attempt is unsuccessful, the shock energy should be increased in a stepwise fashion.[16] If the patient is hemodynamically stable, IV β-blockers, diltiazem or verapamil may be administered. β-Blockers are preferred if the patient has underlying HFrEF.

Prevention of Recurrence A decision strategy for prevention of recurrent PSVT is presented in Figure 10–8. If the patient's episodes of PSVT are asymptomatic or minimally symptomatic, long-term treatment may not be necessary. However, for patients with symptomatic episodes of PSVT, catheter ablation is a nonpharmacologic treatment option. During this procedure, a catheter is introduced transvenously and directed to the right atrium under fluoroscopic guidance. The catheter is advanced to the AV node and energy is delivered through the catheter to ablate, or destroy, the extranodal pathway of the reentrant circuit. This procedure usually achieves a complete cure of PSVT and obviates the need for long-term antiarrhythmic drug therapy. The complication rate associated with catheter ablation of PSVT is low (< 1%) and includes complete AV block (via inadvertent ablation of the AV node), perforation, pseudoaneurysm, bleeding at the site of catheter insertion in the groin, and pulmonary edema.

Despite the success rates with catheter ablation and the relatively low risk of complications, some patients prefer not to

Table 10–11

Drugs for Termination of Paroxysmal Supraventricular Tachycardia[8,36]

Drug	Mechanism of Action	Dose
Adenosine	Direct AV node inhibition	6 mg IV rapid push followed by rapid saline flush. If no response in 1–2 minutes, 12 mg IV rapid push followed by rapid saline flush. If no response in 1–2 minutes, administer second 12 mg IV rapid push, followed by rapid saline flush
Diltiazem	Direct AV node inhibition	0.25 mg/kg IV over 2 minutes, followed by continuous IV infusion of 5–10 mg/hour, up to 15 mg/hour
Verapamil	Direct AV node inhibition	5–10 mg (0.75–0.15 mg/kg) IV over 2 minutes If no response, administer an additional 10 mg (0.15 mg/kg) IV, then continuous infusion of 0.005 mg/kg/min
β-Blockers	Direct AV node inhibition	Esmolol 500 mcg/kg IV over 1 minute Then 50 mcg/kg/min continuous infusion. If inadequate response, give second loading dose of 500 mcg/kg and increase maintenance infusion to 100 mcg/kg/min. Increment 50 mcg/kg/min dose increases in this manner as necessary to maximum infusion rate of 300 mcg/kg/min Propranolol 1 mg IV over 1 minute; if necessary, repeat 1 mg IV doses at 2-minute intervals, up to 3 doses Metoprolol 2.5–5 mg IV over 2 minutes; if necessary, repeat 2.5–5 mg IV bolus in 10 minutes, up to 3 doses
Digoxin	Vagal stimulation, direct AV node inhibition	0.25–0.5 mg IV bolus; if necessary, repeat 0.25 mg IV bolus every 6–8 hours, to a maximum dose of 1 mg (8–12 mcg/kg) over 24 hours

undergo the procedure or are not suitable candidates. For these patients, drug therapy may be administered to prevent recurrence of PSVT or at least reduce the frequency of recurrent episodes. For patients with normal LV function, oral β-blockers, diltiazem, or verapamil are preferred. In patients for whom a trial of one or more of those drugs provides an unsatisfactory response, oral flecainide or propafenone may be administered; however, flecainide and propafenone are contraindicated in patients with a history of MI or any known underlying CAD, due to an increased risk of death associated with those drugs in that population. For patients with HFrEF, diltiazem, verapamil, flecainide, and propafenone are contraindicated due to negative inotropic effects and the potential to exacerbate HF. In this patient population, oral amiodarone, digoxin, dofetilide, or sotalol may be used.

▶ *Outcome Evaluation*

- Monitor for termination of PSVT and restoration of normal sinus rhythm.
- Monitor for adverse effects of adenosine or any other antiarrhythmic agents administered (Table 10–7).
- In patients taking drug therapy for long-term prevention of recurrence of PSVT, monitor for recurrence of and frequency of symptoms, as well as for adverse drug effects (Table 10–7).

VENTRICULAR ARRHYTHMIAS

Premature Ventricular Complexes

PVCs are ectopic electrical impulses originating in ventricular tissue, resulting in wide, misshapen, abnormal QRS complexes. PVCs have also been known by other terms, ventricular premature beats (VPBs), ventricular premature contractions (VPCs), and ventricular premature depolarizations (VPDs).

▶ *Epidemiology, Etiology, and Pathophysiology*

PVCs occur with variable frequency, depending on age, underlying comorbid conditions, and duration of rhythm monitoring.[37] In a population of healthy individuals, prevalence of PVCs was 0.8%.[6] In another study in which individuals without HF underwent ambulatory ECG monitoring (median duration 22 hours), 0.011% of all heartbeats were PVCs.[6] Prevalence of PVCs increases with age and is approximately 0.5% in individuals less than 20 years of age and 2.7% in people older than 50 years of age.[6,38] Older age, hypertension, concomitant heart disease, and smoking are all associated with increased PVC frequency.[37]

The mechanism(s) responsible for PVCs remains uncertain but are thought to be due to abnormal ventricular automaticity and/or reentry related to enhanced sympathetic nervous system activity and altered electrophysiological characteristics of the heart during myocardial ischemia and following MI.[37] Patients with a low PVC burden and no underlying heart disease are usually not at increased risk of life-threatening cardiovascular events.[37,38] Complex or frequent PVCs, especially in patients with CAD or LV dysfunction, are associated with increased mortality due to sudden cardiac death.[37,38]

▶ *Treatment*

Desired Outcomes Desired outcomes are to alleviate patient symptoms and reduce the risk of PVC-induced cardiomyopathy in patients with very frequent PVCs.

Pharmacologic Therapy **KEY CONCEPT** Asymptomatic PVCs should not be treated with antiarrhythmic drug therapy. Given that complex or frequent PVCs are associated with increased risk of sudden cardiac death in patients with a history of MI, the Cardiac Arrhythmia Suppression Trials (CAST and CAST II) tested the hypothesis that suppression of asymptomatic PVCs with the drugs flecainide, encainide, or moricizine in patients with a recent history of MI would decrease the incidence of sudden cardiac death.[39,40] However, results showed that not only did antiarrhythmic agents not reduce risk of sudden cardiac death, there was a significant *increase* in risk of death in patients who received therapy with encainide or flecainide compared to placebo.[39] During the continuation of the study with moricizine (CAST II), there was a significantly higher incidence of death in the moricizine group compared to the placebo group during the first 2 weeks of therapy.[40] Additional evidence suggests that other Vaughan Williams class I agents, including quinidine, procainamide, and disopyramide, also increase risk of death in patients with complex PVCs following MI.[37,38]

Clinical Presentation and Diagnosis of PVCs

- PVCs are usually categorized as simple or frequent/repetitive: simple PVCs occur as infrequent, isolated single abnormal beats; frequent/repetitive PVCs occur frequently (at least one PVC on a 12-lead ECG or ≥ 30 per hour) and/or in specific patterns. Very frequent PVCs are defined as greater than 10,000 to 20,000 per day
- Two consecutive PVCs are referred to as a couplet. The term *bigeminy* refers to a PVC occurring with every other beat; *trigeminy* means a PVC occurring with every third beat; *quadrigeminy* means a PVC occurring every fourth beat

Symptoms

- Most patients with simple or complex PVCs are asymptomatic. Occasionally, patients with complex or frequent PVCs may experience palpitations, lightheadedness, or dizziness. Patients with very frequent PVCs can develop reversible PVC-induced cardiomyopathy (a form of LV dysfunction associated with symptoms of HF)

KEY CONCEPT In patients with symptomatic PVCs with no structural heart disease, treatment with β-blockers or nondihydropyridine CCBs is recommended to reduce PVC frequency and improve symptoms.[38] If β-blockers or nondihydropyridine CCBs are ineffective or poorly tolerated, these patients can be treated with antiarrhythmic drugs (eg, flecainide, propafenone, sotalol, amiodarone) or catheter ablation.[37,38]

For patients with symptomatic PVCs and underlying structural heart disease, treatment with β-blockers is recommended.[37,38] β-blockers reduce mortality in this population and effectively suppress PVCs.[37,38] Patients with frequent symptomatic PVCs who do not respond adequately to β-blockers, nondihydropyridine CCBs, or antiarrhythmic drugs, or who do not tolerate those medications, can undergo catheter ablation. For patients with PVC-induced cardiomyopathy, drug therapy with β-blockers or amiodarone or catheter ablation are recommended to reduce PVC frequency and improve symptoms and LV function.

▶ *Outcome Evaluation*

- Monitor patients for PVC frequency and symptom relief.
- Monitor for adverse effects of β-blockers: bradycardia, hypotension, fatigue, masking symptoms of hypoglycemia, glucose intolerance (in diabetic patients), wheezing or shortness of breath (in patients with severe asthma or chronic obstructive pulmonary disease [COPD]).

  Venlafaxine

Ventricular Tachycardia

VT is a series of three or more consecutive PVCs at a rate greater than 100 beats/min. VT is defined as nonsustained if it lasts greater than or equal to 3 beats and terminates spontaneously; sustained VT lasts greater than 30 seconds or requires termination because of hemodynamic instability in less than 30 seconds.[5] VT is usually monomorphic, meaning each QRS complex displays the same shape, axis, and amplitude. VT may occasionally be polymorphic, with QRS complexes displaying various shapes, axes, and amplitudes.

▶ *Epidemiology, Etiology, and Pathophysiology*

Prevalence of monomorphic VT in the general population is unknown.[6] In populations at risk, the VT incidence is variable, depending on underlying etiologies and comorbidities. Etiologies of VT are presented in Table 10–12. VT is common in patients with ischemic heart disease, occurring in 5% to 10% of patients hospitalized for acute MI.[38] Nonsustained VT occurs in 20% to 80% of patients with HF.[41] Other VT etiologies include electrolyte abnormalities such as hypokalemia, hypoxia, and drugs. VT occurring in the absence of structural heart disease is referred to as “idiopathic” VT. Some patients with idiopathic VT have verapamil-sensitive VT, while others have outflow tract VT, indicating the VT originates in the outflow tract of the right or left ventricle.[38] VT is usually initiated by a precisely timed PVC, occurring during the relative refractory period, which provokes reentry within ventricular tissue. Sustained VT requires immediate intervention, because if untreated, the rhythm may cause sudden cardiac death via hemodynamic instability and absence of a pulse (pulseless VT) or via degeneration of VT into VF.

▶ *Treatment*

Desired Outcomes Desired outcomes are to terminate the arrhythmia, restore sinus rhythm, and prevent sudden cardiac death.

Pharmacologic Therapy Hemodynamically unstable VT should be terminated immediately using synchronized DCC.[38,42] In the event VT is present but the patient does not have a palpable pulse (and therefore no blood pressure), asynchronous defibrillation should be performed at 360 J for monophasic waveforms and starting at 120 to 200 J for biphasic waveforms.[42]

Drugs used to terminate hemodynamically stable VT are presented in Table 10–13.[38] A decision algorithm for management of hemodynamically stable VT is presented in Figure 10–9.[38] For patients with structural heart disease who develop VT, DCC is the preferred therapy as it is considered to be more effective than drug therapy. For patients in whom DCC is undesirable (eg, if

Table 10–13

Drugs for Termination of Ventricular Tachycardia[38]

Drug	Loading Dose	Maintenance Dose
Procainamide	20–50 mg/min continuous IV infusion until maximum dose of 10–17 mg/kg is reached	Continuous IV infusion 1–4 mg/min
Amiodarone	150 mg IV over 10 minutes	1 mg/min continuous infusion for 6 hours, then 0.5 mg/min for 18 hours
Sotalol	75 mg IV every 12 hours	—
Verapamil	2.5–5 mg/kg IV bolus every 15–30 minutes	
β-Blockers	Esmolol—see Table 10–6	See Table 10–6
	Metoprolol—see Table 10–6	See Table 10–6
	Propranolol—see Table 10–6	See Table 10–6

IV, intravenous.

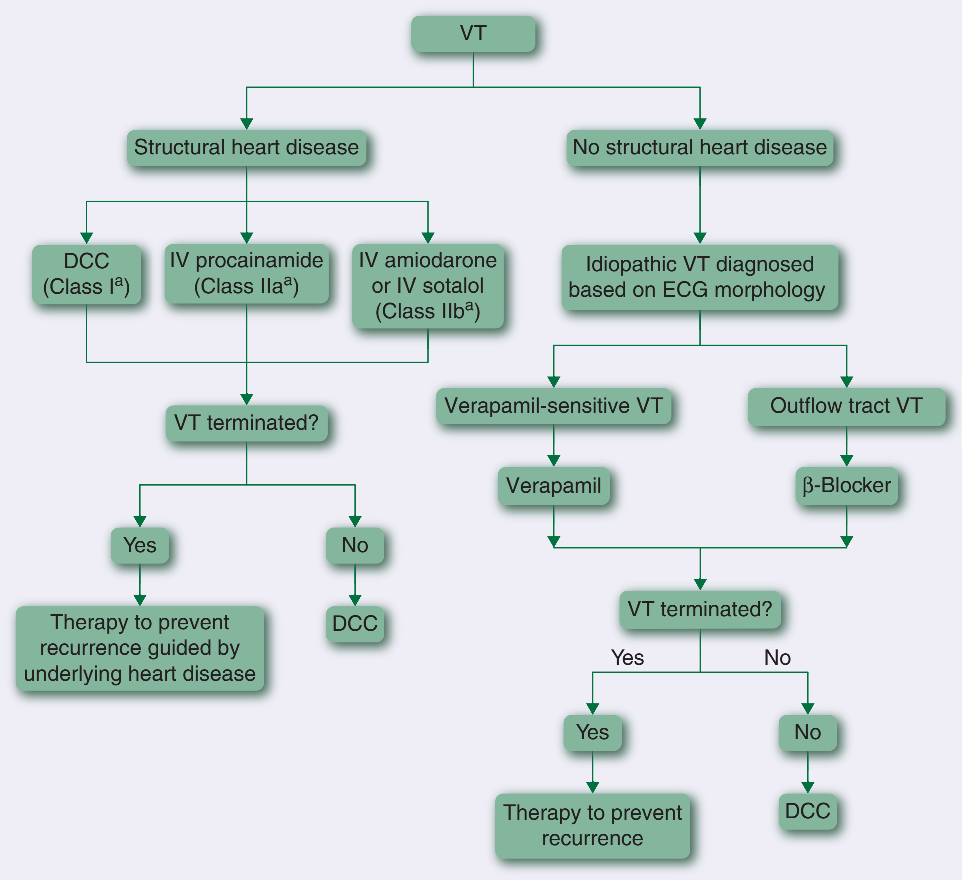
Clinical Presentation and Diagnosis of VT

Symptoms

- Symptoms depend primarily on heart rate and include palpitations, dizziness, light-headedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope
- Patients with nonsustained VT may be asymptomatic if the arrhythmia duration is sufficiently short. However, if the rate is rapid, patients with nonsustained VT may experience symptoms
- Patients with sustained VT are usually symptomatic, provided the rate is fast enough to provoke symptoms. Patients with rapid sustained VT may be hemodynamically unstable
- In some patients, sustained VT results in the absence of a pulse or may deteriorate to VF, resulting in sudden cardiac death

Diagnosis

- Diagnosis of VT requires ECG confirmation
- VT is characterized by wide, misshapen QRS complexes, with the rate varying from 140 to 250 beats/min
- In most patients with VT, shape and appearance of the QRS complexes are consistent and similar, referred to as monomorphic VT. However, some patients experience polymorphic VT, in which shape and appearance of the QRS complexes vary



VT
Structural heart disease
No structural heart disease

[a]Class I recommendations represent strong level of evidence; Class IIa recommendations represent moderate level of evidence; and Class IIb recommendations represent weak level of evidence. (DCC, direct current cardioversion; ECG, electrocardiogram; IV, intravenous; VT, ventricular tachycardia.)

patients have eaten a meal that day and cannot be safely sedated for DCC), IV procainamide is the drug of choice. IV amiodarone or sotalol are recommended for patients in whom VT is unresponsive to procainamide.[38]

For patients with idiopathic VT for which the arrhythmia is verapamil-sensitive, verapamil should be administered (Figure 10–9). For patients with outflow tract VT, IV β-blockers are preferred agents.[38]

Nonpharmacologic Therapy: Prevention of Sudden Cardiac Death KEY CONCEPT In patients who have experienced VT and are at risk for sudden cardiac death from recurrent ventricular arrhythmias, an implantable cardioverter-defibrillator (ICD) is the treatment of choice.[38] An ICD is a device that provides internal electrical cardioversion of VT or defibrillation of VF. The ICD does not prevent the patient from developing the arrhythmia, but it reduces the risk that the patient will die of sudden cardiac death as a result of the arrhythmia. Early versions of ICDs required a thoracotomy for implantation; now ICDs are implanted transvenously, similar to pacemakers, markedly reducing incidence of complications. ICDs are indicated for patients who are survivors of sudden cardiac death due to hemodynamically unstable VT or VF.[38]

Patients with ischemic heart disease and LVEF less than or equal to 30% to 35% (0.3–0.35) are at increased risk of sudden cardiac death. ICDs are significantly more effective than antiarrhythmic drugs such as amiodarone or sotalol for reducing risk of sudden cardiac death in these patients and therefore are preferred therapy.[38,43] In addition to the ICD, guideline-directed medical therapy (eg, β-blockers, angiotensin-converting enzyme [ACE] inhibitors/angiotensin receptor blockers/sacubitril/valsartan, and mineralocorticoid receptor antagonists) should also be optimized.[38] However, many patients with ICDs receive concurrent antiarrhythmic drug therapy to reduce the frequency with which patients experience the discomfort of shocks and to prolong battery life of the devices. Combined pharmacotherapy with amiodarone and a β-blocker is more effective than monotherapy with sotalol or β-blockers for reducing frequency of ICD shocks.[44]

▶ *Outcome Evaluation*

- Monitor patients for termination of VT and restoration of normal sinus rhythm.
- Monitor patients for adverse effects of antiarrhythmic drugs (see Table 10–7).

Ventricular Fibrillation

VF is irregular, disorganized, chaotic electrical activity in the ventricles resulting in the absence of ventricular depolarizations and, consequently, lack of pulse, cardiac output, and blood pressure.

▶ *Epidemiology and Etiology*

Annual incidence of out-of-hospital cardiac arrest in the United States is estimated to be 74 to 141 individuals per 100,000

Clinical Presentation and Diagnosis of VF

Symptoms

- VF results in immediate loss of pulse and blood pressure. Patients who are in the standing position at the onset of VF suddenly and immediately collapse to the ground

Diagnosis

- Absence of a pulse does not guarantee VF because pulse may also be absent in patients with asystole, VT, or pulseless electrical activity
- Confirmation of diagnosis with an ECG is necessary to determine appropriate treatment. ECG reveals no organized, recognizable QRS complexes. If treatment is not initiated within a few minutes, death will occur, or at best, resuscitation of the patient with permanent anoxic brain injury

population, or roughly 180,000 to 350,000 people.[6] Only 10% of patients treated for out-of-hospital cardiac arrest by emergency medical services (EMS) survive to hospital discharge.[6] Although some of these deaths are due to asystole, the majority occur as a result of primary VF or VT that degenerates into VF. Etiologies of VF are presented in Table 10–12 and are similar to those of VT.

▶ Treatment

Desired Outcomes Desired outcomes are to (a) terminate VF, (b) achieve return of spontaneous circulation, (c) achieve patient survival to hospital admission (in those with out-of-hospital cardiac arrest) and to hospital discharge, and (d) improve neurologic outcomes.

Pharmacologic and Nonpharmacologic Therapy VF is by definition hemodynamically unstable, due to the absence of a pulse and blood pressure. Initial management includes provision of basic life support, including calling for help and initiation of cardiopulmonary resuscitation (CPR).[42] Oxygen should be administered as soon as it is available. Most importantly, defibrillation should be performed as soon as possible. It is critically important to understand the only means of successfully terminating VF and restoring sinus rhythm is electrical defibrillation. Defibrillation should be attempted using 360 J for monophasic defibrillators, and 120 to 200 J for biphasic shocks, after which CPR should be resumed immediately while the defibrillator charges. If the first shock was unsuccessful, subsequent defibrillation attempts should be performed at equivalent or higher energy doses.[42]

If VF persists following two defibrillation shocks, drug therapy may be administered. KEY CONCEPT The purpose of drug administration for treatment of VF is to facilitate successful defibrillation. Drug therapy alone will not terminate VF. Drugs used for facilitation of defibrillation in patients with VF are presented in Table 10–14.[42] Drug administration should occur during CPR, before or after delivery of a defibrillation shock. The vasopressor agent epinephrine is administered initially because it has been shown that a critical factor in successful defibrillation is maintenance of coronary perfusion pressure, which is achieved via the vasoconstricting effects of this agent. A treatment algorithm for VF is presented in Figure 10–10. Although the vasopressor agent vasopressin can be considered in cardiac arrest, it offers no advantage over epinephrine and is not generally recommended.[42,45] Additionally, the combination of vasopressin and epinephrine offers no advantages over epinephrine alone.[42,45] Thus, epinephrine alone is the vasopressor of choice for use in cardiac arrest as it simplifies the cardiac arrest treatment algorithm.[42,45] Administration of amiodarone and lidocaine leads to improved survival to hospital admission in patients with pulseless VT or VF.[46] Note that amiodarone doses recommended for administration during a resuscitation attempt for VF (see Table 10–14) are different than those used for termination of VT (see Table 10–13).

Table 10–14

Drugs for Facilitation of Defibrillation in Patients With Ventricular Fibrillation[42,46]

Drug	Dose
Epinephrine	1 mg IV/IO every 3–5 minutes
Amiodarone	300 mg IV/IO. One subsequent dose of 150 mg IV/IO may be administered
Lidocaine	1–1.5 mg/kg IV/IO. One subsequent dose of 0.5–0.75 mg/kg may be administered

IO, Intraosseous; IV, intravenous.

▶ Outcome Evaluation

- Monitor the patient for return of pulse and blood pressure and for termination of VF and restoration of normal sinus rhythm.
- After successful resuscitation, monitor the patient for adverse effects of drugs administered (Table 10–7).

Torsades de Pointes

TdP is a specific polymorphic VT associated with prolongation of the QTc interval in the sinus beats that precede the arrhythmia.[1,47]

▶ Epidemiology and Etiology

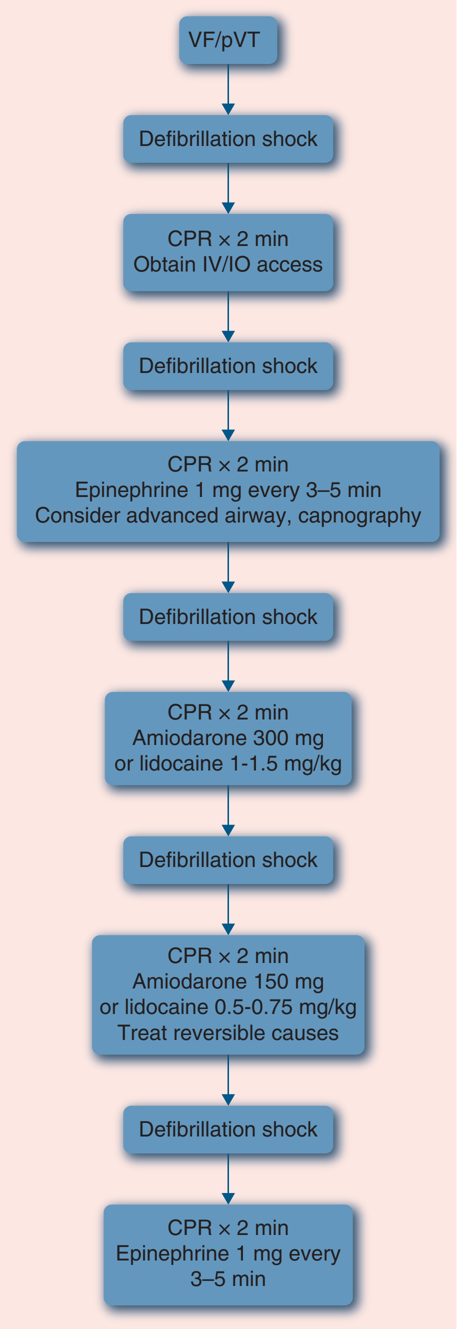
Incidence of TdP in the population at large is unknown although estimates suggest approximately 6% of patients develop QT prolongation when receiving drugs that lengthen the QT interval and roughly 0.3% experience TdP.[6] Incidence of TdP associated with specific drugs ranges from less than 1% to as high as 8% to 10%, depending on dose and plasma concentration of the drug and presence of other TdP risk factors.[47]

TdP may be inherited or acquired. Patients with specific genetic mutations in cardiac potassium channels may have an inherited long QT syndrome, in which the QTc interval is prolonged, and these patients are at risk for TdP.[1,47] Acquired TdP may be caused by numerous drugs (Table 10–15); the list of drugs known to cause TdP continues to expand.[47,48]

▶ Pathophysiology

TdP is caused by circumstances, often drugs, that lead to prolongation in the repolarization phase of the ventricular action potential (Figure 10–2) manifested on the ECG by prolongation of the QTc interval. A common feature of drugs causing QTc prolongation and TdP is blockade of the I_{Kr} (the rapid component of the delayed rectifier potassium current) potassium channel resulting in prolonged ventricular repolarization and QTc interval lengthening. Prolongation of ventricular repolarization promotes development of early ventricular afterdepolarizations during the relative refractory period, which may provoke reentry leading to TdP.[47]

KEY CONCEPT Drug-induced TdP rarely occurs in patients without specific risk factors for the arrhythmia (Table 10–16).[47,48] In most



VF/pVT
Defibrillation shock
CPR × 2 min
Obtain IV/IO access
Defibrillation shock
CPR × 2 min
Epinephrine 1 mg every 3–5 min
Consider advanced airway, capnography
Defibrillation shock
CPR × 2 min
Amiodarone 300 mg
or lidocaine 1-1.5 mg/kg
Defibrillation shock
CPR × 2 min
Amiodarone 150 mg
or lidocaine 0.5-0.75 mg/kg
Treat reversible causes
Defibrillation shock
CPR × 2 min
Epinephrine 1 mg every
3–5 min

FIGURE 10–10. Decision algorithm for resuscitation of VF or pulseless VT. (CPR, cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; pVT, pulseless ventricular tachycardia; VF, ventricular fibrillation.) (Data from Panchal AR, Berg KM, Kudenchuk PJ, et al. 2018 American Heart Association focused update on advanced cardiovascular life support use of antiarrhythmic drugs during and immediately after cardiac arrest: an update to the American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation. 2018;138:e740–e749.)

cases, administration of a drug known to cause TdP is unlikely to trigger the arrhythmia; however, likelihood of the arrhythmia increases in patients with concomitant risk factors. Clinical decision support systems are available to assist in identifying patients at risk for and reduce incidence of QTc prolongation.[49,50]

Table 10–15

Some Drugs[a] Known to Cause Torsades de Pointes[1,47,48]

Amiodarone (rare)
Arsenic trioxide
Azithromycin
Chloroquine/hydroxychloroquine
Chlorpromazine
Ciprofloxacin
Citalopram
Clarithromycin
Cocaine
Disopyramide
Dofetilide
Donepezil
Dronedarone
Droperidol
Erythromycin
Escitalopram
Flecainide
Fluconazole
Haloperidol
Ibutilide
Levofloxacin
Methadone
Moxifloxacin
Ondansetron
Oxaliplatin
Pentamidine
Pimozide
Procainamide
Propofol
Quinidine
Sevoflurane
Sotalol
Thioridazine
Vandetanib

[a] This table does not provide an exhaustive list of drugs that may increase the risk of torsades de pointes. For an exhaustive list, please consult reference 48.

Onset of TdP associated with oral drug therapy is somewhat variable and in some cases may be delayed; often, a patient can be taking a drug known to cause TdP for months or longer without problem until another risk factor for the arrhythmia becomes present, which then may trigger the arrhythmia.

In some patients, TdP may be of short duration and may terminate spontaneously. However, TdP may not terminate on its own, and if left untreated, may degenerate into VF and sudden cardiac death.[1,47] Several drugs, including terfenadine, astemizole, cisapride, and grepafloxacin, have been withdrawn from the US market as a result of causing deaths due to TdP.

Table 10–16

Risk Factors for Drug-Induced Torsades de Pointes (TdP)[1,47,48]

QTc interval > 500 ms
Increase in QTc interval by > 60 ms compared with the pretreatment value
Female sex
Age > 65 years
Heart failure
Electrolyte abnormalities: hypokalemia, hypomagnesemia, hypocalcemia
Bradycardia
Elevated plasma concentrations of QTc interval-prolonging drugs due to drug interactions or absence of dose adjustment for organ dysfunction
Rapid IV infusion of TdP-inducing drugs
Concomitant administration of more than one agent known to cause QTc interval prolongation/TdP
Concomitant administration of potassium-wasting diuretics (eg, loops or thiazides)
Genetic predisposition—congenital long QT syndrome
Sepsis
Previous history of drug-induced TdP
Vomiting/diarrhea leading to electrolyte disturbances

IV, intravenous; ms, milliseconds; QTc, corrected QT interval.

Clinical Presentation and Diagnosis of TdP

Symptoms

- Symptoms associated with TdP depend primarily on heart rate and arrhythmia duration and include palpitations, dizziness, light-headedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope
- TdP may be hemodynamically unstable if the rate is sufficiently rapid
- Like sustained monomorphic VT, TdP may result in the absence of a pulse or may rapidly degenerate into VF, resulting in sudden cardiac death

Diagnosis

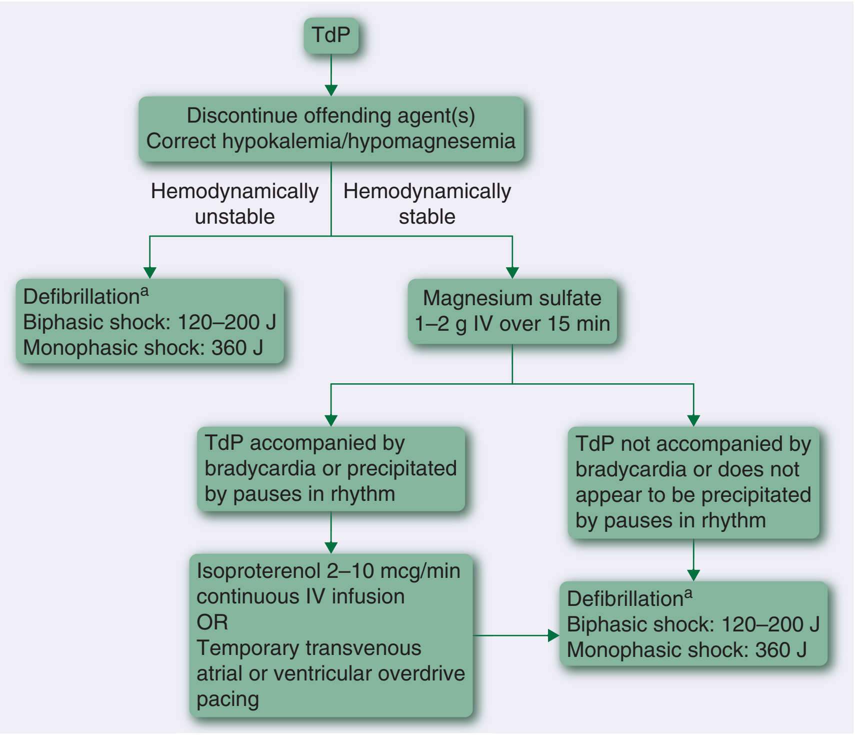
- Diagnosis of TdP requires examination of the arrhythmia on ECG
- TdP, or "twisting of the points," appears on ECG as apparent twisting of the wide QRS complexes around the isoelectric baseline
- Associated with heart rates from 140 to 280 beats/min
- Characteristic feature: a "long-short" initiating sequence that occurs as a result of a PVC followed by a compensatory pause followed by the first beat of the TdP
- Episodes of TdP may self-terminate, with frequent recurrence

▶ *Treatment*

Desired Outcomes Desired outcomes include (a) prevention of TdP, (b) termination of TdP, (c) prevention of recurrence, and (d) prevention of sudden cardiac death.

Pharmacologic and Nonpharmacologic Therapy KEY CONCEPT In patients with risk factors for TdP, drugs with the potential to cause QTc interval prolongation and TdP should be avoided or used with extreme caution, and diligent QTc interval monitoring performed. A decision algorithm for management of TdP is presented in Figure 10–11. Management of drug-induced TdP includes discontinuation of the potential causative agent. Patients with hemodynamically unstable TdP should undergo immediate defibrillation, rather than synchronized DCC, because polymorphic arrhythmias are usually not responsive to DCC. In patients with hemodynamically stable TdP, electrolyte abnormalities such as hypokalemia, hypomagnesemia, or hypocalcemia should be corrected. Hemodynamically stable TdP should be treated with IV magnesium sulfate, irrespective of whether the patient is hypomagnesemic; magnesium has been shown to terminate TdP in normomagnesemic patients.[38,42] Magnesium sulfate should be administered IV in doses of 1 to 2 g, diluted in 50 to 100 mL 5% dextrose in water (D_5W), administered over 15 minutes; doses may be repeated to a total of 6 g.[38] Alternatively, a continuous magnesium infusion (0.5–1 g/hour) may be initiated after the first bolus. In addition, electrolyte repletion with potassium to greater than or equal to 4 mEq/L (mmol/L) and magnesium to greater than or equal to 2 mEq/L (1 mmol/L) is recommended.[38]

For hemodynamically stable TdP that is unresponsive to IV magnesium sulfate and is accompanied by bradycardia or



TdP
Discontinue offending agent(s)
Correct hypokalemia/hypomagnesemia
Hemodynamically unstable
Hemodynamically stable
Defibrillation^a
Biphasic shock: 120–200 J
Monophasic shock: 360 J
Magnesium sulfate
1–2 g IV over 15 min
TdP accompanied by bradycardia or precipitated by pauses in rhythm
TdP not accompanied by bradycardia or does not appear to be precipitated by pauses in rhythm
Isoproterenol 2–10 mcg/min continuous IV infusion
OR
Temporary transvenous atrial or ventricular overdrive pacing
Defibrillation^a
Biphasic shock: 120–200 J
Monophasic shock: 360 J

FIGURE 10–11. Decision algorithm for management of torsades de pointes. [a]As polymorphic arrhythmias do not permit synchronization, defibrillation is recommended, rather than synchronized direct current cardioversion. Administer sedation when possible. Patient Care Process

Collect Information:

- Perform a thorough medication history to determine whether the patient is receiving prescription or nonprescription drugs that may cause or contribute to development of an arrhythmia. See Tables 10–2, 10–3, 10–4, 10–12, and 10–15.
- Determine the patient's serum electrolyte concentrations to determine presence of hypokalemia, hyperkalemia, hypomagnesemia, hypermagnesemia, or hypocalcemia.
- Consider heart rate, blood pressure, and symptoms to determine whether the patient is hemodynamically stable or unstable, and the degree to which symptoms are limiting function and quality of life.
- Review the patients' ECG(s) and/or ECG rhythm strips.

Assess the Information:

- Evaluate the patient for presence of drug-induced diseases, drug allergies, drug interactions, and impaired organ function that can alter drug clearance.
- For patients with preexisting arrhythmias, assess the current drug therapy regimen for efficacy, side effects, and adherence.
- In patients with AF receiving anticoagulation for stroke prevention, evaluate for appropriateness, adverse effects, drug–drug and drug–food interactions, and INR in patients receiving warfarin.
- Assess adherence to current drug therapy regimens.
- Assess the patient's 12-lead ECG or single rhythm strips to determine if an arrhythmia is present, and identify the specific arrhythmia, and evaluate and monitor symptoms.
- Assess information from the chest X-ray, transthoracic echocardiograms or TEEs, laboratory tests, and other physical examination and diagnostic information pertinent to arrhythmias.

Develop a Care Plan:

- Develop drug therapy treatment plans for management of the pertinent arrhythmia: sinus bradycardia, AV block, AF, PSVT, PVCs, VT (including TdP), or VF. See Figures 10–4 through 10–11 and Tables 10–6, 10–7, 10–8, 10–9, 10–10, 10–11, 10–13, and 10–14.

Implement the Care Plan:

- Educate the patient about drug therapy changes, medication administration, potential new adverse effects, and how to manage adverse effects.
- Address patient concerns about arrhythmias and their management.
- Discuss importance of medication adherence and risk factor modification for management of arrhythmias.
- Determine whether the patient has prescription coverage and/or whether recommended agents are included on the institution's formulary.

Follow-up: Monitor and Evaluate:

- Develop specific drug therapy monitoring plans, including assessment of symptoms, ECG, adverse effects of drugs, and potential drug interactions.
- Monitor QTc interval in patients receiving QTc interval-prolonging drugs.
- Provide information regarding safe and effective oral anticoagulation:
    - Notify clinicians in the event of severe bruising, blood in urine or stool, **melena**, **hemoptysis**, **hematemesis**, or frequent **epistaxis**.
    - Patients taking warfarin should avoid radical changes in diet.
    - Avoid alcohol.
    - Do not take nonprescription medications or herbal/alternative/complementary medicines without notifying physician, pharmacist, and/or healthcare team members.
- Provide patient education regarding disease state and drug therapy.

triggered by pauses in rhythm, isoproterenol administered via continuous IV infusion 2 to 10 mcg/min may be administered, or temporary transvenous atrial or ventricular pacing may be employed to increase the heart rate.[38]

▶ *Outcome Evaluation*

- Monitor vital signs (heart rate and blood pressure).
- Monitor the ECG to determine the QTc interval (maintain < 470 ms in males and 480 ms in females) and for the presence of TdP.[1]
- Monitor serum potassium, magnesium, and calcium concentrations. Maintain serum potassium concentrations *greater than or equal to* 4 mEq/L (mmol/L) and magnesium *greater than or equal to* 2 mEq/L (1 mmol/L).
- Monitor for symptoms of tachycardia.
- Monitor for other patient-specific risk factors for QTc prolongation and TdP (eg, drug interactions, impaired organ function).

Abbreviations Introduced in This Chapter

1°	First-degree
2°	Second-degree
3°	Third-degree
ACE	Angiotensin-converting enzyme
ADHF	Acute decompensated heart failure
AF	Atrial fibrillation
aPTT	Activated partial thromboplastin time
ATPase	Adenosine triphosphatase
AV	Atrioventricular
Ca	Calcium
CAD	Coronary artery disease
CAST	Cardiac Arrhythmia Suppression Trial
CCB	Calcium channel blocker
CKD	Chronic kidney disease
COPD	Chronic obstructive pulmonary disease
CPR	Cardiopulmonary resuscitation
CrCl	Creatinine clearance

CYP	Cytochrome P450
DCC	Direct current cardioversion
DOAC	Direct oral anticoagulant
D_5W	5% Dextrose in water
ECG	Electrocardiogram
ED	Emergency department
EMS	Emergency medical services
FDA	Food and Drug Administration
GI	Gastrointestinal
HF	Heart failure
HFrEF	Heart failure with reduced ejection fraction
ICD	Implantable cardioverter-defibrillator
INR	International normalized ratio
IO	Intraosseous
IV	Intravenous
J	Joule
K	Potassium
LV	Left ventricle/ventricular
LVEF	Left ventricular ejection fraction
MI	Myocardial infarction
ms	Milliseconds
Na	Sodium
NYHA	New York Heart Association
P-gp	P-glycoprotein
PAD	Peripheral arterial disease
PSVT	Paroxysmal supraventricular tachycardia
PVC	Premature ventricular complex
QTc	Corrected QT interval
SA	Sinoatrial
TdP	Torsades de pointes
TEE	Transesophageal echocardiogram
TIA	Transient ischemic attack
VF	Ventricular fibrillation
VPB	Ventricular premature beat
VPC	Ventricular premature contraction
VPD	Ventricular premature depolarization
VT	Ventricular tachycardia

Venous Thromboembolism

James C. Lee, Bryan Zobeck, and Edith A. Nutescu

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors and signs and symptoms of deep vein thrombosis (DVT) and pulmonary embolism (PE).
2. Describe the processes of hemostasis and thrombosis.
3. Determine a patient's risk of developing venous thrombosis.
4. Formulate an appropriate prevention strategy for a patient at risk for DVT.
5. Select and interpret laboratory test(s) to monitor antithrombotic medications for safety and efficacy.
6. Identify factors that place a patient at high risk of bleeding while receiving antithrombotic medications.
7. State at least two potential advantages of newer anticoagulants (ie, low-molecular-weight heparins [LMWHs], fondaparinux, oral direct thrombin inhibitors [DTIs], and oral direct factor Xa inhibitors) over traditional anticoagulants (ie, unfractionated heparin and warfarin).
8. Manage a patient with toxicity secondary to an anticoagulant with or without bleeding.
9. Identify relevant factors such as drug–drug and drug–food interactions to optimize anticoagulant medication selection.
10. Formulate an appropriate treatment plan, including duration and monitoring, for a patient who develops a DVT or PE.

INTRODUCTION

Venous thromboembolism (VTE) is one of the most common cardiovascular disorders in the United States. VTE is manifested as deep vein thrombosis (DVT; ie, thrombus causing obstruction of a deep vein in the leg, pelvis, or abdomen) and pulmonary embolism (PE; ie, thrombus causing obstruction of a pulmonary artery or one of its branches and resulting in pulmonary infarction) (Figure 11–1).[1,2] A thrombus is a blood clot attached to the vessel wall composed of platelets, fibrin, and clotting factors that may partially or completely occlude the lumen of a blood vessel and compromise blood flow and oxygen delivery to distal tissue. It is often provoked by prolonged immobility or vascular injury and most frequently seen in patients hospitalized for a serious medical illness, trauma, or major surgery. VTE can also occur with little or no provocation in patients who have an underlying hypercoagulable disorder.

Although VTE may initially cause few or no symptoms, the first overt manifestation of the disease may be sudden death from PE which can occur within minutes, before effective treatment can be given.[2,3] A history of VTE is a significant risk factor for recurrent thromboembolic events.[4-7] Postthrombotic syndrome (PTS) is a complication of VTE that occurs due to damage to the vein caused by a blood clot and leads to development of symptomatic venous insufficiency such as chronic lower extremity swelling, pain, tenderness, skin discoloration, and ulceration.[2]

The treatment of VTE is fraught with substantial risks.[8] KEY CONCEPT Antithrombotic therapies (thrombolytics and anticoagulants) require precise dosing and meticulous monitoring, as well as ongoing patient assessment and education.[4,9,10] Well-organized anticoagulation management services improve quality of care and reduce overall cost. A systematic approach to drug therapy management reduces risks, but bleeding remains a common and serious complication.[10,11] Therefore, preventing VTE is paramount to improving outcomes. When VTE is suspected, a rapid and accurate diagnosis is critical to making appropriate treatment decisions. The optimal use of antithrombotic drugs requires not only an in-depth knowledge of their pharmacology and pharmacokinetic properties but also a comprehensive approach to patient management.[3,12]

EPIDEMIOLOGY AND ETIOLOGY

The true incidence of VTE in the general population is unknown because many patients, perhaps more than 50%, have no overt symptoms or go undiagnosed.[1,12,13] An estimated 2 million people in the United States develop VTE each year, of whom 600,000 are hospitalized and 60,000 die. The estimated annual direct medical costs of managing the disease are well over $1 billion. The incidence of VTE nearly doubles in each decade of life older than 50 years of age and is slightly higher in men. As the population ages, the total number of DVT and PE cases continues to rise.[1,2,13,14]

KEY CONCEPT The risk of VTE is related to several factors including age, history of VTE, major surgery (particularly orthopedic procedures of the lower extremities), trauma, malignancy, pregnancy, estrogen use, and hypercoagulable states (Table 11–1).[5-7] VTE risk factors can be categorized into one of the three elements of Virchow triad: stasis in blood flow, vascular endothelial injury,

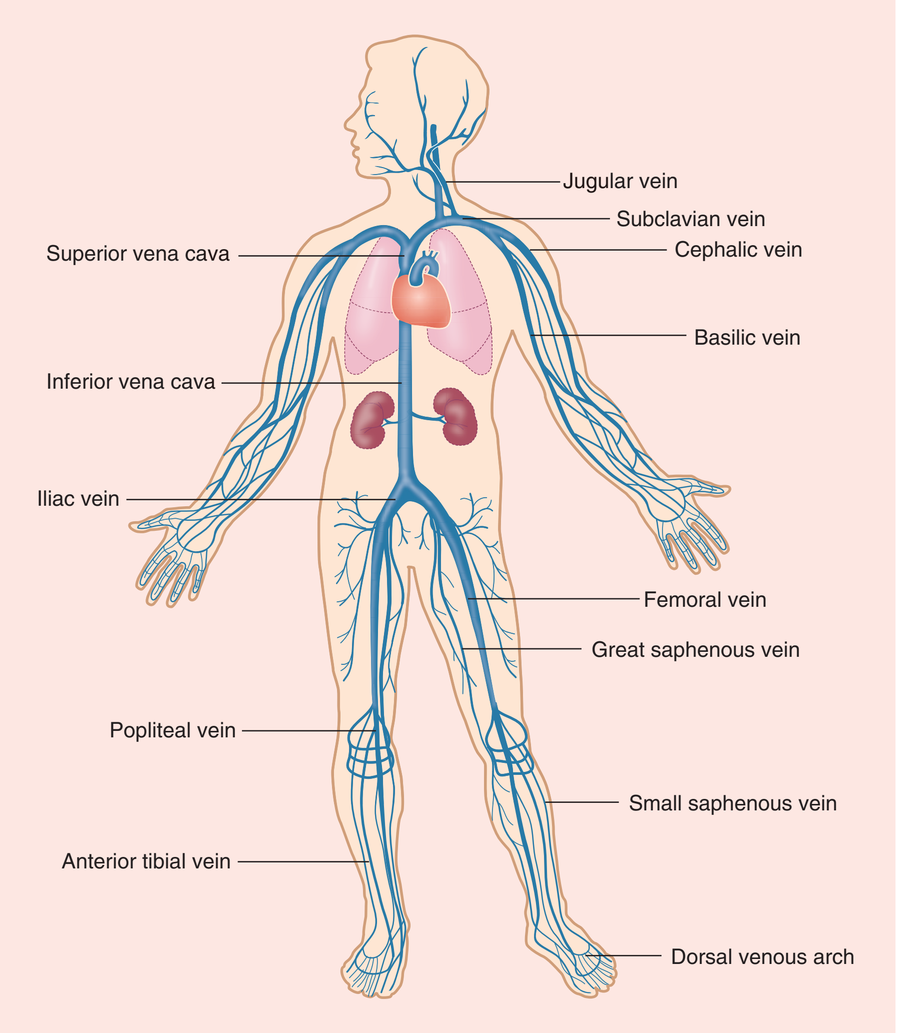

FIGURE 11–1. Venous circulation. (From Witt DM, Clark NP, Vazquez SR. Venous thromboembolism. In: DiPiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill. Available from: https://accesspharmacy.mhmedical.com/content.aspx?bookid=2577&sectionid=219316417. Accessed July 15, 2020.)

and inherited or acquired changes in blood constituents resulting in hypercoagulable states.[15-17] These risk factors are additive, and some can be easily identified in clinical practice.[1,3] A prior history of venous thrombosis (in which blood changes from a liquid to a solid state and produces a blood clot) is perhaps the strongest risk factor for recurrent VTE, presumably because of damage to venous valves and obstruction of blood flow caused by the initial event.[5-7] Rapid blood flow (as in arteries) has an inhibitory effect on thrombus formation, but a slow rate of blood flow (as in veins) reduces the clearance of activated clotting factors in the zone of injury and slows the influx of regulatory substances. Stasis tips the delicate balance of procoagulation and anticoagulation in favor of thrombogenesis. The rate of blood flow in the venous circulation, particularly in the deep veins of the lower extremities, is relatively slow. Valves in the deep veins of the legs, as well as contraction of the calf and thigh muscles, facilitate the flow of blood back to the heart and lungs. Damage to the venous valves and periods of prolonged immobility result in venous stasis. Vessel obstruction, either from a thrombus or external compression, promotes clot propagation. Numerous medical conditions and surgical procedures are associated with reduced venous blood flow and increase the risk of VTE. Greater than normal blood viscosity, seen in myeloproliferative disorders like polycythemia vera, may also contribute to slowed blood flow and thrombus formation.[5-7,16,17]

While a normal endothelium is antithrombotic, damage to the endothelium creates a substrate for platelet binding and activation that ultimately leads to clot formation. Major surgery, trauma, and indwelling central catheters can cause endothelial damage. Smoking and hypertension can also lead to endothelial dysfunction by shifting the balance between clot formation and clot breakdown toward thrombosis.[5-7,16,17]

A growing list of hereditary deficiencies, gene mutations, and acquired diseases has been linked to hypercoagulability (Table 11–1).[18,19] Some patients may have multiple genetic defects. Hereditary deficiencies include activated protein C resistance also known as factor V Leiden, the prothrombin G20210A gene mutation, deficiencies of the natural anticoagulants protein C, protein S, and antithrombin (AT), and high concentrations of factors VIII, IX, and XI. Acquired disorders of hypercoagulability include malignancy, antiphospholipid antibodies, obesity, estrogen use, and pregnancy.[20,21] Estrogen-containing contraceptives, estrogen replacement therapy, and many of the selective estrogen receptor modulators (SERMs) increase the risk of venous thrombosis.[20,22] Although the mechanisms are not clearly understood, estrogens increase serum clotting factor concentrations and induce

Table 11–1

Risk Factors for Venous Thromboembolism (VTE)

Risk Factor	Considerations and Examples
Age	Risk doubles with each decade after age 50
History of VTE	Strongest known risk factor
Venous stasis	Major medical illness (eg, heart failure, acute myocardial infarction, ischemic stroke, acute infection)
	Major surgery (eg, general anesthesia for > 30 minutes)
	Paralysis (eg, due to stroke or spinal cord injury)
	Polycythemia vera
	Obesity
	Varicose veins
	Immobility (eg, bed rest for ≥ 3 days during hospital admission)
Vascular injury	Major orthopedic surgery (eg, knee and hip replacement)
	Trauma (especially fractures of the pelvis, hip, or leg)
	Indwelling venous catheters
Hypercoagulable states	Malignancy, diagnosed or occult
	Activated protein C resistance/factor V Leiden
	Prothrombin G20210A gene mutation
	Protein C deficiency
	Protein S deficiency
	Antithrombin deficiency
	Factor VIII excess (> 90th percentile)
	Factor XI excess (> 90th percentile)
	Antiphospholipid antibodies
	Dysfibrinogenemia
	Plasminogen activator inhibitor-1 (PAI-1) excess
	Pregnancy/postpartum
Drug therapy	Estrogen-containing oral contraceptive pills
	Estrogen replacement therapy
	Selective estrogen receptor modulators (SERMs)
	Heparin
	Chemotherapy

activated protein C resistance. Increased serum estrogen concentrations may explain, in part, the increased risk of VTE during pregnancy and the postpartum period.[22]

PATHOPHYSIOLOGY

Hemostasis, the arrest of bleeding following vascular injury, is essential to life.[23] Within the vascular system, blood remains in a fluid state, transporting oxygen, nutrients, plasma proteins, and waste. When a vessel is injured, a dynamic interplay between thrombogenic (activating) and antithrombotic (inhibiting) forces results in the local formation of a hemostatic plug that seals the vessel wall and prevents further blood loss (Figures 11–2 and 11–3). A disruption of this delicate system of checks and balances may lead to inappropriate clot formation within the blood vessel that can obstruct blood flow or embolize to a distant vascular bed.

Under normal circumstances, endothelial cells lining the inside of blood vessels maintain blood flow by producing a number of substances that inhibit platelet adherence, prevent activation of the coagulation cascade, and facilitate fibrinolysis.[16,17,23] Vascular injury exposes the subendothelium. Platelets adhere to the subendothelium with their glycoprotein (GP) Ib surface receptors and facilitated by von Willebrand factor (vWF). This causes platelets to become activated, releasing a number of procoagulant substances that stimulate circulating platelets to expose GP IIb and IIIa surface receptors subsequently allowing platelets to adhere to one another, resulting in platelet aggregation (Figure 11–2). The damaged vascular tissue releases tissue factor that activates the extrinsic pathway of the coagulation cascade (Figure 11–3).[23]

The clotting cascade is a stepwise series of enzymatic reactions that results in the formation of a fibrin mesh.[12] Clotting factors circulate in the blood in inactive forms. Once a precursor is activated by specific stimuli, it activates the next clotting factor in the sequence. The final steps in the cascade are the conversion of prothrombin (factor II) to thrombin (factor IIa) and fibrinogen to fibrin. Thrombin plays a key role in the coagulation cascade; it is responsible not only for the activation of fibrin but also for the activation of factors V and VIII, creating a positive feedback loop that greatly accelerates the entire cascade. Thrombin also enhances platelet aggregation.

Traditionally, the coagulation cascade has been divided into three distinct parts: the intrinsic, the extrinsic, and the common pathways. This artificial division is misleading because there are numerous interactions between the three pathways.[16,17,23] A number of tempering mechanisms modulate coagulation (Figure 11–2).[23,24] Without effective self-regulation, the coagulation cascade would proceed unabated until all clotting factors and platelets are consumed.

CLINICAL PRESENTATION AND DIAGNOSIS

Although a thrombus can form in any part of the venous circulation, most begin in the lower extremities. Once formed, a venous thrombus may (a) remain asymptomatic, (b) spontaneously lyse, (c) obstruct the venous circulation, (d) propagate into more proximal veins, (e) embolize, and/or (f) slowly incorporate into the endothelial layer of the vessel.[1,3,16] Most patients with VTE never develop symptoms.[3,25] However, even those who initially experience no symptoms may suffer long-term consequences, such as PTS and recurrent VTE.

Given that VTE can be debilitating or fatal, it is important to treat it quickly and aggressively.[1,2,12] However, because major bleeding induced by antithrombotic drugs can be equally harmful, it is also important to avoid treatment when the diagnosis is not reasonably certain. Assessment should focus on patient-specific risk factors during the medical history (Table 11–1).[1,2,12] Venous thrombosis is uncommon in the absence of risk factors, and the effects of these risk factors are additive. If a patient has multiple risk factors, VTE should be strongly suspected even when the symptoms are very subtle.

KEY CONCEPT The symptoms of DVT or PE are nonspecific, and it is extremely difficult to distinguish VTE from other disorders on clinical symptoms alone.[1-3,25] Therefore, objective tests are required to confirm or rule out the diagnosis. Patients with DVT frequently present with unilateral leg pain on the affected leg, swelling that can persist after a night's sleep, and cyanosis of the skin in the affected leg (Table 11–2). Similarly, PTS, a long-term complication of DVT caused by damage to the venous valves, produces chronic lower extremity swelling, pain, and tenderness that lead to skin discoloration and ulceration. To distinguish acute DVT from PTS and other possible diagnoses, a clinical prediction rule that incorporates signs, symptoms, and risk factors can be used to categorize the patient as at low, intermediate, or high probability of having acute DVT. This model, known as the Wells criteria, is summarized in Table 11–2.[2,3,12] If the clinical probability of DVT is low, the D-dimer test can be used to confirm the

FIGURE 11–2. Hemostasis and thrombosis. (From Witt DM, Clark NP, Vazquez SR. Venous thromboembolism. In: DiPiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill. Available from: https://accesspharmacy.mhmedical.com/content.aspx?bookid=2577&sectionid=21931641. Accessed July 15, 2020.)

patient does not have DVT. The D-dimer test is a quantitative measure of fibrin breakdown in the serum and a marker of acute thrombotic activity. D-dimer assays are sensitive but not specific markers for VTE, so a negative D-dimer test can be used to rule out the diagnosis of DVT.

If the D-dimer test is positive in a low-probability patient, or if the patient has a moderate or high probability of DVT, then an objective radiographic test is used to confirm the diagnosis of DVT. Contrast venography allows visualization of the entire venous system in the lower extremities. This radiographic contrast study is the most accurate and reliable method for diagnosis of DVT and considered the gold standard in clinical trials.[3,25,26] However, venography is an expensive, invasive procedure that is technically difficult to perform and evaluate. Severely ill patients may be unable to tolerate the procedure, and many develop hypotension and cardiac arrhythmias. Furthermore, the contrast material is irritating to vessel walls and toxic to the kidneys. For these reasons, noninvasive testing using duplex ultrasonography is preferred.

Like DVT, the nonspecific nature of the signs and symptoms of PE requires further evaluation. Table 11–3 describes the Wells criteria, a validated prediction model that can be used to stratify patients into high, moderate, and low probability of PE.[3,25-27] In patients with a low clinical probability of PE, diagnosis of PE can be ruled out if D-dimer testing is negative. If D-dimer testing is positive, or if the patient has a moderate or high clinical probability of PE, diagnostic imaging studies should be performed. Pulmonary angiography allows visualization of the pulmonary arteries and is the gold standard for diagnosing PE but is an extremely invasive procedure. Diagnosis of VTE can be made if there is a persistent intraluminal filling defect observed on multiple X-ray films. However, as with DVT, a noninvasive test is preferred, such as computed tomographic pulmonary angiography, magnetic resonance imaging (MRI), and ventilation/perfusion (V/Q) scans.

PREVENTION

Given that VTE is often clinically silent and potentially fatal, prevention strategies have the greatest potential to improve patient outcomes.[5-7] The goal of an effective VTE prophylaxis program is to identify all patients at risk, determine each patient's level of risk, and select and implement regimens that provide sufficient protection for the level of risk.[5-7] **KEY CONCEPT** At the time of hospital admission, transition of care, and prior to discharge, all patients should be evaluated for risk of VTE, and appropriate prophylaxis strategies should be routinely used. Prophylaxis should be continued throughout the period of risk.

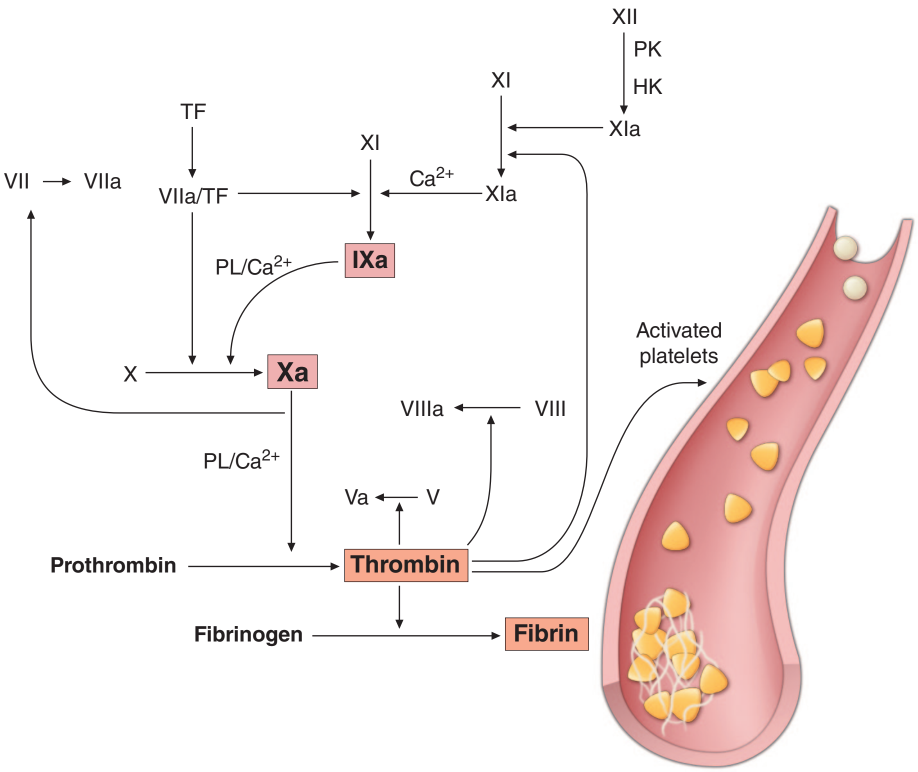

FIGURE 11–3. Summary of coagulation pathways. Specific coagulation factors ("a" indicates activated form) are responsible for the conversion of soluble plasma fibrinogen into insoluble fibrin. This process occurs via a series of linked reactions in which the enzymatically active product subsequently converts the downstream inactive protein into an active serine protease. The activation of thrombin leads to additional stimulation of platelets. (Ca^{2+}, calcium; HK, high-molecular-weight kininogen; PK, prekallikrein; PL, phospholipid surface; TF, tissue factor.) (From Freedman JE, Loscalzo J. Arterial and venous thrombosis. In: Longo DL, Fauci AS, Kasper DL, et al., eds. Harrison's Principles of Internal Medicine, 20th ed. New York, NY: McGraw-Hill; 2018.)

Table 11–2

Clinical Model/Modified Wells Criteria for Evaluating the Pretest Probability of Deep Vein Thrombosis (DVT)

Clinical Characteristic	Score
Active cancer (cancer treatment within previous 6 months or currently on palliative treatment)	+1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	+1
Recently bedridden for 3 days or more, or major surgery within the previous 12 weeks requiring general or regional anesthesia	+1
Localized tenderness along the distribution of the deep venous system	+1
Entire leg swollen	+1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below tibial tuberosity)	+1
Pitting edema confined to the symptomatic leg	+1
Collateral superficial veins (nonvaricose)	+1
Previously documented DVT	+1
Alternative diagnosis at least as likely as DVT	–2

Assess the patient for the presence of any of the 9 clinical characteristics listed above
Assign a score of "+1" for each characteristic that is present.
Tally the total score.
If an alternative diagnosis is at least as likely as DVT, then subtract 2 points from the total points tallied above.
In patients with symptoms in both legs, the more symptomatic leg is used.

Risk Score Interpretation

Total Risk Score	Clinical Probability of DVT
0	Low
1	Moderate
2	Moderate
3 or higher	High

Clinical Presentation and Diagnosis of DVT

General

Most commonly develops in patients with identifiable risk factors (Table 11–1) during or following a hospitalization. Many patients have asymptomatic disease.

Symptoms

Patient may complain of persistent unilateral leg swelling, pain, warmth, and/or skin discoloration. Symptoms are nonspecific, and objective testing must be performed to establish the diagnosis.

Signs

- Superficial veins may be dilated, and a "**palpable cord**" may be felt in the affected leg.
- May experience unilateral leg edema with measurable difference in leg circumference compared to the unaffected leg, erythema, increase in warmth, and tenderness with palpation of calf muscles.
- May experience pain in the popliteal or calf region in the affected leg when the examiner dorsiflexes the foot while the knee is flexed/slightly bent (Homans sign).
- Note: Physical examination signs can be unreliable. Homans sign can also be unreliable.

Clinical Probability

Apply the Wells criteria to determine the probability that the patient's signs, symptoms, and risk factors are the result of DVT (Table 11–2).

Laboratory Tests

- Initial laboratory evaluation should include complete blood count (CBC) with differential, coagulation studies (such as **prothrombin time** [PT]/**international normalized ratio** [INR], activated partial thromboplastin time [aPTT]), serum chemistries with renal and liver function, and urinalysis.
- Serum concentrations of D-dimer, a by-product of thrombin generation, will be elevated in an acute event. A negative D-dimer in a patient with low clinical probability of DVT can be used to rule out DVT.
- Patient may have an elevated erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count.

Diagnostic Tests

- Duplex ultrasonography is the most commonly used test to diagnose DVT. It is a noninvasive test that can measure the rate and direction of blood flow and visualize clot formation in proximal veins of the legs. It cannot reliably detect small blood clots in distal veins. Coupled with a careful clinical assessment, it can confirm or rule out (exclude) the diagnosis in most cases. Repeat testing may be necessary if the first test is negative and the patient is still symptomatic.
- Venography (also known as phlebography) is the gold standard for diagnosis of DVT. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

There are several risk assessment models available for estimating VTE risk specific to hospitalized medical and surgical patients.[5-7,12] While none of these models have been extensively validated, the Padua prediction score is recommended for assessment of medical patients (Table 11–4), and the Caprini score is recommended for assessment of general surgical patients (Table 11–5). Bleeding risk should also be assessed to help identify patients in whom the risk of bleeding may outweigh benefits of pharmacologic prophylaxis.[5-7] Table 11–6 lists general and

Table 11–3

Clinical Model/Wells Criteria for Evaluating the Pretest Probability of Pulmonary Embolism (PE)

Clinical Characteristic	Score
Cancer	+1
Hemoptysis	+1
Previous PE or DVT	+1.5
Heart rate > 100 beats/min	+1.5
Recent surgery or immobilization	+1.5
Clinical signs of DVT	+3
Alternative diagnosis less likely than PE	+3

Risk Score Interpretation

Total Risk Score	Clinical Probability of PE
0–1	Low
2–6	Moderate
7 or higher	High

DVT, deep vein thrombosis.

Table 11–4

Risk Factors for Predicting Venous Thromboembolism (VTE) in Hospitalized Medical Patients (Padua Prediction Score)

Risk Factor	Points
Active cancer[a]	3
Previous VTE (with the exclusion of superficial vein thrombosis)	3
Reduced mobility[b]	3
Already known thrombophilic condition[c]	3
Recent (≤ 1 month) trauma and/or surgery	2
Elderly age (≥ 70 years)	1
Heart and/or respiratory failure	1
Acute myocardial infarction or ischemic stroke	1
Acute infection and/or rheumatologic disorder	1
Obesity (body mass index ≥ 30)	1
Ongoing hormonal treatment	1
Cumulative score of ≥ 4 points indicates high risk of VTE	

[a] Patients with local or distant metastases and/or in whom chemotherapy or radiotherapy had been performed in the previous 6 months.

[b] Anticipated bed rest with bathroom privileges (either because of patient's limitations or on physician's order) for at least 3 days.

[c] Carriage of defects of antithrombin, protein C or S, factor V Leiden, G20210A prothrombin mutation, antiphospholipid syndrome.

Adapted with permission from Kahn SR, Lim W, Dunn AS, et al. Prevention of VTE in nonsurgical patients: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest. 2012;141(2 suppl):e195S–e226S.

Clinical Presentation and Diagnosis of PE

General

Most commonly develops in patients with risk factors for VTE (Table 11–1) during or following a hospitalization. Although many patients will have symptoms of DVT prior to developing a PE, many will not, and some patients can be asymptomatic. Patients may die suddenly before effective treatment can be initiated.

Symptoms

- May complain of cough, pleuritic chest pain, chest tightness, shortness of breath with or without exertion, wheezing, orthopnea, or palpitations.
- May present with hemoptysis (spit or cough up blood).
- May complain of dizziness or experience syncope.
- May be misdiagnosed as a myocardial infarction (MI) or pneumonia, and objective testing must be performed to establish the diagnosis.

Signs

- May have tachypnea (increased respiratory rate) and tachycardia (increased heart rate).
- May appear diaphoretic (sweaty) and may have fever.
- Neck veins (external jugular veins) may be distended reflecting increased jugular venous pressure and increased heart pressure.
- The examiner may see use of accessory respiratory muscles and may hear diminished breath sounds, crackles, wheezes, or pleural friction rub during auscultation of the lungs. A parasternal lift or right ventricular S_3, S_4 may be found on the heart examination.
- In massive PE, the patient may appear cyanotic and hypotensive and may appear to have signs of right-sided heart failure. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate the patient is hypoxic.
- In the worst cases, the patient may go into circulatory shock and die within minutes.

Clinical Probability

Apply the Wells criteria to determine the probability that the patient's signs, symptoms, and risk factors are the result of PE (Table 11–3).

Laboratory Tests

- Serum concentrations of D-dimer, a by-product of thrombin generation, will be elevated. A negative D-dimer in a patient with low clinical probability of PE can be used to rule out PE.
- In patients with a low probability for PE, the PE rule-out criterion ("PERC rule") is an alternative to D-dimer testing. In patients who meet all following eight criteria, the likelihood of PE is low, and no further testing is required: age less than 50 years; heart rate less than 100 beats/min; oxyhemoglobin saturation at or above 95% (0.95); no hemoptysis; no estrogen use; no prior DVT or PE; no unilateral leg swelling; and no surgery/trauma requiring hospitalization within the prior 4 weeks.
- May have an elevated ESR and WBC count.
- May have elevated serum lactate dehydrogenase (LDH) or aspartate aminotransferase (AST; serum glutamic-oxaloacetic transaminase [SGOT]) with normal bilirubin.
- Serum troponin I, troponin T, and B-type natriuretic peptide can be elevated in a large PE. These typically resolve within 40 hours if due to PE but persist longer after acute MI.
- Electrocardiogram may show nonspecific ST-segment and T-wave changes and tachycardia. Arterial blood gases may show acute respiratory alkalosis from hyperventilation.

Diagnostic Imaging Tests

- A computed tomography (CT) pulmonary angiography with radiocontrast is the most commonly used test to diagnose PE, but some institutions still use a V/Q scan. Spiral (or helical) CT scans can detect emboli in the proximal pulmonary arteries. A V/Q scan measures the distribution of blood and air flow in the lungs. When there is a large mismatch between blood and air flow in one area of the lung, there is a high probability the patient has a PE.
- Pulmonary angiography is the gold standard for diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with significant risk of mortality.

procedure-specific risk factors for major bleeding complications. Patients with moderate to high risk of VTE should receive pharmacologic prophylaxis. If pharmacologic prophylaxis is contraindicated, such as in patients actively bleeding or at high risk of bleeding, nonpharmacologic prophylaxis should be used (Table 11–7).

Several pharmacologic and nonpharmacologic methods are effective for preventing VTE, and these can be used alone or in combination (Table 11–7).[5-7] Nonpharmacologic methods improve venous blood flow by mechanical means; drug therapy prevents thrombus formation by inhibiting the coagulation cascade.

Nonpharmacologic Therapy

Ambulation as soon as possible following surgery lowers the incidence of VTE in low-risk patients.[5-7] Walking increases venous blood flow and promotes the flow of natural antithrombotic factors into the lower extremities. All hospitalized patients should be encouraged to ambulate as early as possible, and as frequently as possible.

Graduated compression stockings (GCS) are specialized hosiery that provide graduated pressure on the lower legs and feet to help prevent thrombosis. Compared with anticoagulant drugs, GCS are relatively inexpensive and safe; however, they are less effective and not recommended in moderate-to-higher-risk patients.[2] They offer an alternate in low-to moderate-risk patients when pharmacologic interventions are contraindicated. When combined with pharmacologic interventions, GCS have an additive effect. However, some patients are unable to wear compression stockings because of the size or shape of their legs, and some patients may find them hot, confining, and very difficult to put on and remove.

Table 11–5

Risk Factors for Predicting Venous Thromboembolism (VTE) in General Surgical Patients (Modified Caprini Risk Assessment Model for VTE in General Surgical Patients)

Risk Score

1 Point	2 Points	3 Points	5 Points
Age 41–60 years Minor surgery BMI > 25 kg/m^2 Swollen legs Varicose veins Pregnancy or postpartum History of unexplained or recurrent spontaneous abortion Oral contraceptives or hormone replacement Sepsis (< 1 month) Serious lung disease, including pneumonia (< 1 month) Abnormal pulmonary function Acute myocardial infarction Heart failure (< 1 month) History of inflammatory bowel disease Medical patient at bed rest	Age 61–74 years Arthroscopic surgery Major open surgery (> 45 minutes) Laparoscopic surgery (> 45 minutes) Malignancy Confined to bed (> 72 hours) Immobilizing plaster cast Central venous access	Age ≥ 75 years History of VTE Family history of VTE Factor V Leiden Prothrombin G20210A Lupus anticoagulant Anticardiolipin antibodies Elevated serum homocysteine Heparin-induced thrombocytopenia Other congenital or acquired thrombophilia	Stroke (< 1 month) Elective arthroplasty Acute spinal cord injury (< 1 month)

Risk Score Interpretation

Total Risk Score	Risk of VTE
0	Very low (< 0.5%)
1–2	Low (1.5%)
3–4	Moderate (3%)
≥ 5	High (6%)

Table 11–7

Thrombosis Risk Classification and Recommended Venous Thromboembolism Prevention Strategies[5-7]

Indication and Level of Risk	Prevention Strategies
Hospitalized Medical Patients	
Low thrombosis risk	Early ambulation
High thrombosis risk[a] (Padua score > 4)	LMWH, LDUH, fondaparinux, betrixaban
Critically Ill Patients	
High thrombosis risk[a]	LMWH, LDUH
General Surgical Patients	
Very low thrombosis risk (Caprini Score 0)	Early ambulation
Low thrombosis risk (Caprini Score 1–2)	IPC
Moderate thrombosis risk[b] (Caprini Score 3–4)	LMWH, LDUH, IPC
High thrombosis risk[b] (Caprini Score ≥ 5)	LMWH, LDUH, plus GCS or IPC
Cancer Surgery	LMWH, rivaroxaban, apixaban
Major Orthopedic Surgery	
Hip fracture surgery[b]	LMWH, fondaparinux, LDUH, adjusted dose warfarin, aspirin
Hip and knee arthroplasty[b]	LMWH, fondaparinux, LDUH, warfarin, aspirin, apixaban, dabigatran, rivaroxaban

[a] Mechanical methods of prophylaxis with IPC or GCS should be used in patients actively bleeding or those at high risk of bleeding complications (see **Table 11–6** for risk factors for major bleeding).

[b] Mechanical methods of prophylaxis with IPC should be used in patients actively bleeding or those at high risk of bleeding complications (see **Table 11–6** for risk factors for major bleeding).

GCS, graduated compression stockings; IPC, intermittent pneumatic compression; LDUH, low-dose unfractionated heparin; LMWH, low-molecular-weight heparin.

Similar to GCS, intermittent pneumatic compression (IPC) devices increase the velocity of blood flow in the lower extremities.[5-7] These devices sequentially inflate a series of cuffs wrapped around the patient's legs from the ankles to the thighs and then deflate in 1- to 2-minute cycles. Although IPC has been shown to reduce the risk of VTE in surgical patients, most studies failed to define the type of device used. IPC was frequently used in combination with other prophylaxis methods, making it difficult to quantify their efficacy. Although IPC is safe to use in patients who have contraindications to pharmacologic therapies, it does have a few drawbacks: it is more expensive than GCS; it is a relatively cumbersome technique; some patients may have difficulty sleeping while using it, and some patients find the devices hot and uncomfortable. To be effective, IPC needs to be used throughout the day. In practice, this is difficult to achieve, and special efforts should be made to ensure the devices are worn and operational for most of the day.

Inferior vena cava (IVC) filters, also known as Greenfield filters, provide short-term protection against PE in very high-risk patients by preventing the embolization of a thrombus formed in the lower extremities into the pulmonary circulation.[5-7] Insertion of a filter into the IVC is a minimally invasive procedure. Despite the widespread use of IVC filters, there are very limited data regarding their effectiveness and long-term safety. The evidence suggests that IVC filters, particularly in the absence of effective antithrombotic therapy, are thrombogenic themselves and increase the long-term risk of recurrent DVT and of filter thrombosis. Although IVC filters can reduce the short-term risk of PE in patients at highest risk, they should be reserved for patients in whom other prophylactic strategies cannot be used. To further reduce the long-term risk of VTE in association with IVC filters, pharmacologic prophylaxis is necessary in patients with IVC filters in place, and warfarin therapy should begin as soon as the patient is able to tolerate it.[2] If used, retrievable filters are preferred, which can be removed once pharmacologic prophylaxis can be safely administered or once the patient is no longer at risk for VTE.

Pharmacologic Therapy

Appropriately selected drug therapies can dramatically reduce the incidence of VTE in medical and surgical patients (Table 11–7). Choice of medication and dose to use for VTE prevention must be based on the patient's level of risk for thrombosis and bleeding risk, as well as the cost and availability of an adequate drug therapy monitoring system.[5-7]

The most extensively studied drugs for the prevention of VTE are unfractionated heparin (UFH), the low-molecular-weight heparins (LMWHs; dalteparin and enoxaparin), fondaparinux, and warfarin.[5-7] Generally, the LMWHs provide improved protection against VTE when compared with low-dose UFH in most medical and surgical patients and when compared to low-dose UFH and warfarin in major orthopedic surgery patients. Fondaparinux is more effective than LMWH in patients undergoing high-risk orthopedic surgery, but it has a heightened risk of bleeding.

For hospitalized general surgical and medical patients, the available evidence supports the use of UFH 5000 units subcutaneously (SC) every 8 to 12 hours, enoxaparin 40 mg SC daily, dalteparin 2500 to 5000 units SC daily, or fondaparinux 2.5 mg SC daily. Betrixaban is also approved for extended VTE prophylaxis in hospitalized adult patients with acute medical illnesses and was found noninferior to prophylactic-dose enoxaparin with no differences in major bleeding. Betrixaban is given as an initial 160-mg dose followed by 80 mg daily, with the dose halved in the setting of severe renal impairment (creatinine clearance [CrCl] 15–30 mL/min [0.25–0.5 mL/s]) or concomitant use of P-glycoprotein (P-gp) inhibitors.[28]

For the prevention of VTE following major orthopedic surgery, current evidence supports the use of UFH, LMWH, fondaparinux, adjusted dose warfarin, aspirin, and the direct oral anticoagulants (DOACs; apixaban, dabigatran, edoxaban, and rivaroxaban). The role of aspirin for VTE prevention is controversial as it produces a very modest reduction in VTE following orthopedic surgeries of the lower extremities.[5]

The effectiveness of UFH, aspirin, and warfarin is lower than LMWH, and long-term safety data are lacking for apixaban, dabigatran, and rivaroxaban; thus the American College of Chest Physicians (ACCP) guidelines recommend the use of LMWH or fondaparinux preferentially over other pharmacologic options in major orthopedic surgery patients.[5] The appropriate prophylactic dose for each LMWH product in orthopedic surgery is indication specific; however, enoxaparin 30 mg SC twice daily or 40 mg SC daily, and dalteparin 5000 units SC daily are the most commonly used regimens. The dose of fondaparinux is 2.5 mg SC daily.

The dose of warfarin, another commonly used option for prevention of VTE following orthopedic surgery, must be adjusted to maintain an INR between 2 and 3.[5] Oral administration and low drug acquisition cost give warfarin some advantages over the LMWHs and fondaparinux. However, warfarin does not achieve its full antithrombotic effect for several days and requires frequent monitoring and periodic dosage adjustments, making therapy cumbersome. Warfarin should only be used when a systematic patient monitoring system is available.

The oral factor Xa inhibitors rivaroxaban and apixaban are also options for VTE prevention following hip and knee replacement surgery and in high-risk cancer patients and offer a convenient alternative to traditional anticoagulants.[5,29-31] Both agents have shown superior efficacy compared to LMWH with a similar rate of bleeding complications in orthopedic surgery patients. Rivaroxaban is given at a fixed dose of 10 mg once daily, and apixaban is given at a fixed dose of 2.5 mg twice daily. Both are given without the need for routine laboratory monitoring and dosing adjustments (as with warfarin) and without the inconvenience of administration by injection (as with LMWH and fondaparinux).

The oral direct thrombin inhibitor (DTI) dabigatran is another option for VTE prevention following orthopedic surgery but is only approved for use following hip replacement surgery. Dabigatran is given as an initial 110-mg dose, followed by 220 mg once daily. Dabigatran should not be used in those with CrCl less than 30 mL/min (0.50 mL/s) or concomitantly with P-gp inhibitors.

Optimal duration for VTE prophylaxis is not well established but should be given throughout the period of risk. For patients who have undergone total knee replacement, total hip replacement, or hip fracture repair, prophylaxis is recommended for a minimum of 10 to 14 days; however, extending it up to 35 days is recommended due to continued VTE risk up to 1 month postsurgery.[5-7]

Patient Encounter 1

A 32-year-old woman (BMI 23 kg/m^2) with a recent history of 3-day hospitalization due to traumatic injuries sustained from a motor vehicle crash is readmitted to the hospital with increasing left leg pain and redness, fever, and fatigue. She is diagnosed with osteomyelitis and started on antibiotic therapy.

PMH: Left leg type II fracture status post reduction and immobilization.

FH: Father died at 55 years due to PE; mother died at 63 years due to breast cancer; sister with history of DVT at 37 years.

SH: Occasional alcohol use. Employed in county government. Lives at home with spouse and pets.

Home Meds: Norethindrone/ethinyl estradiol 0.5 m/0.035 mg daily, hydrocodone-acetaminophen 10 mg/325 mg every 4 hours as needed, ibuprofen 600 mg twice daily as needed.

Allergies: amoxicillin (anaphylaxis)

VS: BP 135/70 mm Hg, HR 72 beats/min, RR 16 breaths/min, T 38.7°C (101.7°F), Wt 67 kg (147 lb).

Labs: WBC 22.4 × 10^3/mm^3 (22.4 × 10^9/L); estimated glomerular filtration rate (eGFR) 80 mL/min/1.73 m^2; CrCl 78 mL/min (1.30 mL/s).

Hospital Treatment: cefazolin 2 g IV every 7 hours, hydrocodone-acetaminophen 10/325 mg PO every 4 to 6 hours as needed, ibuprofen 400 mg PO every 4 to 6 hours as needed.

Which risk factor(s) predispose this patient to VTE?

What is her estimated risk for developing VTE?

Given her presentation and history, create an appropriate VTE prophylaxis plan including the pharmacologic agent, dose, route and frequency of administration, duration of therapy, and monitoring parameters.

TREATMENT

Desired Therapeutic Outcomes

The goal of VTE treatment is to prevent short- and long-term complications of the disease. The aim of initial therapy is to prevent propagation or local extension of the clot, embolization, hemodynamic collapse, and death. The goal of long-term and extended therapy is to prevent complications such as PTS, pulmonary hypertension, and recurrent VTE.[2,12]

General Treatment Principles

Anticoagulant drugs are considered the mainstay of therapy for patients with VTE, and the therapeutic strategies for DVT and PE are similar.[2,12] Management decisions are guided by balancing the risks and benefits of various treatment options. Treatment of VTE can be divided into three phases: acute (first 5–10 days), long term (first 3 months), and extended (beyond 3 months).[12] The acute treatment phase of VTE is typically accomplished by administering a fast-acting parenteral anticoagulant or a DOAC (Table 11–8). The long-term and extended phase treatments of VTE are usually accomplished using oral anticoagulant agents such as warfarin, or one of the DOACs.[2,12] In certain populations, such as patients with cancer and women who are pregnant, the LMWHs are the preferred agents during long-term and extended treatment phases due to better safety or efficacy.[2,31] The etiology of VTE will guide the duration of therapy. VTE can be provoked (by transient or persistent risk factors), unprovoked (or idiopathic), and cancer associated. Patients with unprovoked or cancer-associated VTE have a significantly higher risk of recurrence compared to patients with provoked VTE.[2,12,31]

KEY CONCEPT In the absence of contraindications, treatment of VTE should initially include a rapidly acting DOAC (eg, apixaban, rivaroxaban, edoxaban) or a rapid-acting injectable anticoagulant (eg, UFH, LMWH, fondaparinux). If warfarin is used for oral anticoagulation, it should be initiated on the same day as the parenteral anticoagulant, and the parenteral agent should be overlapped for a minimum of 5 days and until the INR is greater than or equal to 2 for at least 24 to 48 hours. If dabigatran or edoxaban is used for oral anticoagulation, they should be initiated after 5 to 10 days of initial treatment with a parenteral

Table 11–8

Pharmacologic Options for the Acute Phase Treatment of Venous Thromboembolism (VTE)

Parenteral Anticoagulants

UFH

IV administration:[a] use weight-based dosing nomogram (**Table 11–10**)

Or

SC administration: 17,500 units (250 units/kg) given every 12 hours (an initial 5000-unit IV bolus dose is recommended to obtain rapid anticoagulation)

Adjust subsequent doses to attain a goal aPTT based on the institution-specific therapeutic range

Or

SC administration: 333 units/kg followed by 250 units/kg given every 12 hours (fixed-dose unmonitored dosing regimen)

LMWHs

Dalteparin: 200 units/kg SC once daily *or* 100 units/kg SC twice daily

Enoxaparin: 1.5 mg/kg SC once daily *or* 1 mg/kg SC twice daily; if CrCl < 30 mL/min (0.50 mL/s): 1 mg/kg SC once daily

Factor Xa Inhibitor

Fondaparinux[b]:

For body weight ≤ 50 kg (110 lb), use 5 mg SC once daily
For body weight 50–100 kg (110–220 lb), use 7.5 mg SC once daily
For body weight ≥ 100 kg (220 lb), use 10 mg SC once daily

Direct Oral Anticoagulants (DOACs)

Apixaban: 10 mg PO twice daily for the initial 7 days, then 5 mg PO twice daily[c]

Dabigatran: 150 mg PO twice daily after 5–10 days of parenteral anticoagulation[d]

Edoxaban: 60 mg PO once daily or 30 mg[e] PO once daily after 5–10 days of parenteral anticoagulation

Rivaroxaban: 15 mg PO twice daily for the initial 21 days, then 20 mg PO daily[d,f]

[a] IV administration preferred due to improved dosing precision.

[b] Contraindicated in patients with CrCl < 30 mL/min (0.50 mL/s).

[c] After the initial 6 months of therapy, the dose is reduced to 2.5 mg PO twice daily.

[d] Avoid in patients with CrCl < 30 mL/min (0.50 mL/s).

[e] Reduced dose for CrCl 15–50 mL/min (0.25–0.83 mL/s), body weight ≤ 60 kg (132 lb), or concomitant use of P-glycoprotein inhibitors.

[f] In cancer patients, rivaroxaban and edoxaban are the only DOACs recommended for VTE treatment. Rivaroxaban is recommended for both initial and long-term treatment. Edoxaban is recommended only for long-term treatment.

aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; IV, intravenous; LMWHs, low-molecular-weight heparins; SC, subcutaneous; UFH, unfractionated heparin.

anticoagulant. Anticoagulation therapy should be continued for a minimum of 3 months. However, duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.[2,12]

Pharmacologic Therapy

▸ *Thrombolytics*

The role of thrombolysis in the treatment of VTE is controversial.[2,12,32] Compared with anticoagulants, thrombolytics restore venous patency more quickly; however, the bleeding risk associated with their use is significantly higher. In patients with DVT, thrombolytics decrease short-term pain and swelling and prevent destruction of the venous valves. While they may decrease the incidence and severity of PTS, clinical trials have failed to show reduction in recurrent DVT, PE, or death[32]; therefore, their use in most patients is not recommended.[2,12] In a select group of high-risk patients with massive iliofemoral DVT who are at risk of venous gangrene and limb loss, thrombolysis may be considered. See Table 11–9.

In patients with acute PE, use of thrombolytics provides short-term benefits such as restoring pulmonary artery patency and hemodynamic stability.[2,12,32] However, systemic thrombolysis does not reduce mortality and is associated with a greater risk of major bleeding.[12] Given the relative lack of data to support their routine use, thrombolytics should be reserved for select high-risk circumstances. Candidates for thrombolytic therapy are patients with acute massive embolism who are hemodynamically

Table 11–9

Thrombolysis for the Treatment of Venous Thromboembolism

- Thrombolytic therapy should be reserved for patients who present with PE with shock, hypotension, or massive DVT with limb gangrene
- Diagnosis must be objectively confirmed before initiating thrombolytic therapy
- Thrombolytic therapy is most effective when administered as soon as possible after PE diagnosis, but benefit may extend up to 14 days after symptom onset

FDA-Approved PE Thrombolytic Regimens

- Streptokinase 250,000 units IV bolus over 30 minutes followed by 100,000 units/hour for 12–24 hours[a]
- Urokinase 4400 units/kg IV bolus over 10 minutes followed by 4400 units/kg/hour for 12–24 hours[a]
- Alteplase (rt-PA) 100 mg IV over 2 hours

Non–FDA-Approved Thrombolytic Regimens

- Reteplase two 10-unit IV boluses given 30 minutes apart
- Tenecteplase weight-adjusted IV bolus over 5 seconds (30–50 mg with a 5-mg step every 10 kg from < 60 to > 90 kg)

- Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (ie, recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke, or intracranial hemorrhage)
- Baseline laboratories should include CBC and blood typing in case transfusion is needed
- IV UFH should not be used during IV thrombolytic therapy. Neither the aPTT nor any other anticoagulation parameter should be monitored during the thrombolytic infusion
- aPTT should be measured following the completion of thrombolytic therapy:
  - If aPTT < 2.5 times the control value, UFH infusion should be started and adjusted to maintain aPTT in therapeutic range
  - If aPTT > 2.5 times the control value, remeasure every 2–4 hours and start UFH infusion when aPTT is < 2.5
- Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

[a] Two-hour infusions of streptokinase and urokinase are as effective and safe as alteplase; 2-hour infusion times are preferred over longer infusion times.

aPTT, activated partial thromboplastin time; CBC, complete blood count; DVT, deep vein thrombosis; FDA, Food and Drug Administration; IV, intravenous; PE, pulmonary embolism; rt-PA, recombinant tissue plasminogen activator; UFH, unfractionated heparin.

Patient Encounter 2

A 62-year-old woman with a new diagnosis of ovarian cancer is admitted to the hospital for debulking surgery.

PMH: Depression × 19 years; obesity × 25 years, ulcerative colitis × 35 years, history of hip fracture 8 years ago with subsequent lower left extremity DVT, treated with LMWH and warfarin for 3 months.

FH: Mother died at 72 years due to ovarian cancer; brother 55 years old with type 2 diabetes; maternal grandmother died at 65 years due to breast cancer.

SH: Smoked half a pack per day for 25 years, quit 15 years ago; occasional alcohol use. Lives alone and expects to be discharged to a rehabilitation facility postoperatively before returning home.

Home Meds: Sertraline 100 mg by mouth daily; oxycodone 5–10 mg by mouth every 5 hours as needed for pain; St. John's wort 2 capsules daily.

Allergies: NKDA

VS: BP 110/60 mm Hg, HR 55 beats/min, RR 18 breaths/min, T 37.0°C (98.6°F), Wt 127 kg (280 lb), BMI 41 kg/m^2.

Labs: Hemoglobin, hematocrit, platelets, and liver function tests (LFTs) within normal limits; eGFR 96 mL/min/1.73 m^2; CrCl 94 mL/min (1.57 mL/s).

Which risk factor(s) predispose this patient to VTE?

How should postoperative VTE be prevented?

How long should she receive VTE prophylaxis?

What education about VTE prophylaxis should she receive?

unstable (systolic blood pressure [SBP] < 90 mm Hg) and at low risk for bleeding. Current guidelines recommend a short infusion time (2 hours) over a prolonged infusion time (24 hours) and administration through a peripheral vein over a pulmonary artery catheter.[2,12]

▶ *Unfractionated Heparin*

UFH has traditionally been the drug of choice for indications requiring rapid anticoagulation including the acute treatment of VTE. Unlike thrombolytics, UFH and other anticoagulants will not dissolve a formed clot but prevent its propagation and growth.[2,9] Heparin exerts its anticoagulant effect by augmenting the natural anticoagulant, AT. See Figure 11–4.

UFH can be administered via the intravenous (IV) or subcutaneous (SC) route.[2,9] See Table 11–8. When rapid anticoagulation is required, UFH should be administered IV, and an initial bolus dose should be given. For the treatment of VTE, UFH is generally given as a continuous IV infusion. The half-life of UFH is dose dependent and ranges from 30 to 90 minutes but may be significantly longer, up to 150 minutes, with high doses. UFH is eliminated by two mechanisms: (a) enzymatic degradation via a saturable zero-order process, and (b) renally via a first-order process. Lower UFH doses are primarily cleared via enzymatic processes, whereas higher doses are primarily renally eliminated. Clearance of UFH can be impaired in patients with renal and hepatic dysfunction. Patients with active thrombosis may require higher UFH doses due to a more rapid elimination or variations in the plasma concentrations of heparin-binding proteins.

Certain patient-specific situations may require UFH higher doses to achieve a therapeutic anticoagulant effect. AT deficiency and elevated factor VIII levels are common in pregnant patients. AT deficiency has been linked to higher UFH dose requirements. The requirement of these higher UFH doses is termed *heparin resistance*. Factor VIII elevations can result in altered activated partial thromboplastin time (aPTT) response to UFH, and monitoring with antifactor Xa levels is recommended.[2,9,10]

The dose of UFH required to achieve a therapeutic anticoagulant response is correlated to the patient's weight.[2,9] Weight-based dosing regimens should be used to exceed the therapeutic threshold in the first 24 hours after initiating treatment.[9,10] Achieving a therapeutic aPTT in the first 24 hours after initiating UFH is critical because it has been shown to lower the risk of recurrent VTE. For nonobese patients, the actual body weight should be used to calculate the initial UFH dose (Table 11–10). For obese patients, using the actual body weight to calculate the initial dose is also generally recommended; however, data are limited in morbidly obese patients, that is, weight more than 150 kg (330 lb). Some experts recommend using an adjusted body weight (ABW) in these patients instead. The infusion rate is then adjusted based on laboratory monitoring of the patient's response.[9,10] (See Table 11–10.)

KEY CONCEPT Due to significant interpatient variability and changes in patient response over time, UFH requires close monitoring and periodic dose adjustment. The response to UFH can be monitored using a variety of laboratory tests including the aPTT, whole blood clotting time, activated clotting time (ACT), antifactor Xa activity, and plasma heparin concentration.[9,10] Although it has several limitations, the aPTT is the most widely used test in clinical practice to monitor UFH. Traditionally, therapeutic aPTT range is defined as 1.5 to 2.5 times the control aPTT value. However, due to variations in reagents and instruments used to measure the aPTT in different laboratories, each institution should establish a therapeutic range for UFH. The institution-specific therapy range should correlate with a plasma heparin concentration of 0.2 to 0.4 units/mL (kU/L) by protamine titration or 0.3 to 0.7 units/mL (kU/L) by an amidolytic antifactor Xa assay.[4,27] An aPTT should be obtained at baseline, 6 hours after initiating the heparin infusion, and 6 hours after each dose change because this is the time required to reach steady state. UFH dose is then adjusted based on the aPTT measurement and institutional-specific therapeutic range (Table 11–10). In patients with heparin resistance, antifactor Xa concentrations may be a more accurate method of monitoring the patient's response.[9,10]

Side effects associated with UFH include bleeding, thrombocytopenia, hypersensitivity reactions, and with prolonged use, alopecia, hyperkalemia, and osteoporosis.[9,10] **KEY CONCEPT** Bleeding is the most common adverse effect associated with antithrombotic drugs including UFH therapy.[8] A patient's risk of major hemorrhage is related to the intensity and stability of therapy, age, concurrent drug use, history of gastrointestinal bleeding, risk of falls or trauma, and recent surgery. Several risk factors can increase the risk of UFH-induced bleeding (Table 11–11). The risk of bleeding is related to intensity of anticoagulation. Higher aPTT values are associated with an increased risk of bleeding. The risk of major bleeding is 1% to 5% during the first few days of treatment.[2,9,10] In addition to the aPTT, hemoglobin, hematocrit, and blood pressure should be monitored. Concurrent use of UFH with other antithrombotic agents, such as thrombolytics and antiplatelet agents, also increases bleeding risk. Patients receiving UFH therapy should be closely monitored for signs and symptoms of bleeding, including epistaxis, hemoptysis, hematuria, hematemesis, **hematochezia**, **melena**, severe headache, and joint pain. If major bleeding occurs, UFH should be stopped immediately and the source of bleeding treated.[9,10] If necessary, use protamine

FIGURE 11–4. Mechanism of action of unfractionated heparin, low-molecular-weight heparin (LMWH), and fondaparinux. (From Witt DM, Clark NP. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill; 2014:266.)

sulfate as an antidote to reverse the effects of UFH. The usual dose is 1 mg protamine sulfate per 100 units of UFH, up to a maximum of 50 mg, given as a slow IV infusion over 10 minutes. The effects of UFH are neutralized in 5 minutes, and the effects of protamine persist for 2 hours. If bleeding is not controlled or the anticoagulant effect rebounds, repeated doses of protamine may be administered.[9,10]

Heparin-induced thrombocytopenia (HIT) is a very serious adverse effect associated with UFH use. Platelet counts should be monitored at baseline and every 2 to 3 days throughout the course of UFH therapy.[9,10] HIT should be suspected if the platelet count drops by more than 50% from baseline or to below 150 × $10^3/\text{mm}^3$ (150 × 10^9/L). HIT should also be suspected if thrombosis occurs despite UFH use. Immediate discontinuation of all heparin-containing products including the use of LMWHs and heparin-based flushes is required. Alternative anticoagulation with parenteral DTIs should be initiated. In patients with contraindications to anticoagulation therapy, UFH should not be administered (Table 11–12).

UFH may be used to treat VTE during pregnancy. UFH should be used with caution in the peripartum period due to risk of maternal hemorrhage. UFH is not secreted into breast milk and is safe for use by women who wish to breast-feed.[2,9,10,20] For treatment of VTE in children, the UFH dose is 50 units/kg bolus followed by an infusion of 20,000 units/m^2 per 24 hours. Alternatively, a loading dose of 75 units/kg followed by an infusion of 28 units/kg/hour if younger than 12 months and 20 units/kg/hour if older than 1 year may be considered.[33]

▶ *Low-Molecular-Weight Heparins*

Compared with UFH, LMWHs have improved pharmacodynamic and pharmacokinetic properties.[9,10,12] They exhibit less binding to plasma and cellular proteins, resulting in a more predictable anticoagulant response. Consequently, routine monitoring of anticoagulation activity and dose adjustments are not required in most patients. LMWHs have longer plasma half-lives, allowing once- or twice-daily administration, improved SC bioavailability, and dose-independent renal clearance. In addition, LMWHs have a more favorable side effect profile than UFH. They are also associated with a lower incidence of HIT, osteopenia, and osteoporosis. Two LMWHs are currently available in the United States: dalteparin and enoxaparin.

Table 11–10

Weight-Based[a] Dosing for UFH Administered by Continuous IV Infusion for Venous Thromboembolism

Initial Loading Dose	Initial Infusion Rate
80 units/kg (maximum = 10,000 units)	18 units/kg/hour (maximum = 2300 units/hour)
	Maintenance Infusion Rate
aPTT (seconds)	*Dose Adjustment*
< 37 (or < 12 seconds below institution-specific therapeutic range)	80 units/kg bolus then increase infusion by 4 units/kg/hour
37–47 (or 1–12 seconds below institution-specific therapeutic range)	40 units/kg bolus then increase infusion by 2 units/kg/hour
48–71 (within institution-specific therapeutic range)	No change
72–93 (or 1–22 seconds above institution-specific therapeutic range)	Decrease infusion by 2 units/kg/hour
> 93 (or > 22 seconds above institution-specific therapeutic range)	Hold infusion for 1 hour then decrease by 3 units/kg/hour

[a] Use actual body weight for all calculations. Adjusted body weight (ABW) may be used for morbidly obese patients (> 130% of ideal body weight [IBW]).

ABW = IBW + (Actual body weight − IBW) × 0.7

aPTT, activated partial thromboplastin time; IV, intravenous; UFH, unfractionated heparin.

Like UFH, LMWHs prevent the propagation and growth of formed thrombi.[9] The anticoagulant effect is mediated through a specific pentasaccharide sequence that binds to AT. The primary difference in the pharmacologic activity of UFH and LMWH is their relative inhibition of thrombin (factor IIa) and factor Xa. Smaller heparin fragments (as in LMWHs) cannot bind AT and thrombin simultaneously (Figure 11–4). The SC bioavailability of the LMWHs is greater than 90%. Peak anticoagulant effect of the LMWHs is reached 3 to 5 hours after a SC dose. The elimination half-life is 3 to 6 hours and is agent-specific. In patients with renal impairment, the half-life of LMWHs is prolonged.[9,10,12]

Table 11–11

Risk Factors for Major Bleeding While on Anticoagulation

Increased anticoagulation intensity (eg, INR > 5, aPTT > 120 seconds)
Initiation of therapy (first few days and weeks)
Unstable anticoagulation response (eg, variable INR response)
Age older than 65 years
Concurrent antiplatelet drug use
Concurrent NSAID or aspirin use
History of gastrointestinal bleeding
Recent surgery or trauma
High risk for fall/trauma (eg, elderly, sedentary/bedbound, high-risk medications)
Heavy alcohol use
Renal failure
Cerebrovascular disease
Active malignancy

aPTT, activated partial thromboplastin time; INR, international normalized ratio; NSAID, nonsteroidal anti-inflammatory drug.

Table 11–12

Contraindications to Anticoagulation Therapy

General
- Active bleeding
- Hemophilia or other hemorrhagic tendencies
- Severe liver disease with elevated baseline PT/INR
- Severe thrombocytopenia (platelet count $< 20 \times 10^3/\text{mm}^3$ [$20 \times 10^9/\text{L}$])
- Malignant hypertension
- Inability to meticulously supervise and monitor treatment

Drug-Specific Contraindications

UFH
- Hypersensitivity to UFH
- History of HIT

LMWHs
- Hypersensitivity to LMWH, UFH, pork products, methylparaben, or propylparaben
- History of HIT or suspected HIT

Fondaparinux
- Hypersensitivity to fondaparinux
- Severe renal insufficiency (CrCl < 30 mL/min [0.50 mL/s])
- Body weight < 50 kg (110 lb) for prophylaxis
- Bacterial endocarditis
- Thrombocytopenia with a positive in vitro test for antiplatelet antibodies in the presence of fondaparinux

Lepirudin
- Hypersensitivity to hirudins

Argatroban
- Hypersensitivity to argatroban

Warfarin
- Hypersensitivity to warfarin
- Pregnancy
- History of warfarin-induced skin necrosis
- Inability to obtain follow-up PT/INR measurements
- Inappropriate medication use or lifestyle behaviors

Dabigatran
- Mechanical prosthetic heart valves
- Hypersensitivity to dabigatran

Apixaban
- Hypersensitivity to apixaban

Rivaroxaban
- Hypersensitivity to rivaroxaban

CrCl, creatinine clearance; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; LMWHs, low-molecular-weight heparins; PT, prothrombin time; UFH, unfractionated heparin.

Dose of LMWHs for the treatment of VTE is determined based on the patient's weight and is administered SC once or twice daily (Table 11–8). Due to their predictable anticoagulant effect, routine monitoring is not necessary in most patients.[9] LMWHs have been evaluated in many randomized trials and have been shown to be at least as safe and effective as UFH for the treatment of VTE.[2,12] Indeed, the rate of mortality was lower in patients treated with an LMWH in clinical trials. This mortality benefit was primarily seen in patients with cancer.[34]

Prior to initiating treatment with an LMWH, baseline laboratory tests should include PT/INR, aPTT, CBC, and serum creatinine (SCr). Monitor the CBC with platelet count every 3 to 5 days during the first 2 weeks of therapy, and every 2 to 4 weeks with extended use.[9,10] Use LMWHs cautiously in patients with renal impairment due to the potential of drug accumulation and risk of bleeding. Specific dosing recommendations for patients with a CrCl less than 30 mL/min (0.50 mL/s) are currently available for enoxaparin but are lacking for other LMWH agents (Table 11–8).

Current guidelines recommend the use of UFH over LMWH in patients with severe renal dysfunction (CrCl < 30 mL/min [0.50 mL/s]).[2]

KEY CONCEPT Most patients with an uncomplicated DVT and PE can be managed safely at home.[2] LMWHs can be easily administered in the outpatient setting, thus enabling treatment of VTE at home. Several large clinical trials have demonstrated the efficacy and safety of LMWHs for outpatient treatment of DVT and PE, and this approach is commonly utilized in clinical practice.[2,34] Patients with DVT with normal vital signs, low bleeding risk, no other comorbid conditions requiring hospitalization, and who are stable may have anticoagulant initiated at home. Although the treatment of patients with PE in the outpatient setting is more controversial, patients with submassive PE who are hemodynamically stable can be safely treated in the outpatient setting as well.[12] Patients considered for outpatient therapy must be reliable or have adequate caregiver support and must be able to strictly adhere to the prescribed treatment regimen and recommended follow-up visits. Close patient follow-up is critical to the success of any outpatient DVT treatment program. Home DVT treatment results in cost savings and improved patient satisfaction and quality of life.[2,12,34]

Laboratory methods of measuring a patient's response to LMWH may be warranted in certain situations.[9,35] Although controversial, measurement of antifactor Xa activity has been the most widely used method in clinical practice. Monitoring of antifactor Xa activity may be considered in adult patients who are morbidly obese (weight > 150 kg [330 lb] or body mass index [BMI] > 50 kg/m^2), weigh less than 50 kg (110 lb), or have significant renal impairment (CrCl < 30 mL/min [0.50 mL/s]). Laboratory monitoring may also be useful in children, pregnant women, and those on long-term therapy.[35]

As with UFH, bleeding is the major complication associated with LMWHs. The incidence of major bleeding reported in clinical trials is less than 3%.[8,9] Minor bleeding, especially bruising at the injection site, occurs frequently. Protamine sulfate will partially reverse the anticoagulant effects of the LMWHs and should be administered in the event of major bleeding. Due to its limited binding to LMWH chains, protamine only neutralizes 60% of their antithrombotic activity. If the LMWH was administered within the previous 8 hours, give 1 mg protamine sulfate per 1 mg of enoxaparin or 100 antifactor Xa units of dalteparin. If bleeding is not controlled, give another 0.5 mg of protamine sulfate for every antifactor Xa 100 units of LMWH. Give smaller protamine doses if more than 8 hours have lapsed since the last LMWH dose.

The incidence of HIT is lower with LMWHs than with UFH.[9,10] However, LMWHs cross-react with heparin antibodies in vitro and should not be given as an alternative anticoagulant in patients with a diagnosis or history of HIT. Monitor platelet counts every few days during the first 2 weeks and periodically thereafter.

In patients undergoing spinal and epidural anesthesia or spinal puncture, spinal and epidural hematomas have been linked to the use of LMWHs. In patients with indwelling epidural catheters, concurrent use of LMWHs and all other agents that impact hemostasis should be avoided. When inserting and removing the indwelling epidural catheters, the timing of LMWH administration around catheter manipulation should be carefully coordinated. Catheter manipulation should only occur at minimal or trough anticoagulant levels.[9,10]

LMWHs are a convenient alternative to UFH for the treatment of VTE in pregnant women.[9,20] The LMWHs do not cross the placenta. Because the pharmacokinetics of LMWHs may change during pregnancy, monitoring of antifactor Xa activity every 4 to 6 weeks to make dose adjustments is recommended.[35] LMWHs have also been used to treat VTE in pediatric patients. Children younger than 1 year require higher doses (eg, enoxaparin 1.5 mg/kg SC every 12 hours). Monitor antifactor Xa activity to guide dosing in children.[33]

▶ *Factor Xa Inhibitors*

Parenteral Fondaparinux is an indirect inhibitor of factor Xa and exerts its anticoagulant activity by accelerating AT.[9,36] Due to its small size, fondaparinux exerts inhibitory activity specifically against factor Xa and has no effect on thrombin (Figure 11–4). After SC administration, fondaparinux is completely absorbed, and peak plasma concentrations are reached within 2 to 3 hours.[9,36] It has a half-life of 17 to 21 hours, permitting once-daily administration, but the anticoagulant effects of fondaparinux will persist for 2 to 4 days after stopping the drug. In patients with renal impairment, fondaparinux clearance is reduced, and the anticoagulant effect persists even longer. Fondaparinux does not require routine coagulation monitoring or dose adjustments.

Fondaparinux is not metabolized in the liver and therefore has few drug interactions.[9,36] However, concurrent use with other antithrombotic agents increases the risk of bleeding. Unlike the heparins, factor Xa inhibitors do not affect platelet function and do not react with the heparin platelet factor (PF)-4 antibodies seen in patients with HIT. Thus, they have a theoretical role in treatment and prevention of HIT. A few small observational studies report fondaparinux use in the management of patients with HIT. Based on these data some centers use fondaparinux in patients with subacute HIT or a history of HIT who require anticoagulation therapy.[9]

Fondaparinux is as safe and effective as IV UFH for the treatment of PE and SC LMWH for the treatment of DVT.[9,35] The recommended dose for fondaparinux in the treatment of VTE is based on the patient's weight (Table 11–8). Fondaparinux is renally eliminated, and accumulation can occur in patients with renal dysfunction. Due to the lack of specific dosing guidelines, fondaparinux is contraindicated in patients with severe renal impairment (CrCl < 30 mL/min [0.50 mL/s]). Baseline renal function should be measured and monitored closely throughout therapy. Based on limited data, monitoring antifactor Xa activity to guide fondaparinux dosing is not recommended.[9,36]

As with other anticoagulants, the major side effect associated with fondaparinux is bleeding. Fondaparinux should be used cautiously in elderly patients because their risk of bleeding is higher. Patients receiving fondaparinux should be carefully monitored for signs and symptoms of bleeding. A CBC should be obtained at baseline and monitored periodically to detect the possibility of occult bleeding. In the event of major bleeding, fresh-frozen plasma and factor concentrates should be given. Fondaparinux is not reversed by protamine.[9,36] Data are limited regarding the use of fondaparinux during pregnancy, and its use in pediatric patients has not been studied.[36]

Oral Apixaban, rivaroxaban, edoxaban, and betrixaban are direct inhibitors of factor Xa, part of a newer generation of oral anticoagulants also referred to as direct-acting oral anticoagulants (DOACs).[29,30,37,38] Apixaban and rivaroxaban have been evaluated and approved by the Food and Drug Administration (FDA) for the treatment of VTE (DVT and PE) and reduction in the risk of recurrence of DVT and PE. Edoxaban is also approved for VTE treatment. Rivaroxaban had similar efficacy and safety when compared to traditional therapy with LMWH and a vitamin K

Table 11–13

Dosing of the Direct Oral Anticoagulants in the Treatment of Venous Thromboembolism (VTE) and Their Reversal Agents

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Acute VTE	150 mg BID after 5–10 days of parenteral anticoagulation	15 mg BID × 3 weeks then 20 mg once daily with food	10 mg BID for 7 days, then 5 mg BID	60 mg once daily
Prevention of VTE recurrence	150 mg BID	10 mg once daily with food (after 6 months of acute treatment)	2.5 mg BID (after 6 months of acute treatment)	n/a
Dosage adjustments and/or thresholds for avoidance	Any P-gp *inducer*: avoid concurrent use Any P-gp *inhibitor* with CrCl < 50 mL/min (0.83 mL/s): avoid concurrent use CrCl < 30 mL/min (0.50 mL/s): avoid use	CrCl 30–50 mL/min (0.50–0.83 mL/s): use with caution CrCl < 30 mL/min (0.50 mL/s): avoid use	Dual strong CYP3A4 and P-gp inhibitors: If dose > 2.5 mg BID, decrease by 50% If already taking 2.5 mg BID and dual strong CYP3A4 and P-gp inhibitor: avoid use No dose adjustment in renal impairment or end-stage renal disease required	CrCl 15–50 mL/min (0.25–0.83 mL/s) or body weight ≤ 60 kg (132 lb), or concurrent use with certain P-gp inhibitors: 30 mg once daily
FDA-approved reversal agent	Idarucizumab 5 g IV by infusion or bolus	Recombinant inactivated coagulation Factor Xa High dose: 800 mg IV bolus + 960 mg IV infusion Low dose: 400 mg IV bolus + 480 mg IV infusion	Recombinant inactivated coagulation Factor Xa High dose: 800 mg IV bolus + 960 mg IV infusion Low dose: 400 mg IV bolus + 480 mg IV infusion	n/a

antagonist in the treatment of patients with VTE. One study suggests rivaroxaban may be inferior to warfarin in patients with triple positive antiphospholipid antibody syndrome.[39] Apixaban was noninferior in preventing recurrent VTE or VTE-related death but resulted in lower major bleeding events when compared to LMWH and warfarin therapy. Rivaroxaban and apixaban can be used as monotherapy without parenteral anticoagulation overlap, allowing for a single oral regimen approach for treating and preventing recurrent VTE. Edoxaban was noninferior to warfarin in recurrent VTE and associated with less major or clinically relevant nonmajor bleeding. Unlike the other oral factor Xa inhibitors, edoxaban is initiated after completing 5 to 10 days of initial treatment with a parenteral anticoagulant. See Table 11–13.

The DOACs inhibit a serine protease single target within the common pathway of the coagulation cascade during the final stages of clot formation. See Figure 11–5. This specificity provides a linear dose response and wider therapeutic index that allows for fixed dosing and precludes the need for routine coagulation monitoring.[4,12,29,30,37,38] Apixaban, rivaroxaban, edoxaban, and betrixaban are competitive, selective, and potent direct inhibitors of factor Xa that bind in a reversible manner to the active site of both free-floating factor Xa and factor Xa within the prothrombinase complex, thereby attenuating thrombin generation. These agents have intrinsic anticoagulant activity and do not require a cofactor to exert their effect as with UFH and the LMWHs.[4,12,29,30,37,38]

The pharmacokinetic and pharmacodynamic properties of DOACs are significantly different than those of warfarin. See

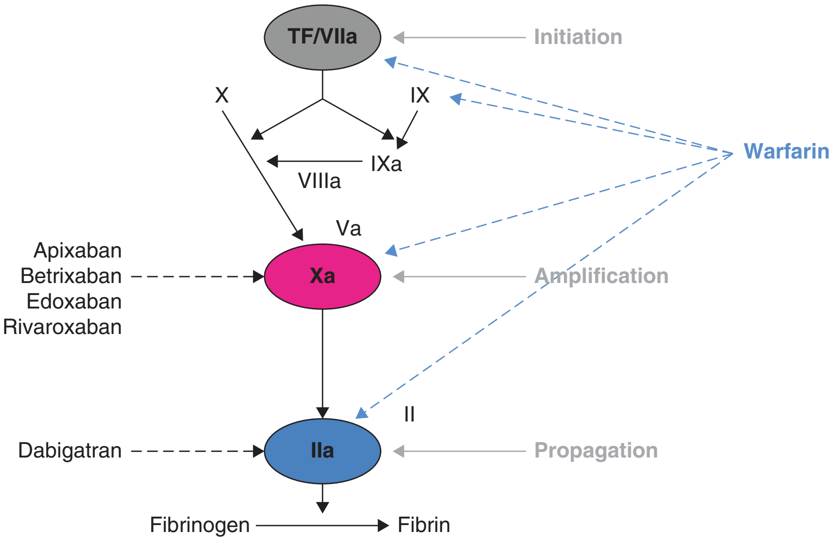

FIGURE 11–5. Mechanism of action of the oral anticoagulants and their targets of inhibition in relationship to other oral anticoagulants. (TF, tissue factor.) (Adapted from Weitz JI, Bates SM. New anticoagulants. J Thromb Haemost. 2005;3:1843–1853.)

Table 11–14. They have a more rapid onset and offset of action and shorter half-lives compared to warfarin. However, missed doses may be more prone to result in therapeutic complications than longer half-life therapies such as warfarin. DOACs are all eliminated renally to varying degrees (see Table 11–14), and dose adjustment or avoidance in patients with renal impairment may be needed.[4,12,29,30,37,38] See Table 11–13. All DOACs are substrates of the P-gp transport system, and the Xa inhibitors are also substrates of the hepatic cytochrome P-450 (CYP) isoenzyme system. Any inhibition or induction of these metabolic systems will alter their absorption.[29,30,37,38] There are currently no universally available standardized laboratory assays to measure the anticoagulant effect of DOACs. This can create challenges in situations where reversal of anticoagulation is required such as in cases of major bleeding or need for emergency surgery.[12,29,30,37-39] Fresh-frozen plasma, factor concentrates, or recombinant factor VIIa may be given in the event of a major life-threatening bleed.

Apixaban has dual pathways of elimination, with approximately 27% being cleared renally and the remainder eliminated via the fecal route. Elderly, low weight (< 50 kg [110 lb]), and patients with renal impairment can have increased exposure to apixaban, while gender and race do not appear to have clinically relevant influence. Pharmacokinetic modeling suggests apixaban does not accumulate significantly or require dose adjustment in patients with CrCl below 25 mL/min/1.73 m^2 (0.24 mL/s/m^2), but clinical data in this patient population are limited. Apixaban pharmacokinetics are not significantly altered in patients with mild- (Child-Pugh A) -to-moderate (Child-Pugh B) hepatic impairment. However, apixaban has not been studied in patients with severe hepatic impairment and is not recommended for

Table 11–14

Pharmacologic and Pharmacokinetic Characteristics of Direct Oral Anticoagulants

Property	Apixaban	Dabigatran	Rivaroxaban	Edoxaban	Betrixaban
Mechanism of action	Factor Xa inhibitor	Direct thrombin inhibitor	Factor Xa inhibitor	Factor Xa inhibitor	Factor Xa inhibitor
Bioavailability (%)	50%	3%–7%	80%–100% for 10-mg dose 66% for 20-mg dose[a]	62%	34%
T_{max} (hours)	1–3	1–3	2–4	1–2	3–4
Onset of effect	Within 3 hours	Within 3 hours	Within 4 hours	Within 2 hours	n/a
Half-life (hours)	8–15	12–17	5–13	10–14	19–27

Table 11–15

Drug Interactions and Monitoring Recommendations for Direct Oral Anticoagulants

	Apixaban	Rivaroxaban	Dabigatran	Edoxaban	Betrixaban
Drug interactions	Avoid concomitant use with strong dual inhibitors of CYP3A4 and P-gp (eg, ketoconazole, ritonavir, erythromycin) or reduce apixaban dose Avoid concomitant use with strong dual inducers of CYP3A4 and P-gp (eg, rifampin, phenytoin, carbamazepine) Concomitant use with antiplatelet agents, fibrinolytics, heparin, aspirin, and chronic NSAID increases bleeding risk	Avoid concomitant use with strong dual inhibitors of CYP3A4 and P-gp (eg, ketoconazole, ritonavir, erythromycin) Avoid concomitant use with strong dual inducers of CYP3A4 and P-gp (eg, rifampin, phenytoin, carbamazepine) Avoid concomitant use with other anticoagulants	Avoid concomitant use with P-gp inducers (eg, rifampin) P-gp inhibitors and impaired renal function can lead to increased exposure to dabigatran: Avoid concomitant use with severe renal impairment (CrCl < 30 mL/min [0.50 mL/s]) For moderate renal impairment, reduce dose to 75 mg twice daily when used concomitantly with dronedarone or systemic ketoconazole or avoid concomitant use	Avoid concomitant use with P-gp inducers (eg, rifampin) Concomitant use with coagulants, antiplatelet drugs, and thrombolytics may increase the risk of bleeding	For concomitant use of P-gp inhibitors (eg, amiodarone, azithromycin, verapamil, ketoconazole, clarithromycin): reduce dose to 80 mg × 1 then 40 mg daily Concomitant use of anticoagulants, antiplatelet drugs, and thrombolytics may increase the risk of bleeding.
Monitoring	Baseline laboratory assessment: Hemoglobin/hematocrit, liver function, renal function, PT/INR At every visit: Adherence, signs/symptoms of bleeding or thromboembolism, side effects, concomitant medications (including over-the-counter) Annual laboratory assessment: Hemoglobin/hematocrit, renal function, liver function If CrCl 30–60 mL/min (0.50–1.0 mL/s), > 75 years, or fragile: renal function every 6 months If CrCl 15–30 mL/min (0.25–0.50 mL/s): renal function every 3 months If condition changes that might impact anticoagulation therapy: check renal and/or liver function				

CrCl, creatinine clearance; CYP, cytochrome P-450; INR, international normalized ratio; NSAID, nonsteroidal anti-inflammatory drug; P-gp, P-glycoprotein; PT, prothrombin time.

use in these patients. There are no adequate studies in pregnant women, and its use during pregnancy is likely to increase bleeding risk. Use in pediatric patients has not been studied.[29] Apixaban is a substrate of both the CYP 3A4/5 and P-gp systems, and it may be subject to a number of drug interactions (Table 11–15).[29] See Tables 11–13, 11–14, and 11–15 for pertinent drug interactions, monitoring, and dosing recommendations.

While routine anticoagulation monitoring is not required, there may be clinical scenarios where knowing the patient's degree of anticoagulation may be necessary.[40] A drug-specific chromogenic anti-Xa assay may be used to measure apixaban plasma concentrations; however, this assay is not readily available in most laboratories. Other tests such as the PT, aPTT, and INR are not recommended to assess the anticoagulant effects of apixaban.[29,40] Baseline and periodic patient assessment including adherence, side effects, and renal and liver function should be conducted (Table 11–15).[41]

Rivaroxaban's bioavailability is dose dependent.[30] At a dose of 10 mg, bioavailability is 80% to 100% and may be taken without regard for food. At higher doses, bioavailability is approximately 66% in the fasted state, which is increased to greater than 80% by food intake. Thus, rivaroxaban 15- and 20-mg tablets should be taken with the largest meal of the day. See Table 11–14. Like apixaban, rivaroxaban does not induce or inhibit CYP isoenzymes, but may be affected by medications that are substrates for this enzymatic pathway.[30] Rivaroxaban has a dual mode of elimination, with approximately 35% excreted unchanged in the urine and the remaining two-thirds (in the form of inactive metabolites) excreted fairly equally between the renal and hepatobiliary route.[30] Rivaroxaban is a P-gp substrate, not only at the level of gut absorption, but also at the level of elimination in the kidney. Medications that are substrates for the P-gp transport system may impact plasma concentrations of rivaroxaban.[30,41]

While patients with renal impairment can have increased exposure to rivaroxaban, gender, race, age, and extremes of weight (< 50 kg [110 lb] or > 120 kg [265 lb]) have not been shown to significantly impact its pharmacokinetics or pharmacodynamics. Rivaroxaban should be avoided in patients with CrCl less than 30 mL/min (0.50 mL/s) when used for VTE treatment.[30] See Table 11–13. Mild hepatic impairment has minimal impact on the pharmacokinetics and pharmacodynamics of rivaroxaban. Patients with moderate hepatic impairment (Child-Pugh B) have significantly increased exposure to rivaroxaban, and its use in patients with severe liver disease has not been studied.[30] There are no well-controlled studies in pregnant women and pediatric patients, and dosing of rivaroxaban in these patients has not been established.

Rivaroxaban should not be used concomitantly with medications that are dual P-gp and strong CYP3A4 inhibitors or inducers.[30,41] See Table 11–15. Use with weaker combined P-gp and CYP3A4 substrates should be undertaken with caution and only if benefit of use outweighs risk. Concomitant use of rivaroxaban with antiplatelet and nonsteroidal anti-inflammatory agents should be done with extreme caution due to the additive antithrombotic effects and heightened risk of bleeding. As with apixaban, a drug-specific chromogenic anti-Xa assay may be used to measure rivaroxaban activity. Rivaroxaban prolongs the aPTT and PT in a dose-dependent manner, but the PT is more sensitive to rivaroxaban than the aPTT.[29,40,41] Because it is widely available and has a low level of complexity, the PT may be used in a qualitative manner to quickly determine the presence of rivaroxaban. A normal result with most PT reagents would exclude clinically significant anticoagulant activity. The PT and INR are not suitable for measurement of rivaroxaban activity.

Edoxaban is 62% orally bioavailable and dose dependent and is 55% bound to plasma protein. Edoxaban undergoes minimal CYP3A4 metabolism, hydrolysis, and conjugation, although an active primary metabolite is formed via hydrolysis with renal elimination accounting for approximately half of edoxaban elimination. Edoxaban should not be used in those with moderate or severe hepatic impairment (Child-Pugh B and C). Individuals weighing 60 kg (132 lb) or less should receive a reduced dose of 30 mg daily. Similar to apixaban and rivaroxaban, chromogenic antifactor Xa can be considered to evaluate the presence of edoxaban. Edoxaban may affect PT and aPTT, but these measures should not be considered reliable measures of serum concentrations or anticoagulation intensity. Similar to other DOACs, concomitant use of edoxaban with P-gp inducers, particularly rifampin, should be avoided.[37,40,41]

Betrixaban is 34% orally bioavailable and, unlike rivaroxaban, administration with a low- or high-fat meal leads to reduced betrixaban exposure. Betrixaban should thus be administered with food. Betrixaban is mainly excreted through feces (85%), 11% through urine, and 1% metabolized via CYP1A1, 1A2, 2B6, 2C9, 2C19, 2D6, and 3A4. A reduced dose is recommended if severe renal impairment (CrCl 15–30 mL/min [0.25–0.50 mL/s]) or concomitant use of P-gp inhibitors is present. Betrixaban has not been evaluated in the setting of hepatic impairment, and its use in this patient population should be avoided. Recommended duration of treatment for betrixaban is 35 to 42 days.[38]

Inactivated recombinant coagulation factor Xa is a recombinant modified human factor Xa decoy protein that binds to the active site of factor Xa inhibitors with high affinity, thereby preventing DOAC-mediated factor Xa inhibition. This agent is administered intravenously and has been approved for reversal of rivaroxaban and apixaban.[42] A high or low dose is administered based on the DOAC used, DOAC dose taken, and time elapsed since last DOAC dose.

▶ *Direct Thrombin Inhibitors*

Given that thrombin is the central mediator of coagulation and amplifies its own production, it is a natural target for pharmacologic intervention.[9,43,44] DTIs bind thrombin and prevent interactions with their substrates (Figure 11–6).

Parenteral Parenteral DTIs are considered drugs of choice for the treatment of VTE in patients with a diagnosis or history of HIT.[9,43,44] Several injectable DTIs are approved for use in the United States including lepirudin, bivalirudin, argatroban, and desirudin. All have been used to treat thrombosis in patients with HIT, but only lepirudin and argatroban are FDA approved for this indication. However, as of 2012, lepirudin is no longer commercially available in the United States. Data with some DTIs (desirudin, bivalirudin) for the treatment of HIT are limited, and there are no high-quality studies that directly compare one DTI with another. DTIs differ in terms of their chemical structure, binding to the thrombin molecule, and pharmacokinetic profiles. See Table 11–16. Unlike heparins, DTIs do not require AT as a cofactor and do not bind to plasma proteins. Therefore, they produce a more predictable anticoagulant effect. DTIs have a targeted specificity for thrombin, the ability to inactivate clot-bound thrombin, and an absence of platelet interactions that can lead to HIT.[9,43,44]

Oral Small molecule DTIs have been structurally modified for oral administration.[43] One agent, dabigatran, is currently approved in the United States for treatment of VTE.[45] Dabigatran was found to be as effective and safe as warfarin in the treatment and prevention of recurrent VTE.[12,45] Like edoxaban, patients should be anticoagulated with UFH or LMWH for the initial 5 to 10 days of therapy and then transitioned to dabigatran for VTE treatment.[2,12,45] See Table 11–13. Similar to other DOACs, dabigatran can be given in fixed doses without the need for routine coagulation monitoring and has a fast onset and offset of action, offering more convenient anticoagulation options for patients and providers.[45]

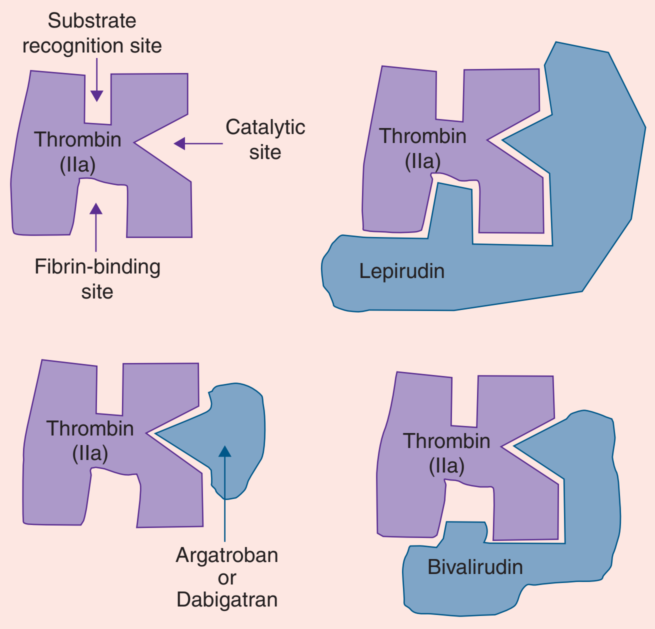

FIGURE 11–6. Mechanism of action of intravenous direct thrombin inhibitors, their binding sites, and relative inhibition of the thrombin catalytic and fibrin-binding sites. (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill; 2011:326.)

Dabigatran is a direct reversible, competitive inhibitor of thrombin and an oral prodrug of dabigatran etexilate.[43-45] Dabigatran is converted to its active form dabigatran etexilate by serum esterases that are independent of CYP pathways. See Table 11–14. Dabigatran has an oral bioavailability of approximately 3% to 7% and requires an acidic environment for absorption. The prodrug is contained in small pellets coated with an acid core. These pellets are enclosed in a capsule shell. This specific capsule formulation improves the dissolution and absorption of the prodrug, independent of gastric pH. Therefore, the capsules should not be broken, chewed, or opened before administration. Dabigatran demonstrates 35% protein binding and is a substrate of the efflux transporter P-gp. Although the absence of CYP metabolism decreases potential for many drug interactions, coadministration with P-gp substrates, inhibitors, or inducers may affect the efficacy of dabigatran.[41,43] See Table 11–15.

Approximately 80% of dabigatran is eliminated in the urine, and its use is not recommended for VTE treatment in patients with a CrCl less than 30 mL/min (0.50 mL/s) due to increased risk of drug exposure and bleeding.[45] Subjects with severe liver disease were excluded from clinical trials of dabigatran. In those with moderate hepatic impairment (Child-Pugh B), the pharmacokinetic profile of dabigatran is not affected. Gender, age, race,

ACT, activated clotting time; aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; FDA, Food and Drug Administration; HITTS, heparin-induced thrombocytopenia and thrombosis syndrome; INR, international normalized ratio; IV, intravenous; PCI, percutaneous coronary intervention; SC, subcutaneous; SCr, serum creatinine; VTE, venous thromboembolism.

or extremes of weight (< 50 kg [110 lb] or > 110 kg [243 lb]) do not significantly impact dabigatran pharmacology.

Dabigatran prolongs the aPTT, PT, thrombin time (TT), and ecarin clotting time (ECT) assays in a dose-dependent manner.[40,45] Peak values greater than 2.5 times control may indicate supratherapeutic levels. A normal aPTT would indicate a lack of clinically relevant anticoagulant activity. The aPTT may be used in a qualitative manner to determine the presence of anticoagulation with dabigatran. It should not be used to quantitate dabigatran plasma concentrations. The PT is relatively insensitive to dabigatran, and the INR is not suitable for measurement of dabigatran due to significant variability. The TT, diluted thrombin time (dTT), and ECT exhibit a linear dose-response with therapeutic dabigatran plasma concentrations. Unfortunately, none of these assays are widely available in practice. It is important to note that quantitative thresholds beyond which a patient would be at increased risk of clotting or bleeding have not been established for any of the DOACs.[40,43,45]

Contraindications to use of DTIs and risk factors for bleeding are similar to those of other antithrombotic agents (Tables 11–11 and 11–12). Bleeding is the most common side effect reported. Concurrent use of DTIs with thrombolytics or antiplatelet agents significantly increases bleeding complications.[46] Idarucizumab, a humanized monoclonal antibody fragment specific to dabigatran and its acyl glucuronide metabolites, binds free and thrombin-bound dabigatran with 350 times higher affinity compared to thrombin and is indicated for dabigatran reversal.[47] Idarucizumab is administered as two consecutive 2.5-g infusions or as a single bolus 5-g IV injection. Serious adverse reactions include thromboembolic risk accompanying dabigatran reversal, hypersensitivity reactions, and serious adverse events in those with hereditary fructose intolerance. Fresh-frozen plasma, factor concentrates, or recombinant factor VIIa may also be given in the event of a major life-threatening bleed; however, their efficacy for this use has not been established. DTIs can increase PT/INR and interfere with the accuracy of monitoring and dosing of warfarin therapy. Data on use of DTIs in pregnancy are very limited. Use of DTIs in pediatric patients has not been established.[45]

▶ *Warfarin*

KEY CONCEPT Warfarin had been the primary oral anticoagulant used in the United States when long-term or extended anticoagulation is required, but its use has decreased in favor of DOACs. Warfarin is FDA approved for prevention and treatment of VTE.[48] Although very effective, warfarin has a narrow therapeutic index, requiring frequent dose adjustments and careful patient monitoring.[4,10,11,48]

Warfarin exerts its anticoagulant effect by inhibiting production of the vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X, as well as the anticoagulant proteins C and S (Figure 11–7). Warfarin has no effect on circulating coagulation factors that have been previously formed, and its therapeutic antithrombotic activity is delayed for 5 to 7 days (potentially longer in slower metabolizers). This delay is related to half-lives of the clotting factors: 60 hours for factor II (prothrombin), 4 to 6 hours for factor VII, 24 hours for factor IX, and 48 to 72 hours for factor X. Proteins C and S, the natural anticoagulants, are inhibited more rapidly due to their shorter half-lives, 8 to 10 hours and 30 hours, respectively. Reductions in the concentration of natural anticoagulants before the clotting factors are depleted can lead to a paradoxical hypercoagulable state

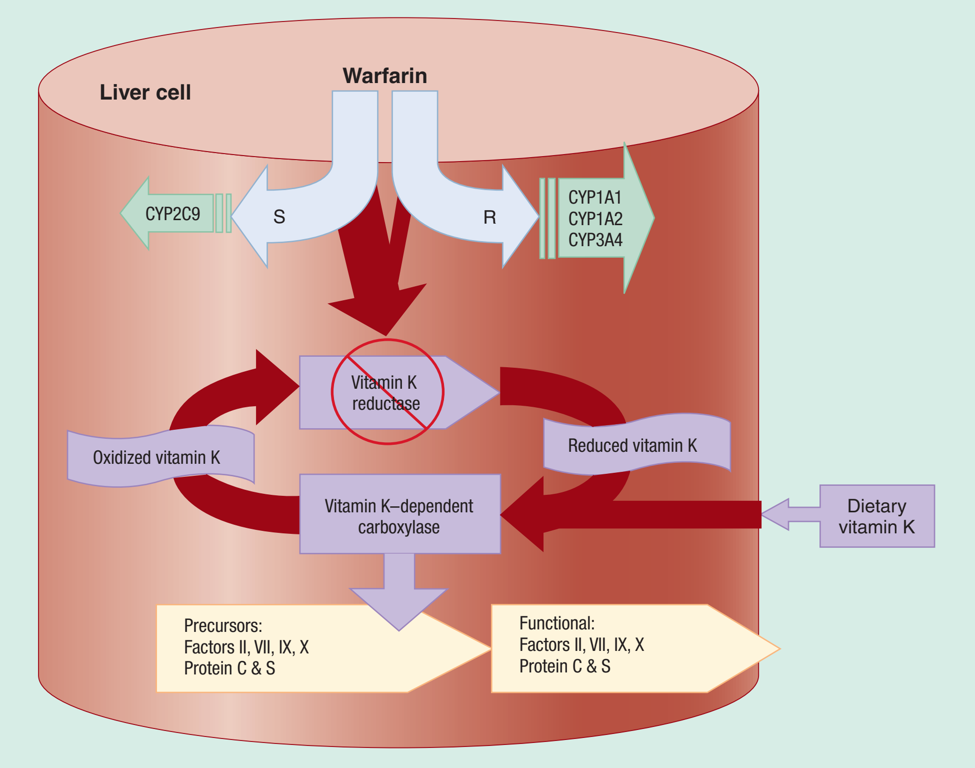

FIGURE 11–7. Pharmacologic activity and metabolism of warfarin and its downstream effects on the vitamin K cycle and clotting factor production. (CYP, cytochrome P-450 isoenzyme; S, S-warfarin; R, R-warfarin.) (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill; 2011:328.)

during the first few days of warfarin therapy. It is for this reason that patients with acute thrombosis should receive a fast-acting anticoagulant (heparin, LMWH, or fondaparinux) while transitioning to warfarin therapy. Use of DOACs as bridging agents has not been well evaluated or approved.[4,10,11,48]

Warfarin is metabolized in the liver via several isoenzymes including CYP 1A2, 3A4, 2C9, 2C19, 2C8, and 2C18 (Figure 11–7).[4,10,11,48] Hepatic metabolism of warfarin varies greatly among patients, leading to large interpatient differences in dose requirements and genetic variations in these isoenzymes. Multiple studies have demonstrated that *VKORC1* and *CYP2C9* genotypes influence the interpatient variability in warfarin dose requirements, together explaining up to 45% of overall dose variance. Several algorithms that incorporate *CYP2C9* genotype and *VKORC1* haplotype with other patient characteristics to predict warfarin maintenance dosing requirements have been developed and showed efficacy in better predicting warfarin stable doses when compared to clinical algorithms. Based on these data, the FDA recommends incorporating patient's genotype information in guiding warfarin dosing when such information is available.[48] See Table 11–17.[48] Guidelines published by the Clinical Pharmacogenetics Implementation Consortium are available to guide, interpret, and apply genotype information to warfarin dosing.[49] Although randomized studies to date showed mixed results of pharmacogenomic-based warfarin dosing on clinical and health utilization outcomes, careful analyses of study design and single-nucleotide polymorphisms tested in relation to the study patient population are necessary to appropriately interpret the implications and validity of genotype-guided dosing study outcomes. Therefore, pharmacogenomic-based dosing has not yet been widely adopted in clinical practice, and some guidelines recommend against routine ordering of preemptive genetic testing.[2,4]

Warfarin displays nonlinear kinetics. Small-dose adjustments can lead to large changes in anticoagulant response.[4,10,11,48]

Table 11–17

Food and Drug Administration Recommended Warfarin Initial Daily Doses Based on *CYP2C9* and *VKORC1* Genotypes[48]

	CYP2C9					
VKORC1	***1/*1**	***1/*2**	***1/*3**	***2/*2**	***2/*3**	***3/*3**

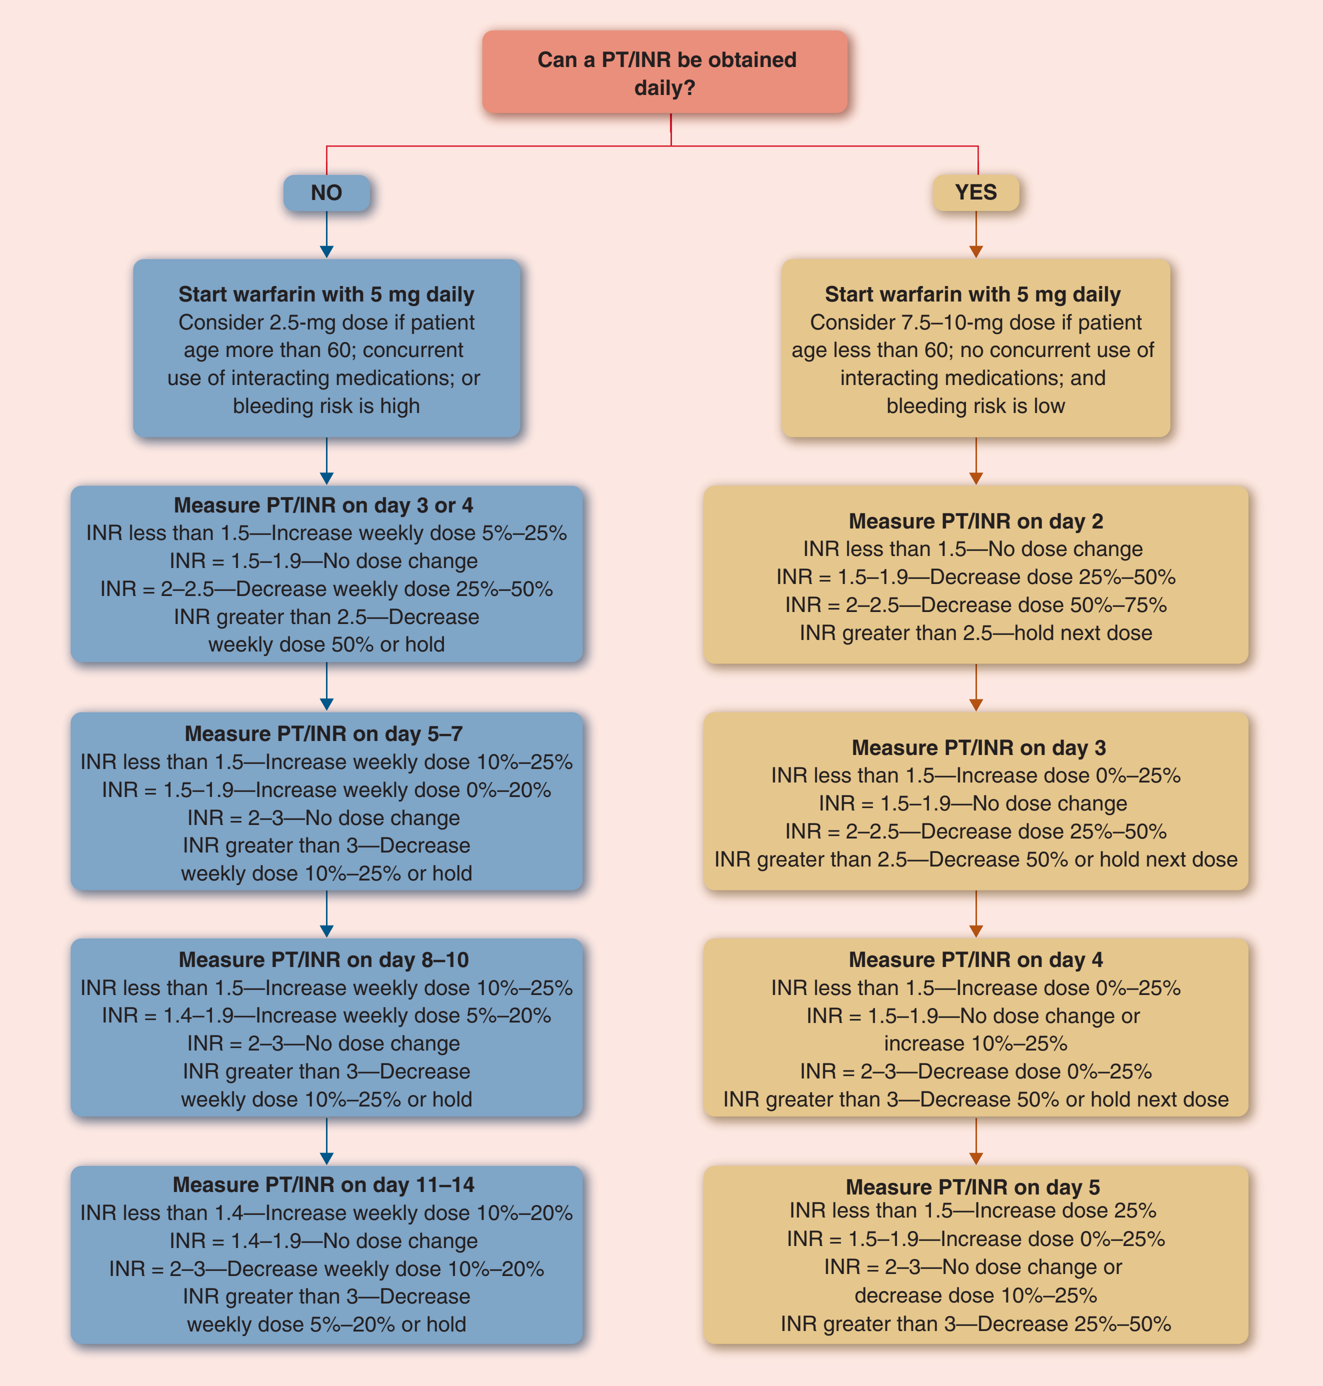
CYP, cytochrome P-450.

The dose of warfarin is determined by each patient's individual response to therapy and the desired intensity of anticoagulation. In addition to hepatic metabolism and genotype, warfarin dose requirements are influenced by diet, drug–drug interactions, and health status. Therefore, warfarin dose must be determined by frequent clinical and laboratory monitoring. Although there are conflicting data regarding the optimal warfarin induction regimen, when the patient's genotype is unknown, most patients can start with 5 mg daily, and subsequent doses are determined based on INR response (Figure 11–8). When initiating therapy, it is difficult to predict the precise warfarin maintenance dose a patient will require. Patients who are younger (< 55 years) and otherwise healthy can safely use higher warfarin "initiation" doses (eg, 7.5–10 mg). A more conservative "initiation" dose (eg, 4 mg or less) should be given to patients older than 75 years, patients with heart failure, liver disease, or poor nutritional status, and patients who are taking interacting medications or are at high risk of bleeding. Loading doses of warfarin (eg, 15–20 mg) are not



Can a PT/INR be obtained daily?
NO
YES
Start warfarin with 5 mg daily
Consider 2.5-mg dose if patient age more than 60; concurrent use of interacting medications; or bleeding risk is high
Start warfarin with 5 mg daily
Consider 7.5–10-mg dose if patient age less than 60; no concurrent use of interacting medications; and bleeding risk is low
Measure PT/INR on day 3 or 4
INR less than 1.5—Increase weekly dose 5%–25%
INR = 1.5–1.9—No dose change
INR = 2–2.5—Decrease weekly dose 25%–50%
INR greater than 2.5—Decrease weekly dose 50% or hold
Measure PT/INR on day 2
INR less than 1.5—No dose change
INR = 1.5–1.9—Decrease dose 25%–50%
INR = 2–2.5—Decrease dose 50%–75%
INR greater than 2.5—hold next dose
Measure PT/INR on day 5–7
INR less than 1.5—Increase weekly dose 10%–25%
INR = 1.5–1.9—Increase weekly dose 0%–20%
INR = 2–3—No dose change
INR greater than 3—Decrease weekly dose 10%–25% or hold
Measure PT/INR on day 3
INR less than 1.5—Increase dose 0%–25%
INR = 1.5–1.9—No dose change
INR = 2–2.5—Decrease dose 25%–50%
INR greater than 2.5—Decrease 50% or hold next dose
Measure PT/INR on day 8–10
INR less than 1.5—Increase weekly dose 10%–25%
INR = 1.4–1.9—Increase weekly dose 5%–20%
INR = 2–3—No dose change
INR greater than 3—Decrease weekly dose 10%–25% or hold
Measure PT/INR on day 4
INR less than 1.5—Increase dose 0%–25%
INR = 1.5–1.9—No dose change or increase 10%–25%
INR = 2–3—Decrease dose 0%–25%
INR greater than 3—Decrease 50% or hold next dose
Measure PT/INR on day 11–14
INR less than 1.4—Increase weekly dose 10%–20%
INR = 1.4–1.9—No dose change
INR = 2–3—Decrease weekly dose 10%–20%
INR greater than 3—Decrease weekly dose 5%–20% or hold
Measure PT/INR on day 5
INR less than 1.5—Increase dose 25%
INR = 1.5–1.9—Increase dose 0%–25%
INR = 2–3—No dose change or decrease dose 10%–25%
INR greater than 3—Decrease 25%–50%

FIGURE 11–8. Initiation of warfarin therapy. (INR, international normalized ratio; PT, prothrombin time.) (From Witt DM, Clark NP, Vazquez SR. Venous thromboembolism. Patient Encounter 3, Part 1

A 48-year-old woman presents to the emergency department complaining of shortness of breath, chest pain, and dizziness. She started having left calf pain approximately 5 days ago and feeling short of breath and experiencing chest pain (7/10) last evening. She could not sleep, and her shortness of breath has gotten progressively worse in the last several hours. She was hospitalized because she was suspected to have a PE. Due to the nature of her job, she does not have prescription insurance during the summer months.

PMH: Obesity × 20 years, asthma, stage 4 chronic kidney disease, hypertension; type 2 diabetes mellitus

FH: Mother with history of PE and died of an MI; paternal grandmother had clots (DVT) in her legs

SH: Full-time bus driver

Current Meds: Albuterol metered-dose inhaler as needed; Ortho-Tri-Cyclen Lo by mouth daily, lisinopril 10 mg daily, insulin glargine 40 units once daily, insulin aspart 15 units before meals, renal multivitamin daily; ginseng one to two tablets by mouth daily as needed; multivitamin one tablet by mouth daily

Allergies: NKDA

PE:

VS: BP 138/64 mm Hg, HR 102 beats/min, RR 20 breaths/min, T 38°C (100.4°F), Wt 96 kg (211 lb; BMI 35.3 kg/m^2), Ht 65 in (165 cm)

Labs: CBC and LFTs within normal limits; eGFR 16 mL/min/1.73 m^2; CrCl 12 mL/min (0.2 mL/s)

Procedures/Tests

ECG: Normal sinus rhythm; no ischemic changes

CXR: Cardiomegaly present without infiltrates

V/Q scan: High probability of PE

What symptoms and findings are consistent with diagnosis of PE? What are the most likely etiologies for PE in this case?

What are appropriate initial acute-phase treatment and long-term and extended treatment options for PE in this patient?

If UFH is chosen as the initial acute-phase anticoagulation treatment option for this patient's PE, what is the goal aPTT?

What is the patient's goal INR for warfarin therapy?

How long should she remain on anticoagulation therapy?

Given the list of medications the patient took prior to hospitalization, should any of these be discontinued or changed? If changed, what alternative therapy would you recommend?

recommended and can create false impressions that a therapeutic INR has been achieved in 2 to 3 days and lead to potential future overdosing.[4,10,11,48] Before initiating therapy, screen the patient for any contraindications to anticoagulation therapy and risk factors for major bleeding (Tables 11–11 and 11–12). Conduct a thorough medication history including the use of prescription and nonprescription drugs and any herbal supplements to detect interactions that may affect warfarin dosing requirements.

In patients with acute VTE, a rapid-acting anticoagulant (UFH, LMWH, or fondaparinux) should be overlapped with warfarin for a minimum of 5 days and until the INR is greater than 2 and stable. This is important because the full antithrombotic effect of warfarin will not be reached until 5 to 7 days or even longer after initiating warfarin therapy. Typical maintenance dose of warfarin for most patients will be between 25 and 55 mg per week, although some patients require higher or lower doses stemming from their genotype or other clinical factors. Adjustments in maintenance warfarin dose should be determined based on the total weekly dose and by reducing or increasing the weekly dose by increments of 5% to 25%. When adjusting the maintenance dose, wait at least 7 days to ensure a steady state has been attained on the new dose before checking the INR again. Checking the INR too soon can lead to inappropriate dose adjustments and unstable anticoagulation status.[4,10,11,48]

KEY CONCEPT Warfarin requires frequent laboratory monitoring to ensure optimal outcomes and minimize complications. PT is the most frequently used test to monitor warfarin's anticoagulant effect. PT measures biological activity of factors II, VII, and X. Due to wide variation in reagent sensitivity, different thromboplastins will result in different PT results, potentially leading to inappropriate dosing decisions.[4,10,11,48] To standardize result reporting, the World Health Organization developed a reference thromboplastin and recommended the INR to monitor warfarin therapy. INR corrects for the differences in thromboplastin reagents. Goal or target INR for each patient is based on the indication for warfarin therapy. For treatment and prevention of VTE, the INR target is 2.5 with an acceptable range of 2 to 3. Before initiating warfarin therapy, a baseline PT/INR and CBC should be obtained. After initiating warfarin therapy, INR should be monitored at least every 2 to 3 days during the first week of therapy. Once a stable response to therapy is achieved, INR monitoring is performed less frequently, weekly for the first 1 to 2 weeks, then every 2 weeks, and every 4 to 6 weeks thereafter if the warfarin dose and the patient's health status are stable.[4,10,11,48,50] At each encounter, the patient should be carefully questioned regarding any factors that may influence the INR result. These factors include adherence to therapy, use of interacting medications, consumption of vitamin K–rich foods, alcohol use, and general health status. Patients should also be questioned about symptoms related to bleeding and thromboembolic events. Warfarin dose adjustments should take into account not only the INR result but also patient-related factors that influence the result. Structured anticoagulation therapy management services (anticoagulation clinics) have been demonstrated to improve the efficacy and safety of warfarin therapy. Some patients engage in self-testing and self-management by using a point-of-care PT/INR device approved for home use. Highly motivated and well-trained patients are good candidates for self-testing or self-management.[50]

KEY CONCEPT Similar to other anticoagulants, warfarin's primary side effect is bleeding.[8] Warfarin can unmask an existing lesion. Incidence of warfarin-related bleeding appears to be highest during the first few weeks of therapy. The annual incidence of major bleeding ranges from 1% to 10% depending on the quality of warfarin therapy management. Bleeding in the gastrointestinal tract is most common. Intracranial hemorrhage (ICH) is one of the most serious complications because it often causes severe disability

Patient Encounter 3, Part 2

Following discussion with the patient regarding her insurance, she is discharged home on warfarin therapy. She was referred to a local area antithrombosis center for monitoring of her oral anticoagulation therapy and has been maintained on warfarin 6 mg daily for the last 3 months. The patient presents today for a routine visit for anticoagulation monitoring and her INR is 5.6. She reports that 3 days ago she was started on a 1-week course of metronidazole, which was prescribed by her primary care physician for bacterial vaginosis. She also reports that she is trying to lose weight and her intake of vitamin K–rich foods (kale, turnip greens, brussels sprouts) has increased significantly over the last month. She has no other complaints today and denies any signs or symptoms of bleeding.

What is the most likely explanation for elevated INR?

Should she be given vitamin K? If yes, discuss the dose, route of administration, and an appropriate patient monitoring plan.

How will you manage the patient's warfarin therapy? Outline a plan including specific dose changes, timing of monitoring, and patient education

and death. The intensity of anticoagulation therapy is related to bleeding risk. Higher INRs result in higher bleeding risk, and risk of ICH increases when the INR exceeds 4.[4,10,11] Instability and wide fluctuations in the INR are also associated with higher bleeding risk. In cases of warfarin overdose or overanticoagulation, vitamin K may be used to reverse warfarin's effect. Vitamin K can be given by IV or oral route; the SC route is not recommended as vitamin K is erratically absorbed and frequently ineffective. The IV route is reserved for cases requiring urgent reversal and when patients have life-threatening bleeding. Anaphylactoid reactions have been reported with rapid IV administration; therefore, slow infusion is recommended. An oral dose of vitamin K will reduce INR within 24 hours. If INR is still elevated after 24 hours, another dose of oral vitamin K can be given. The dose of vitamin K should be based on the degree of INR elevation and whether bleeding is present. A dose of 2.5 mg orally is recommended when INR is greater than 10 and there is no active bleeding, while a higher dose of 10 mg given via slow IV is recommended in cases when life-threatening bleeding is present. Higher doses (eg, 10 mg) can lead to prolonged warfarin resistance. In cases of life-threatening bleeding, fresh-frozen plasma or clotting factor concentrates should also be administered, in addition to IV vitamin K. In patients in whom INR is less than 10, and there is no active bleeding or imminent risk of bleeding, simply withholding warfarin until INR decreases to within therapeutic range and reducing the weekly dose with more frequent monitoring is appropriate.[4,10,11,48]

Nonhemorrhagic side effects related to warfarin are rare but can be severe when they occur. Warfarin-induced skin necrosis (incidence $< 0.1\%$) presents as an eggplant-colored skin lesion or a maculopapular rash that can progress to necrotic gangrene. It usually manifests in fatty areas such as the abdomen, buttocks, and breasts, and generally appears during the first week of therapy. Patients with protein C or S deficiency or those who receive large loading doses of warfarin are at greatest risk.[48] The mechanism is thought to be due to imbalances between procoagulant and anticoagulant proteins early in the course of warfarin therapy. Warfarin-induced purple toe syndrome is another rare side effect; patients present with a purplish discoloration of their toes. If these side effects are suspected, warfarin therapy should be discontinued immediately, and an alternative anticoagulant should be started. There is a theoretical risk that warfarin may cause accelerated bone loss with long-term use, but to date there is no evidence to support this concern. Warfarin is teratogenic and should be avoided during pregnancy. Women of childbearing potential should be instructed to use an effective form of contraception.

KEY CONCEPT Warfarin is prone to numerous clinically significant drug–drug and drug–food interactions (Tables 11–18, 11–19, and 11–20).[10,11,48] Patients on warfarin should be questioned at every encounter to assess for any potential interactions with foods, drugs,

Table 11–18

Clinically Significant Drug Interactions With Warfarin

Increase Anticoagulation Effect (↑ INR)	Decrease Anticoagulation Effect (↓ INR)	Increase Bleeding Risk

INR, international normalized ratio.

herbal products, and nutritional supplements. When an interacting drug is initiated or discontinued, more frequent monitoring should be instituted. In addition, the dose of warfarin can be modified (increased or decreased) in anticipation of the expected impact on the INR.[10,11,48] Warfarin-related drug interactions can generally be divided into two major categories: pharmacokinetic and pharmacodynamic. Pharmacokinetic interactions are most commonly due to changes in hepatic metabolism or binding to plasma proteins. Drugs that affect the CYP2C9, CYP3A4, and CYP1A2 have the greatest impact on warfarin metabolism. Interactions that impact the metabolism of the S-isomer result in greater changes in the INR than interactions affecting the R-isomer. Pharmacodynamic drug interactions enhance or diminish the anticoagulant effect of warfarin, increasing the risk of bleeding or clotting, but may not alter the INR. There are increasing reports regarding dietary supplements, nutraceuticals, and vitamins that can interact with warfarin. Patients on warfarin may experience changes in the INR due to fluctuating intake of dietary vitamin K. Patients should be instructed to maintain a consistent diet and avoid large fluctuations in vitamin K intake rather than strictly avoiding vitamin K–rich foods.[4,10,11,48]

Nonpharmacologic Therapy

▶ *Thrombectomy*

Most cases of VTE can be successfully treated with anticoagulation. In some cases, removal of the occluding thrombus by surgical intervention may be warranted. Surgical or mechanical thrombectomy can be considered in patients with massive iliofemoral DVT when there is a risk of limb gangrene due to venous occlusion.[2,12] The procedure can be complicated by recurrence of thrombus formation. In patients who present with massive PE, pulmonary embolectomy can be performed in patients with contraindications to thrombolytic therapy, when thrombolysis has failed clinically, or when thrombolysis will not have sufficient time to take effect. The usual practice is to administer heparin by IV infusion to achieve a therapeutic aPTT during the operation, and postoperatively and thereafter give warfarin for the usual recommended duration.[2,12]

▶ *Inferior Vena Cava Filters*

An IVC filter is indicated in patients with newly diagnosed proximal DVT or PE who have a contraindication to anticoagulation therapy.[2,12] IVC interruption is accomplished through minimally invasive means by insertion via internal jugular vein or femoral

Table 11–20

Vitamin K Content of Select Foods[a]

Very High (> 200 mcg)	High (100–200 mcg)	Medium (50–100 mcg)	Low (< 50 mcg)
Brussels sprouts	Basil	Apple, green	Apple, red
Chickpea	Broccoli	Asparagus	Avocado
Collard greens	Canola oil	Cabbage	Beans
Coriander	Chive	Cauliflower	Breads and grains
Endive	Coleslaw	Lettuce, green leaf, romaine	Carrot
Kale	Cucumber (unpeeled)	Mayonnaise	Celery
Lettuce, red leaf	Green onion/scallion	Pistachios	Cereal
Parsley	Lettuce, butterhead	Squash, summer	Coffee
Spinach	Mustard greens		Corn
Swiss chard	Soybean oil		Cucumber (peeled)
Tea, black			Dairy products
Tea, green			Eggs
Turnip greens			Fruit (varies)
Watercress			Lettuce, iceberg
			Meats, fish, poultry
			Pasta
			Peanuts
			Peas
			Potato
			Rice
			Tomato

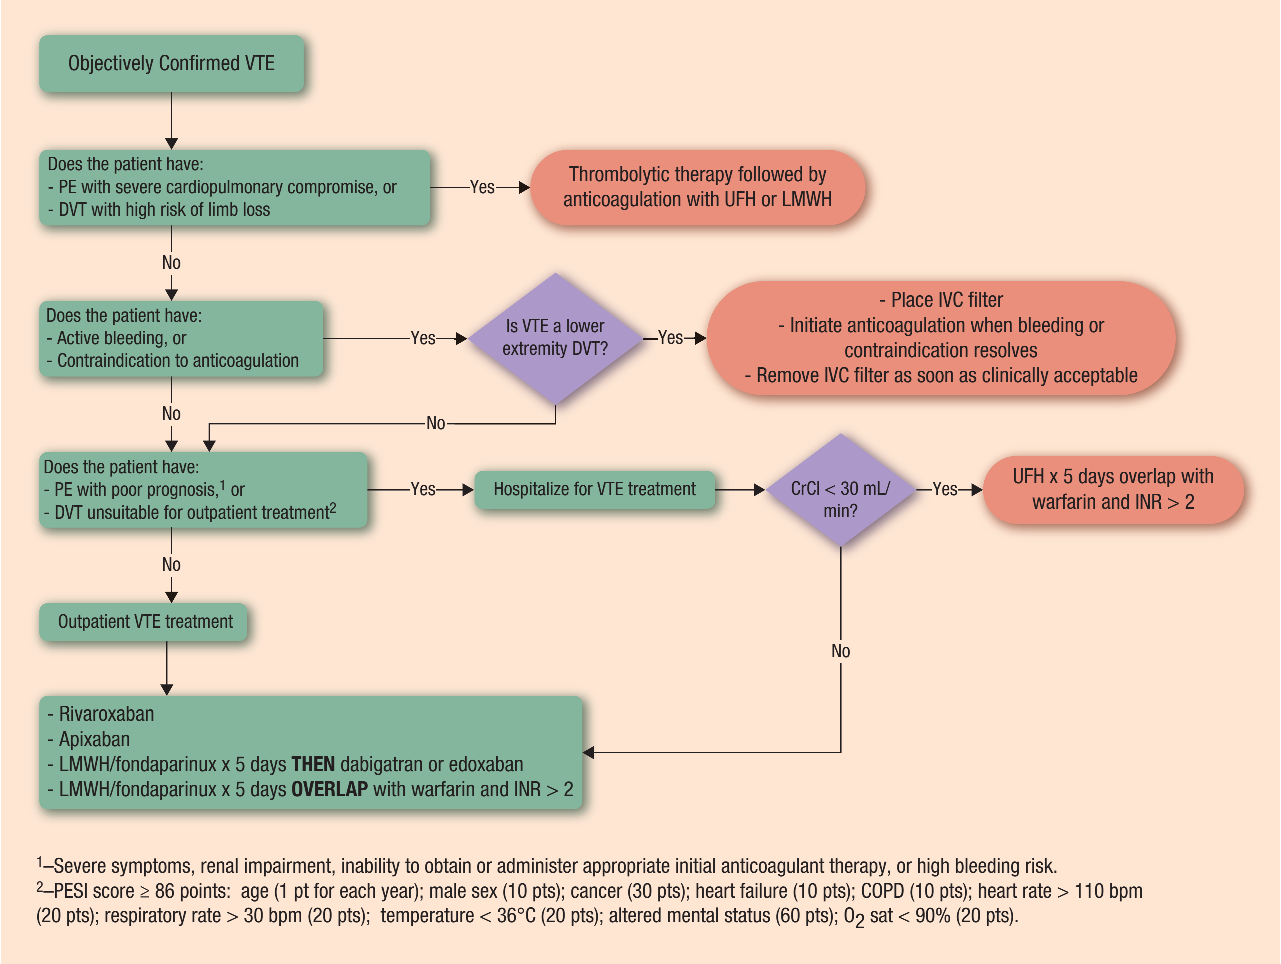
[a] Approximate amount of vitamin K per 100 g (3.5 oz) serving.

vein access and advancing the filter into the IVC using ultrasound or fluoroscopic guidance. One of the risks associated with IVC filters is development of thrombosis on the filter itself. Therefore, anticoagulation therapy should be resumed as soon as contraindications resolve. Temporary or retrievable filters are frequently used, and filters should be removed once therapy is completed.[15]

APPROACH TO TREATING PATIENTS WITH VTE

A treatment algorithm for VTE is presented in Figure 11–9. Note that LMWH or fondaparinux are preferred over UFH for acute VTE treatment; however, in patients with CrCl less than 30 mL/min (0.50 mL/s), UFH is the preferred treatment approach. For the long-term and extended treatment phases, DOACs are recommended over warfarin to prevent recurrent thrombosis. In patients with cancer-associated thrombosis, LMWHs are an alternative option for the acute, long-term, and extended phases of treatment due to efficacy in preventing recurrent thromboembolic events.[2,31,34]

Anticoagulation therapy is continued for a minimum of 3 months but should be given longer depending on the underlying etiology of the VTE, thrombus location, and the patient's risk factors.[2,12] Determining optimal duration of anticoagulation involves weighing the risk of recurrent VTE against the risk of bleeding associated with anticoagulation therapy and determining patient preference regarding treatment duration. Patients with provoked VTE by transient risk factors (eg, surgery, trauma) or an isolated distally located DVT require therapy for 3 months. Patients with unprovoked VTE have a recurrence risk of at least 10% after 1 year and at least 30% at 5 years, thus most such patients require extended if not indefinite anticoagulation, particularly in those with PE or proximally located DVT and PE, and if the patient carries low-to-moderate bleeding risk. Patients with low-to-moderate bleeding risk who have a second unprovoked VTE should receive extended or indefinite anticoagulation and those at high bleeding risk should be treated for 3 months. Patients who are recommended to receive indefinite anticoagulation should have periodic visits to assess bleeding risk and patient preference/quality of life to determine if anticoagulation should continue. Patient preference should always be a strong consideration when deciding on extended duration anticoagulation.[2,12]



Objectively Confirmed VTE
Does the patient have:
- PE with severe cardiopulmonary compromise, or
- DVT with high risk of limb loss
Yes
Thrombolytic therapy followed by anticoagulation with UFH or LMWH
No
Does the patient have:
- Active bleeding, or
- Contraindication to anticoagulation
Yes
Is VTE a lower extremity DVT?
Yes
- Place IVC filter
- Initiate anticoagulation when bleeding or contraindication resolves
- Remove IVC filter as soon as clinically acceptable
No
No
Does the patient have:
- PE with poor prognosis,1 or
- DVT unsuitable for outpatient treatment2
Yes
Hospitalize for VTE treatment
CrCl < 30 mL/min?
Yes
UFH x 5 days overlap with warfarin and INR > 2
No
No
Outpatient VTE treatment
- Rivaroxaban
- Apixaban
- LMWH/fondaparinux x 5 days THEN dabigatran or edoxaban
- LMWH/fondaparinux x 5 days OVERLAP with warfarin and INR > 2

[1]–Severe symptoms, renal impairment, inability to obtain or administer appropriate initial anticoagulant therapy, or high bleeding risk.

[2]–PESI score ≥ 86 points: age (1 pt for each year); male sex (10 pts); cancer (30 pts); heart failure (10 pts); COPD (10 pts); heart rate > 110 bpm (20 pts); respiratory rate > 30 bpm (20 pts); temperature < 36°C (20 pts); altered mental status (60 pts); O_2 sat < 90% (20 pts).

FIGURE 11–9. Acute treatment of VTE. (bpm, beats/min; COPD, chronic obstructive pulmonary disease; CrCl, creatinine clearance [30 mL/min is equivalent to 0.50 mL/s]; DVT, deep vein thrombosis; INR, international normalized ratio; IVC, inferior vena cava; LMWH, low-molecular-weight heparin; O_2 sat, oxygen saturation [90% is equivalent to 0.90 when expressed as a fraction]; PE, pulmonary embolism; PESI, pulmonary embolism severity index; UFH, unfractionated heparin; VTE, venous thromboembolism.) OUTCOME EVALUATION

- KEY CONCEPT Achieve optimal outcomes by (a) preventing the occurrence of VTE in patients who are at risk, (b) administering effective treatments in a timely manner to patients who develop VTE, (c) preventing treatment-related complications, and (d) reducing the likelihood of long-term complications including recurrent events.
- Given that VTE is often clinically silent and potentially fatal, strategies to increase widespread use of prophylaxis have the greatest potential to improve patient outcomes. Thus, relying

Patient Care Process

Collect Information:

- Obtain and review from the medical record: past medical history, family history, social history, physical assessment findings, and laboratory and diagnostic testing results.
- Complete a medication history of prescription and nonprescription medication and dietary supplement use. Identify any allergies to medications and other substances.
- Interview the patient and review records to identify lifestyle habits such as dietary patterns, alcohol and illicit drug use, smoking status, medication use–related preferences and beliefs, and socioeconomic factors that affect access to medications and health care.

Assess the Information:

- Based on clinical assessment and physical examination, determine whether the patient is experiencing signs or symptoms of VTE (Table 11–1 and Clinical Presentation and Diagnosis of DVT and PE).
- Apply the Wells criteria to determine the probability that the patient's signs, symptoms, and risk factors are the result of DVT and/or PE (Tables 11–2 and 11–3).
- Review relevant laboratory (eg, D-dimer, PT/INR, aPTT, antifactor Xa activity, SCr, CrCl, blood urea nitrogen [BUN], serum albumin, liver function tests, CBC with platelets) and diagnostic tests (eg, venous ultrasound, V/Q, or CT scan). See Clinical Presentation and Diagnosis of DVT and PE.
- Assess pertinent family history (ie, hypercoagulable disorders, pregnancy loss, DVT, PE).
- Determine if diagnosis of VTE is confirmed based on clinical criteria and/or diagnostic testing.
- Assess whether the VTE is a new or recurrent event and whether the VTE is an idiopathic or triggered event.
- Assess severity of VTE and whether patient is a candidate for outpatient therapy.
- Assess risk of bleeding and check for any contraindications to anticoagulation therapy (Tables 11–6, 11–11, and 11–12).
- Assess dietary and medication profiles, including over-the-counter medications and herbal therapies used at home for potential drug–drug and drug–food interactions with anticoagulation therapy (Tables 11–15, 11–18, and 11–19).
- If the patient is already receiving anticoagulation therapy, assess efficacy, safety, and adherence to therapy.

Develop a Care Plan:

- Once diagnosis of VTE has been confirmed with an objective test, initiate anticoagulation therapy at full therapeutic doses. If there is high clinical suspicion of VTE, anticoagulation therapy may be initiated while waiting for results of diagnostic tests (Figure 11–9).
- Determine the most appropriate anticoagulant therapy and dose options based on patient clinical characteristics, insurance coverage, plans for outpatient therapy, complexity of anticoagulation management, and patient preferences (Tables 11–8, 11–9, 11–10, and 11–13).
- Determine optimal duration of anticoagulation therapy by weighing the risk of recurrent VTE against the risk of bleeding and considering patient preferences regarding treatment duration.

Implement the Care Plan:

- Educate the patient on purpose of therapy and importance of adherence, proper monitoring, potential drug–drug and drug–food interactions, dietary consistency with vitamin K–containing foods if treated with warfarin, taking appropriate birth control measures in females, adherence with anticoagulants and with laboratory monitoring, potential side effects, and procedures to follow in case of emergency.
- Address any patient concerns about anticoagulation treatment and its management.
- Devise a structured plan for long-term monitoring of anticoagulation therapy; if treated with warfarin, determine if patient is candidate for anticoagulation self-testing.
- Refer the patient to a specialized anticoagulation monitoring service if available or another designated specialized provider.
- Evaluate patient's medical insurance status and assess coverage level for oral and injectable anticoagulant medications and coverage for follow-up monitoring visits and/or anticoagulation self-testing devices and supplies.

Follow-up: Monitor and Evaluate:

- Follow a structured plan for periodic long-term monitoring of anticoagulation therapy.
- Reevaluate risks and benefits of continuing anticoagulation therapy beyond the initial 3 months; patients who are recommended to receive indefinite anticoagulation should have periodic visits to assess bleeding risk and patient preference/quality of life to determine if anticoagulation should continue.
- Periodically reassess patient adherence, concurrent medications to screen for drug interactions, dietary habits to screen for drug–diet interactions, and renal and liver function tests.
- Monitor the patient to determine if there is worsening or new symptoms related to VTE.
- Evaluate the patient to determine if he/she is experiencing any side effects such as overt bruising or bleeding, as well as changes in stool or urine color.

on early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated.

- Effective VTE prophylaxis programs screen all patients admitted to the hospital for VTE risk factors, determine each patient's level of risk, and select and implement prevention strategies that provide sufficient protection for the level of risk.
- Periodically evaluate patients who are receiving VTE prophylaxis for signs and symptoms of DVT, such as swelling, pain, warmth, and redness of lower extremities, and for signs and symptoms of PE, such as chest pain, shortness of breath, palpitations, and hemoptysis.
- Providing effective treatment in a timely manner is the primary goal for patients who develop VTE. Treat DVT and PE quickly and aggressively with effective doses of anticoagulant drugs.
- Short-term aims of therapy are to prevent propagation or local extension of the clot, embolization, and death.
- Regularly monitor patients for development of new symptoms or worsening of existing symptoms.
- All anticoagulant drugs require precise dosing and meticulous monitoring. Closely monitor patients receiving anticoagulant therapy for signs and symptoms of bleeding including epistaxis, hemoptysis, hematuria, hematemesis, hematochezia, melena, severe headache, and joint pain. If major bleeding occurs, stop therapy immediately and treat the source of bleeding. In addition, closely monitor patients for potential drug–drug and drug–food interactions and adherence with the prescribed regimen.
- Long-term goals of therapy are to prevent complications such as PTS, pulmonary hypertension, and recurrent VTE.
- Continue long-term anticoagulation therapy for an appropriate duration based on etiology of the initial clot and presence of ongoing risk factors.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. Stuart Haines, an author of this chapter in previous editions of this book.

Abbreviations Introduced in This Chapter

ABW	Adjusted body weight
ACCP	American College of Chest Physicians
ACT	Activated clotting time
aPTT	Activated partial thromboplastin time
AST	Aspartate aminotransferase
AT	Antithrombin
BCRP	Breast cancer resistance protein
BMI	Body mass index
BUN	Blood urea nitrogen
CABG	Coronary artery bypass graft
CBC	Complete blood count
CrCl	Creatinine clearance
CT	Computed tomography
CYP	Cytochrome P-450
DOAC	Direct oral anticoagulant
DTI	Direct thrombin inhibitor
dTT	Diluted thrombin time
DVT	Deep vein thrombosis
ECT	Ecarin clotting time
eGFR	Estimated glomerular filtration rate
ESR	Erythrocyte sedimentation rate
FDA	Food and Drug Administration
FXa	Factor Xa
GCS	Graduated compression stockings
GP	Glycoprotein
HIT	Heparin-induced thrombocytopenia
HITTS	Heparin-induced thrombocytopenia and thrombosis syndrome
IBW	Ideal body weight
ICH	Intracranial hemorrhage
INR	International normalized ratio
IPC	Intermittent pneumatic compression (device)
IV	Intravenous
IVC	Inferior vena cava
LDH	Lactate dehydrogenase
LDUH	Low-dose unfractionated heparin
LFT	Liver function test
LMWH	Low-molecular-weight heparin
MI	Myocardial infarction
MRI	Magnetic resonance imaging
MTT	Methyl-tetrazole-thiomethyl
NSAID	Nonsteroidal anti-inflammatory drug
PAI-1	Plasminogen activator inhibitor-1
PCI	Percutaneous coronary intervention
PE	Pulmonary embolism
PF	Platelet factor
P-gp	P-glycoprotein
PT	Prothrombin time
PTS	Postthrombotic syndrome
rt-PA	Recombinant tissue plasminogen activator (alteplase)
SCr	Serum creatinine
SBP	Systolic blood pressure
SC	Subcutaneous
SGOT	Serum glutamic-oxaloacetic transaminase
SERM	Selective estrogen receptor modulator
TT	Thrombin time
UFH	Unfractionated heparin
V/Q	Ventilation/perfusion (scan)
VTE	Venous thromboembolism
vWF	von Willebrand factor
WBC	White blood cell

12 Stroke

Susan R. Winkler

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Differentiate types of cerebrovascular disease including transient ischemic attack (TIA), ischemic stroke (cerebral infarction), and hemorrhagic stroke.
2. Identify modifiable and nonmodifiable risk factors associated with ischemic stroke and hemorrhagic stroke.
3. Explain the pathophysiology of ischemic stroke and hemorrhagic stroke.
4. Describe the clinical presentation of TIA, ischemic stroke, and hemorrhagic stroke.
5. Formulate strategies for primary prevention of acute ischemic stroke.
6. Evaluate treatment options for acute ischemic stroke.
7. Determine whether fibrinolytic therapy is indicated in a patient with acute ischemic stroke.
8. Evaluate the role of endovascular therapy in a patient with acute ischemic stroke.
9. Formulate strategies for secondary prevention of acute ischemic stroke.
10. Evaluate treatment options for acute hemorrhagic stroke.

INTRODUCTION

Cerebrovascular disease comprises stroke, as well as carotid stenosis, vertebral stenosis and intracranial stenosis, aneurysms, and vascular malformations. Stroke is the second most common cause of death worldwide and is the fifth leading cause of death in the United States. Stroke is an acute medical emergency, and rapid treatment dependent on the type of stroke (ischemic or hemorrhagic) is critical. Treatment of risk factors and preventive measures are also paramount in the management of stroke. Decades of progress in treatment and prevention have resulted in a decrease in both stroke incidence and stroke case fatality rates.[1] Stroke mortality rates are higher in women than men and geographic variability exists, with higher mortality rates observed in the southeastern United States, termed the “stroke belt.”

EPIDEMIOLOGY

Approximately 795,000 strokes occur in the United States each year. New strokes account for 610,000 of this total; recurrent strokes account for the remaining 185,000. Stroke incidence increases with age, especially after age 55 years, resulting in an increased incidence in the elderly population.[2] Stroke is the leading cause of long-term disability in adults, with 90% of survivors having residual deficits. Moderate-to-severe disability is seen in 70% of stroke survivors, and 15% to 30% of survivors are permanently disabled. The American Heart Association estimates there are currently over 7 million stroke survivors in the United States. Societal impact and economic burden are great, with total costs of $33.9 billion reported in the United States in 2013.

ETIOLOGY AND CLASSIFICATION

Strokes can either be ischemic (87% of all strokes) or hemorrhagic (13% of all strokes). **KEY CONCEPT** Ischemic stroke, which may be thrombotic or embolic, is the abrupt development of a focal neurological deficit that occurs due to inadequate blood supply to an area of the brain. A thrombotic occlusion occurs when a **thrombus** forms inside an artery in the brain. An embolic stroke typically occurs when a piece of thrombus, originating either inside or outside of the cerebral vessels, breaks loose and is carried to the site of occlusion in the cerebral vessels. An extracerebral source of emboli is often the heart, leading to cardioembolic stroke.

KEY CONCEPT Hemorrhagic stroke is a result of bleeding into the brain and other spaces within the central nervous system (CNS) and includes subarachnoid hemorrhage (SAH), intracerebral hemorrhage (ICH), and subdural **hematomas**. SAH results from sudden bleeding into the space between the inner and middle layers of the meninges, most often due to trauma or rupture of a cerebral **aneurysm** or **arteriovenous malformation** (AVM). ICH is bleeding directly into the brain parenchyma, often as a result of chronic uncontrolled hypertension. Subdural hematomas result from bleeding under the dura covering the brain and most often occur as a result of head trauma. For hemorrhagic events associated with stroke, refer to the Clinical Presentation and Diagnosis of Stroke text box.

Cerebral Ischemic Events

There are two main classifications of cerebral ischemic events: transient ischemic attack (TIA) and ischemic stroke (cerebral infarction). A TIA is a transient episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia without acute infarction. TIAs have a rapid onset and short duration, typically lasting less than 1 hour and often less than 30 minutes. Symptoms vary depending on the area of the brain affected; however, no deficit remains after the attack.[3] **KEY CONCEPT** TIAs are a risk factor for acute ischemic stroke and represent a continuum in cerebral ischemic events from TIA to ischemic stroke.[4] Ischemic stroke is similar to TIA; however, tissue injury and infarction are present, and in many patients, residual deficits remain after the event. A standardized tissue-based definition of cerebral infarction has been established as brain, spinal cord, or retinal cell death attributable to ischemia, based on neuropathological, neuroimaging, and/or clinical evidence of permanent injury.[5]

Risk Factors

Assessment of risk factors for ischemic stroke and hemorrhagic stroke is an important component of stroke prevention, diagnosis, and treatment. Major goals in the long-term management of ischemic stroke involve primary prevention (prevention of first stroke) and secondary prevention (prevention of a recurrent stroke). Risk factors for ischemic stroke are divided into modifiable and nonmodifiable (Table 12–1). Hypertension is one of the major risk factors for both ischemic and hemorrhagic stroke. Other risk factors for hemorrhagic stroke include trauma, cigarette smoking, cocaine use, heavy alcohol use, anticoagulant use, and cerebral aneurysm and AVM rupture.[6,7] Every patient should have risk factors assessed and treated, if possible, because management can decrease the occurrence and/or recurrence of stroke.

Table 12–1

Nonmodifiable and Modifiable Risk Factors for Ischemic Stroke

Nonmodifiable Risk Factors
- Age (> 55 years)
- Gender (males > females at older ages; females have higher incidence of stroke due to having a longer lifespan; females have increased mortality from stroke)
- Race and ethnicity (American Indian/Alaska Natives, African American, Asian/Pacific Islander, Hispanic)
- Genetic predisposition
- Low birth weight

Well-Documented and Modifiable Risk Factors
- Hypertension (most important risk factor)
- Cardiac disease
  - Atrial fibrillation (most important and treatable cardiac cause of stroke)
  - Valvular heart disease
  - Left atrial enlargement
  - Structural abnormalities such as atrial septal aneurysm
  - Acute myocardial infarction
- Transient ischemic attacks or prior stroke (major independent risk factor)
- Diabetes (independent risk factor)
- Dyslipidemia
- Asymptomatic carotid stenosis
- Oral contraceptive use (with estrogen content > 50 mcg)
- Postmenopausal hormone therapy
- Sickle cell disease
- Lifestyle factors
  - Cigarette smoking
  - Excessive alcohol use
  - Physical inactivity
  - Obesity
  - Diet
  - Cocaine and intravenous drug use
  - Low socioeconomic status

Less Well-Documented or Potentially Modifiable Risk Factors
- Increased hematocrit
- Metabolic syndrome
- Hyperhomocysteinemia
- Migraine (risk not clear)
- Sleep disordered breathing (ie, sleep apnea)

PATHOPHYSIOLOGY

Ischemic Stroke

In ischemic stroke, there is an interruption of the blood supply to an area of the brain either due to thrombus formation or an embolism. Loss of cerebral blood flow results in tissue hypoperfusion, tissue hypoxia, and cell death. Thrombus formation usually starts with lipid deposits in the vessel wall that cause turbulent blood flow. This leads to vessel injury and exposure of vessel collagen to blood. This vessel injury initiates the platelet aggregation process due to the exposed subendothelium. Platelets release adenosine diphosphate (ADP), which causes platelet aggregation and consolidation of the platelet plug. Thromboxane A_2 is released, contributing to platelet aggregation and vasoconstriction. The vessel injury also activates the coagulation cascade, which leads to thrombin production. Thrombin converts fibrinogen to fibrin, leading to clot formation as fibrin molecules, platelets, and blood cells aggregate. Refer to Figures 8–3, 11–3, and 11–4 for a depiction of these processes.

After the initial event, secondary events occur at the cellular level that contribute to cell death. Regardless of the initiating event, the cellular processes that follow may be similar. Excitatory amino acids such as glutamate accumulate within the cells, causing intracellular calcium accumulation. Inflammation occurs and oxygen free radicals are formed resulting in the common pathway of cell death.

There is often a core of ischemia containing unsalvageable brain cells. Surrounding this core is an area termed the ischemic penumbra. In this area, cells are still salvageable; however, this is time-sensitive. Without restoration of adequate perfusion, cell death continues throughout a larger area of the brain, ultimately leading to neurological deficits.

Hemorrhagic Stroke

The pathophysiology of hemorrhagic stroke is related to the presence of blood in the brain tissue and/or surrounding spaces resulting in compression. The hematoma that forms may continue to grow and enlarge after the initial bleed, and early growth is associated with a poor outcome. Brain tissue swelling and injury is a result of inflammation caused by thrombin and other blood products. This can lead to increased intracranial pressure (ICP) and herniation. Delayed cerebral ischemia, or vasospasm, is a potential consequence of aneurysmal SAH that results in vasoconstriction of cerebral vessels and clinical symptoms of ischemia.

PRIMARY PREVENTION OF ISCHEMIC STROKE

Aspirin

Use of aspirin (ASA) in patients with no history of stroke or ischemic heart disease reduced the incidence of nonfatal myocardial infarction (MI) but not stroke. Primary prevention guidelines recommend ASA for general cardiovascular prophylaxis (not specific to stroke) in men and women with a 10-year cardiovascular risk of greater than 10% and in women who are at high risk for stroke. ASA may be considered for prevention of a first stroke in patients with chronic kidney disease, and cilostazol may be considered for prevention of a first stroke in patients with peripheral arterial disease. The benefits must be weighed against the risk of major bleeding. Due to lack of benefit observed in clinical trials, ASA is not recommended for primary prevention in patients with diabetes and asymptomatic peripheral arterial disease, or in those at low risk.[8]

Clinical Presentation and Diagnosis of Stroke

General

- Patient may not be able to reliably report history due to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

Symptoms of Ischemic Stroke

- The patient may complain of weakness on one side of the body, facial droop, inability to speak, loss of vision, vertigo, headache, or falling.

Signs of Ischemic Stroke

- Patients usually have multiple signs of neurological dysfunction, and specific deficits are determined by the area of the brain involved.
- Hemiparesis or monoparesis occur commonly, as does a hemisensory deficit.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- Aphasia is seen commonly in patients with anterior circulation strokes.
- Patients may also suffer from dysarthria, visual field defects, and altered levels of consciousness.

Signs and Symptoms of Hemorrhagic Stroke

- A sudden severe headache, nausea, vomiting, and photophobia may be the first signs and symptoms. Patients may complain the headache is "the worst headache of my life."
- Neck pain and nuchal rigidity (stiffness) may also be experienced.

**It is important to note that diagnosis of type of stroke cannot be made solely on signs and symptoms because overlap occurs between types of stroke.

Laboratory Tests

- There are no specific laboratory tests for stroke.
- Tests for hypercoagulable states, such as protein C deficiency and antiphospholipid antibody, should be done only when cause of stroke cannot be determined based on presence of well-known risk factors.

Other Diagnostic Tests

- Computed tomography (CT) scan of the head will reveal an area of hyperintensity (white) identifying that a hemorrhage has occurred. CT scan will either be normal or hypointense (dark) in an area where an infarction has occurred. It may take 24 hours (and rarely longer) to reveal the area of infarction on a CT scan.
- Magnetic resonance imaging (MRI) of the head will reveal areas of ischemia earlier and with better resolution than a CT scan. Diffusion-weighted imaging can reveal an evolving infarct within minutes.
- Carotid Doppler studies will determine whether the patient has a high degree of stenosis (blockage of an artery) in the carotid arteries, which are the vessels that supply blood to the brain (extracranial disease).
- Electrocardiogram (ECG) will determine whether the patient has atrial fibrillation (AF), a major risk factor for cardioembolic stroke.
- Transthoracic echocardiogram will identify whether there are heart valve abnormalities or problems with wall motion of the heart resulting in emboli to the brain.

▶ *Diabetes*

Diabetes is an independent risk factor for stroke. Intensive glycemic control has not been shown to reduce stroke risk in either type 1 or type 2 diabetes mellitus. Adequate control of blood pressure (BP) to a target level of less than 130/80 mm Hg and management of dyslipidemia are recommended in individuals with diabetes. The use of a statin is also recommended to prevent a first stroke.[8-10] Hypertension guidelines recommend initial therapy that includes a thiazide-type diuretic, calcium channel blocker (CCB), angiotensin-converting enzyme inhibitor (ACE-I), or angiotensin receptor blocker (ARB).[9] The guidelines suggest that in Black patients with diabetes, initial antihypertensive therapy should include a thiazide-type diuretic or a CCB.[9]

Patient Encounter Part 1

A 63-year-old, 101.2-kg (223 lb), 5 ft 9 in (175 cm) White man presents to the emergency department with weakness in his right arm and leg, a right facial droop and speech difficulty that began suddenly 90 minutes earlier. He was attending a family event and was well prior to symptom onset. His past medical history is significant for hypertension, diabetes, and obesity. Social history includes alcohol use of three to four drinks per day on five to six nights per week and smoking one pack per day for 30 years. Current medications include metformin 500 mg twice daily, empagliflozin 10 mg daily, hydrochlorothiazide 50 mg daily, and amlodipine 5 mg daily.

What signs and symptoms does the patient have that are suggestive of stroke?

What nonmodifiable and modifiable risk factors does he have for acute ischemic stroke?

▶ *Dyslipidemia*

Clinical studies have found a relationship between total cholesterol levels and stroke rate. Statin use, in addition to lifestyle modifications, is recommended for primary prevention of ischemic stroke in patients estimated to have a high 10-year risk of cardiovascular events.[8] Treatment recommendations are based on current guidelines for treatment of blood cholesterol.[10] The benefit of other lipid-lowering therapies on stroke risk has not been established.[8]

▶ *Hypertension*

Hypertension is the most important and well-documented risk factor for stroke. Lowering BP in hypertensive patients reduces the relative risk of both ischemic and hemorrhagic stroke. All patients should have BP monitored and controlled appropriately based on current guidelines for BP management.[9] In patients without cardiovascular disease (CVD), treatment with BP-lowering medications is recommended in patients with an estimated 10-year atherosclerotic CVD (ASCVD) risk of 10% or greater and systolic blood pressure (SBP) greater than or equal to 130 mm Hg or diastolic blood pressure (DBP) greater than or equal to 80 mm Hg, or in those patients with an estimated 10-year ASCVD risk less than 10% and an SBP greater than or equal to 140 mm Hg or a DBP greater than or equal to 90 mm Hg.[9] A meta-analysis of multiple trials found that more intensive BP lowering reduced the risk of stroke by 20% over a less-intensive BP-lowering strategy.[11] Many patients require two or more drug therapies to achieve BP control. For primary prevention of stroke, reduction in BP is the main goal because one antihypertensive agent has not been clearly shown to be more beneficial than any other. Refer to Chapter 6, "Hypertension."

▶ *Smoking Cessation*

The relationship between smoking and both ischemic and hemorrhagic stroke is clear. Smoking status should be assessed at every patient visit. Patients should be assisted and encouraged in smoking cessation as stroke risk declines over time after cessation. Effective treatment options are available including counseling, nicotine replacement products, and oral agents.

▶ *Other Treatments*

A number of other disease states and lifestyle factors should be addressed as primary prevention of stroke. AF is an important and well-documented risk for stroke. See Chapter 10, "Arrhythmias," for information on stroke prevention in AF. Asymptomatic carotid stenosis, cardiac disease, sickle cell disease, obesity, excessive alcohol use, and physical inactivity are other risks that should be assessed and managed appropriately.

TREATMENT

Desired Outcomes

Short-term treatment goals for acute ischemic stroke include reducing secondary brain damage by reestablishing and maintaining adequate perfusion to marginally ischemic areas of the brain and protecting these areas from the effects of ischemia (ie, neuroprotection). **KEY CONCEPT** Long-term treatment goals for acute ischemic stroke include prevention of a recurrent stroke through reduction and modification of risk factors and by use of appropriate treatments.

Short-term treatment goals for hemorrhagic stroke include rapid neurointensive care to maintain adequate oxygenation, breathing, and circulation. Management of increased ICP and BP are important in the acute setting. Long-term management includes prevention of complications and of a recurrent bleed and delayed cerebral ischemia. Prevention of long-term disability and death related to stroke is important regardless of stroke type.

General Approach

KEY CONCEPT All patients should have a brain CT or MRI scan to differentiate an ischemic stroke from a hemorrhagic stroke because treatment differs, and fibrinolytic therapy must be avoided until hemorrhagic stroke is ruled out. A noncontrast CT or MRI scan is the most important initial diagnostic test in patients with acute stroke. For those with an ischemic stroke, an evaluation should be done to determine the appropriateness of reperfusion therapy. In hemorrhagic stroke, a surgical evaluation should be completed to assess the need for surgical clipping of an aneurysm or other procedure to control the bleeding and prevent rebleeding and other complications. Figure 12–1 provides an algorithm for initial management of the acute stroke patient.

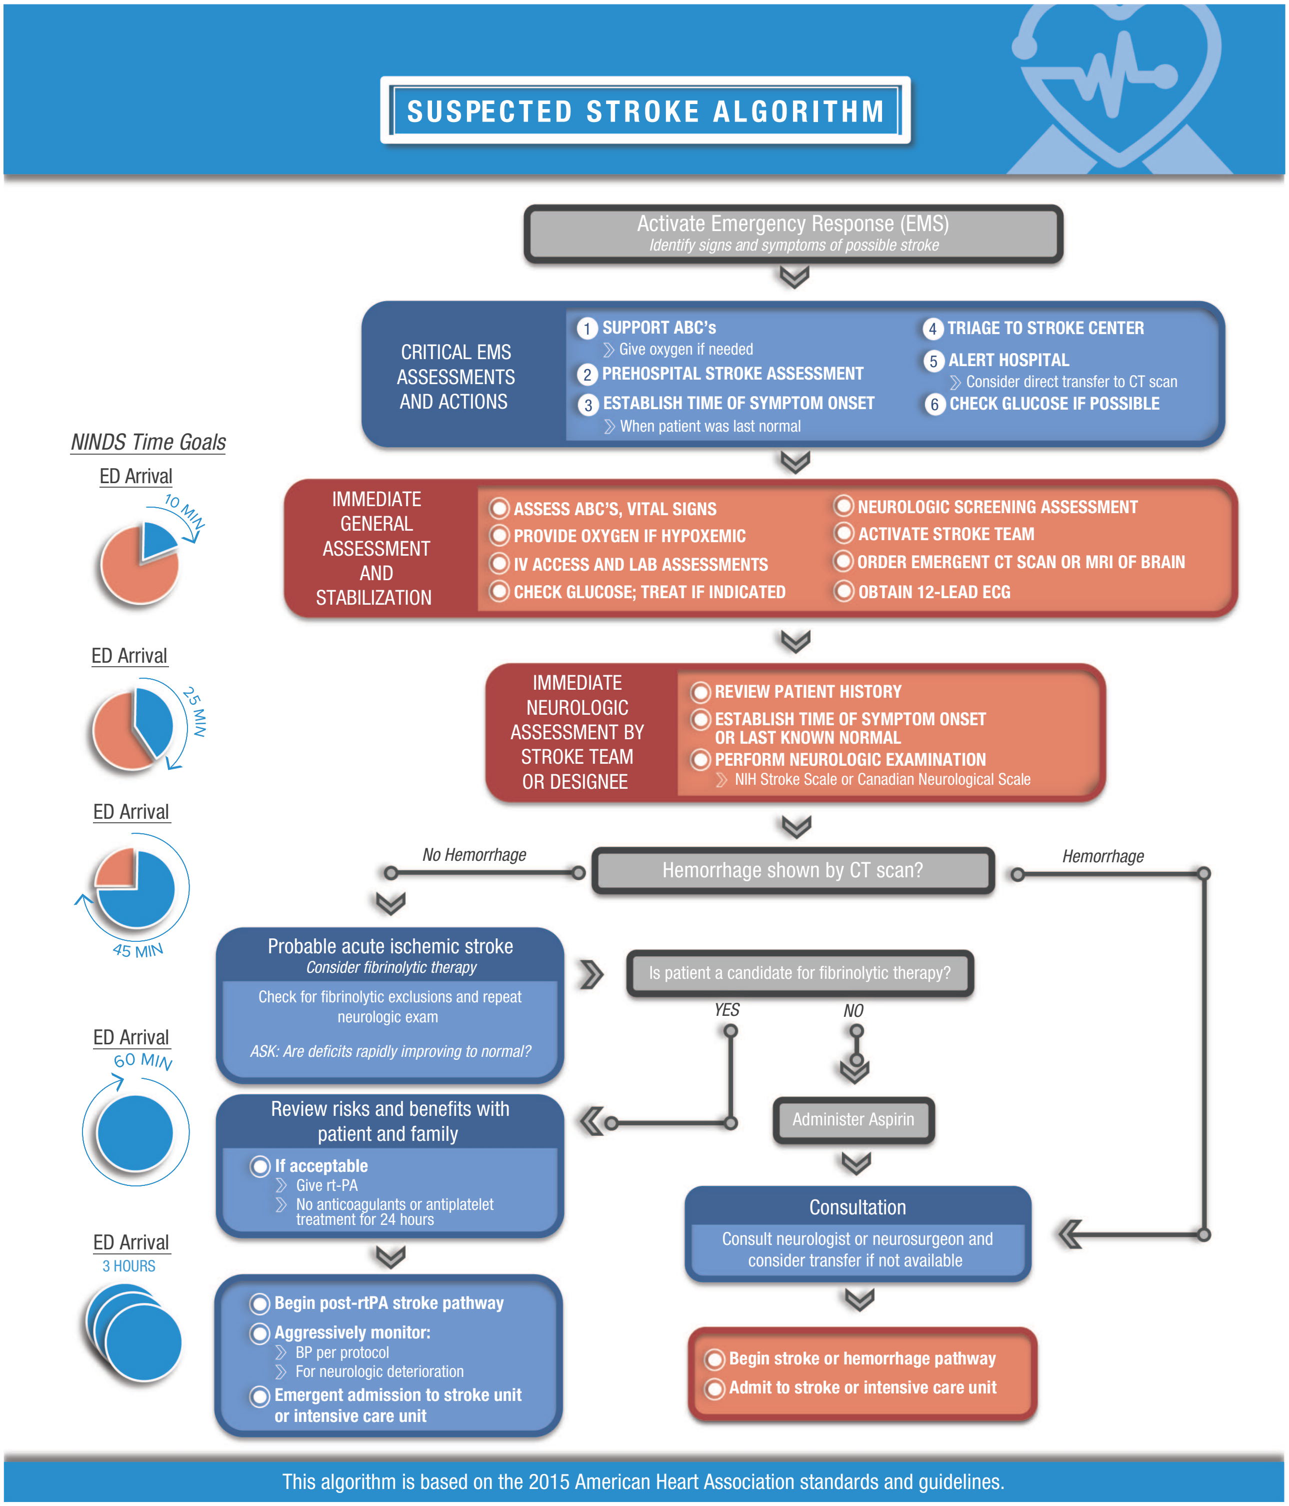
Early Management of Acute Ischemic Stroke

Acute ischemic stroke is a medical emergency. Identification of the time of symptom onset and symptom presentation are important determinants in treatment. The time the patient was last without symptoms is used as the time of stroke onset. Because patients typically do not experience pain, determining the onset time can be difficult. It is also important to document risk factors, previous functional status, and the National Institutes of Health Stroke Scale (NIHSS) to assess stroke severity and current disability due to stroke. The NIHSS is a 42-point scale that quantifies neurological deficits in stroke patients. It is easy to perform and is used as a measure of daily functioning.

▶ *Supportive Measures*

Acute complications of ischemic stroke include cerebral edema, increased ICP, seizures, and hemorrhagic conversion (ie, conversion of ischemic stroke into hemorrhagic stroke). In the acute setting, supportive interventions and treatments to prevent acute complications should be initiated. Continuous cardiac monitoring, most commonly with a Holter monitor, should be continued for the first 24 hours to screen for AF and other cardiac diseases.[12] Tissue oxygenation should be maintained acutely. Measure oxygen saturation using pulse oximetry and supplement the patient with oxygen if necessary. Oxygen saturation should be maintained at 94% (0.94) or greater.[12] Volume status and electrolytes should be corrected. If required, blood glucose should be corrected because both hyperglycemia and hypoglycemia may worsen brain ischemia. When blood glucose less than 60 mg/dL (3.3 mmol/L) is present, bolus with 25 mL of 50% dextrose immediately. Patients with elevated blood glucose poststroke have been documented to have worse outcomes; therefore, lowering blood glucose to between 140 and 180 mg/dL (7.8–10.0 mmol/L) with subcutaneous insulin is a reasonable approach.[12,13] If the patient is febrile, treat with acetaminophen because fever is associated with brain ischemia and increased morbidity and mortality after stroke. Alternatively, cooling devices can be used.[12] Low-dose unfractionated heparin (UFH) or low-dose low-molecular-weight heparin (LMWH) administered subcutaneously significantly decreases the risk of developing venous thromboembolism (VTE) poststroke. Low-dose UFH or LMWH should be initiated for VTE prophylaxis in patients who are not candidates for intravenous (IV) fibrinolytic therapy. In patients receiving fibrinolytic therapy, VTE prophylaxis with low-dose UFH or LMWH should be delayed until 24 hours after fibrinolytic administration to avoid bleeding complications.

In the setting of acute ischemic stroke, up to 80% of patients have an elevated BP in the first 24 to 48 hours.[9,12] BP should be checked three times with each reading taken 5 minutes apart. BP should be optimized; however, hypertension should generally not be treated in the acute period (12–24 hours) because it may cause decreased blood flow in ischemic areas, potentially increasing the infarction size. The cautious use of antihypertensive medications may be necessary in patients with severely elevated BP (SBP > 220 mm Hg or DBP > 120 mm Hg) who are otherwise candidates for fibrinolytic therapy or endovascular therapy. Antihypertensive therapy may also be necessary



SUSPECTED STROKE ALGORITHM
Activate Emergency Response (EMS)
Identify signs and symptoms of possible stroke
CRITICAL EMS ASSESSMENTS AND ACTIONS
1 SUPPORT ABC's
Give oxygen if needed
2 PREHOSPITAL STROKE ASSESSMENT
3 ESTABLISH TIME OF SYMPTOM ONSET
When patient was last normal
4 TRIAGE TO STROKE CENTER
5 ALERT HOSPITAL
Consider direct transfer to CT scan
6 CHECK GLUCOSE IF POSSIBLE
NINDS Time Goals
ED Arrival
10 MIN
IMMEDIATE GENERAL ASSESSMENT AND STABILIZATION
ASSESS ABC'S, VITAL SIGNS
PROVIDE OXYGEN IF HYPOXEMIC
IV ACCESS AND LAB ASSESSMENTS
CHECK GLUCOSE; TREAT IF INDICATED
NEUROLOGIC SCREENING ASSESSMENT
ACTIVATE STROKE TEAM
ORDER EMERGENT CT SCAN OR MRI OF BRAIN
OBTAIN 12-LEAD ECG
ED Arrival
25 MIN
IMMEDIATE NEUROLOGIC ASSESSMENT BY STROKE TEAM OR DESIGNEE
REVIEW PATIENT HISTORY
ESTABLISH TIME OF SYMPTOM ONSET OR LAST KNOWN NORMAL
PERFORM NEUROLOGIC EXAMINATION
NIH Stroke Scale or Canadian Neurological Scale
ED Arrival
45 MIN
No Hemorrhage
Hemorrhage shown by CT scan?
Hemorrhage
Probable acute ischemic stroke
Consider fibrinolytic therapy
Check for fibrinolytic exclusions and repeat neurologic exam
ASK: Are deficits rapidly improving to normal?
Is patient a candidate for fibrinolytic therapy?
YES
NO
ED Arrival
60 MIN
Review risks and benefits with patient and family
If acceptable
Give rt-PA
No anticoagulants or antiplatelet treatment for 24 hours
Administer Aspirin
ED Arrival
3 HOURS
Consultation
Consult neurologist or neurosurgeon and consider transfer if not available
Begin post-rtPA stroke pathway
Aggressively monitor:
BP per protocol
For neurologic deterioration
Emergent admission to stroke unit or intensive care unit
Begin stroke or hemorrhage pathway
Admit to stroke or intensive care unit
This algorithm is based on the 2015 American Heart Association standards and guidelines.

FIGURE 12–1. Suspected stroke treatment algorithm. (ABC, airway, breathing, and circulation; BP, blood pressure; CT, computed tomography; ECG, electrocardiogram; ED, emergency department; EMS, emergency medical services; IV, intravenous; MRI, magnetic resonance imaging; NIH, National Institutes of Health; NINDS, National Institute of Neurological Disorders and Stroke; rt-PA, alteplase.) in patients with stroke and other medical disorders, including aortic aneurysm rupture, MI, and heart failure, that require immediate lowering of BP. Tables 12–2 and 12–3 provide recommendations on BP management in those eligible and not eligible for fibrinolytic therapy. These recommendations apply to patients being evaluated for endovascular therapy as well as similar BP guidelines have been utilized in these patients.[12] In those not eligible for fibrinolytic or endovascular therapy, if BP reduction is necessary, aim for a 15% reduction in SBP and DBP in the first 24 hours after stroke onset.

Table 12–2

Blood Pressure (BP) Recommendations for Ischemic Stroke (Eligible for Reperfusion Therapy)

Before treatment: If systolic BP > 185 mm Hg or diastolic BP > 110 mm Hg	Use either labetalol 10–20 mg IV over 1–2 minutes (may repeat once after 10 minutes) or nicardipine 5 mg/hour IV (titrate up by 2.5 mg/hour every 5–15 minutes; maximum dose 15 mg/hour) or clevidipine 1–2 mg/hour IV (titrate by doubling the dose every 2–5 minutes; maximum dose 21 mg/hour) or may consider other agents (hydralazine, enalaprilat)
During and after treatment to maintain BP ≤ 180/105 mm Hg:	
• If systolic BP > 180–230 mm Hg or diastolic BP > 105–120 mm Hg	Use either labetalol 10 mg IV over 1–2 minutes followed by labetalol continuous IV infusion 2–8 mg/min or nicardipine 5 mg/hour IV (titrate up by 2.5 mg/hour every 5–15 minutes; maximum dose 15 mg/hour) or clevidipine 1–2 mg/hour IV (titrate by doubling the dose every 2–5 minutes; maximum dose 21 mg/hour)
• If BP not controlled or diastolic BP > 140 mm Hg	Nitroprusside 0.3–0.5 mcg/kg/min titrated by 0.5 mcg/kg/min to response; maximum dose 10 mcg/kg/min

IV, intravenous.

▸ *Fibrinolytic Therapy*

Alteplase American Stroke Association guidelines recommend alteplase (rt-PA; Activase) as first-line acute treatment for ischemic stroke and strongly encourage early diagnosis and treatment of appropriate patients.[12] Alteplase is an IV fibrinolytic approved for acute ischemic stroke treatment within 3 hours of symptom onset based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Trial.[14] Patients treated with alteplase were 30% more likely to have minimal or no disability at 3 months. ICH within 36 hours after stroke onset occurred in 6.4% of those given alteplase versus 0.6% in those given placebo. There was no significant difference in mortality between the two groups at 3 months or 1 year. A dose of 0.9 mg/kg (maximum 90 mg) is recommended; the first 10% is given as an IV bolus, and the remainder is infused over 1 hour.

Subsequent studies that followed the NINDS trial protocol have supported alteplase use in acute ischemic stroke with similar rates for response and ICH occurrence when administered up to 4.5 hours after stroke onset. Current clinical guidelines support this recommendation.[12] Pooled data analyses have found that alteplase provides a beneficial effect on stroke outcomes measured at 3 to 6 months independent of patient age and stroke severity with better neurological outcomes obtained the sooner alteplase is given after stroke symptom onset.[12,15,16] Additional exclusion criteria were initially utilized when alteplase was administered between 3 and 4.5 hours after symptom onset including age greater than 80, use of oral anticoagulants regardless of international normalized ratio (INR), NIHSS greater than 25, and the combination of stroke and diabetes. A scientific advisory from the American Heart Association/American Stroke Association has provided guidance on inclusion and exclusion criteria for alteplase based on clinical trial data and provides levels of evidence for each criteria.[17] This advisory and current guidelines recommend that alteplase may be given 3 to 4.5 hours after symptom onset in patients regardless of age, in those on warfarin with an INR less than or equal to 1.7, in mild disabling stroke, and in those with diabetes and stroke.[12,17] **KEY CONCEPT** Current guidelines recommend alteplase use within 4.5 hours after stroke onset in selected patients regardless of age to improve stroke outcomes. The guidelines recommend that alteplase be started as soon as possible within this window of time and recommend that centers establish internal treatment goals.[12] Alteplase is commonly withheld in patients with minor or rapidly improving stroke symptoms and in patients with stroke symptoms upon awakening. A recent cohort analysis found the risk of stroke to be 9.5% at 5 years after a TIA or mild stroke.[18] An observational study demonstrated a benefit to alteplase treatment in minor stroke.[19] However, a clinical trial comparing aspirin or alteplase within 3 hours of stroke symptom onset for acute, nondisabling stroke found no difference in outcome at 90 days.[20] This study was stopped early due to low recruitment, so while suggestive, these results are not conclusive. Further research is underway to determine a definitive recommendation for minor stroke.[21] Alteplase is currently contraindicated in minor, nondisabling stroke.[12]

Trials have evaluated patients with unknown onset of stroke, but who are greater than 4.5 hours after last known to be well or symptoms upon awakening.[22,23] These trials used specific enrollment criteria based on imaging and compared alteplase to placebo between 4.5 and 9 hours from the time last known to be well.

Table 12–3

Blood Pressure (BP) Recommendations for Ischemic Stroke (Not Eligible for Reperfusion Therapy)

Systolic BP < 220 mm Hg and diastolic BP < 120 mm Hg	Observe unless other end-organ involvement
Systolic BP ≥ 220 mm Hg or diastolic BP 121–140 mm Hg	Labetalol 10–20 mg IV over 1–2 minutes (may repeat every 10–20 minutes; maximum dose 300 mg) or nicardipine IV 5 mg/hour (titrate up by 2.5 mg/hour every 5–15 minutes; maximum dose 15 mg/hour; titrate to response) or clevidipine 1–2 mg/hour IV (titrate by doubling the dose every 2–5 minutes; maximum dose 21 mg/hour; titrate to response)
Diastolic BP > 140 mm Hg	Nitroprusside 0.3–0.5 mcg/kg/min titrated by 0.5 mcg/kg/min to response; maximum dose 10 mcg/kg/min

IV, intravenous.

Table 12–4

Inclusion and Exclusion Criteria for Alteplase (rt-PA) Use in Acute Ischemic Stroke

Inclusion Criteria
- 18 years of age or older
- Clinical diagnosis of ischemic stroke causing a measurable neurological deficit
- Time of symptom onset well established to be < 4.5 hours before treatment would begin

Exclusion Criteria
- Nondisabling mild stroke (NIHSS 0–5)
- Evidence of multilobar infarction on CT scan of the brain (> 1/3 cerebral hemisphere) prior to treatment
- Clinical presentation suggestive of SAH even with a normal head CT or intracranial hemorrhage on imaging
- Active internal bleeding
- Known bleeding diathesis, including but not limited to (a) platelet count less than $100 \times 10^3/\text{mm}^3$ (100×10^9/L); (b) full-dose heparin within 24 hours with an elevated aPTT (> 40 seconds); or (c) current oral anticoagulant use (eg, warfarin) or recent use with an elevated PT (> 15 seconds) or INR (> 1.7)
- Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (aPTT, INR, platelet count, and ECT; TT; or appropriate factor Xa activity assays)
- Blood glucose concentration < 50 mg/dL (2.8 mmol/L)
- Intracranial or intraspinal surgery, significant head trauma, or previous stroke within 3 months
- Previous intracranial hemorrhage
- Intracranial neoplasm
- GI malignancy
- Clinical presentation suggestive of infective endocarditis or aortic arch dissection
- Gastrointestinal hemorrhage within previous 21 days
- SBP > 185 mm Hg or DBP > 110 mm Hg at time of treatment, or patient requires aggressive treatment to reduce BP to within these limits
- Ischemic stroke or severe head trauma within 3 months

Relative Exclusion Criteria
- Consider risk to benefit of IV rt-PA if any relative contraindications are present:
  - Pregnancy
  - Major surgery or serious trauma within 14 days
  - Recent arterial puncture at a noncompressible site in previous 7 days
  - Lumbar puncture within 7 days
  - Known unruptured AVM or aneurysm
  - Urinary tract bleeding
  - Acute MI or MI within 3 months
  - Witnessed seizure at onset of stroke symptoms with postictal residual neurological impairments

Additional Criteria for Treatment Between 3 and 4.5 Hours
- Benefit uncertain in severe strokes (NIHSS ≥ 25)

aPTT, activated partial thromboplastin time; AVM, arteriovenous malformation; BP, blood pressure; CT, computed tomography; DBP, diastolic blood pressure; ECT, ecarin clotting time; GI, gastrointestinal; INR, international normalized ratio; IV, intravenous; MI, myocardial infarction; NIHSS, National Institute of Health Stroke Scale; PT, prothrombin time; SAH, subarachnoid hemorrhage; SBP, systolic blood pressure; TT, thrombin time.

In patients meeting the enrollment criteria, alteplase may be an option in this timeframe if thrombectomy is not available. Table 12–4 details the inclusion and exclusion criteria for administration of alteplase in acute ischemic stroke.

Efficacy is measured by elimination of existing neurological deficits and long-term improvement in neurological status and functioning based on neurological examinations and other outcome measures. BP measurements and neurological examinations should be completed every 15 minutes during and after the infusion of alteplase for 2 hours, every 30 minutes for the next 6 hours, and then every hour until 24 hours after alteplase administration. Patients should be assessed using the NIHSS at baseline and 24 hours after the administration of alteplase.

The major adverse effects of fibrinolytic therapy are bleeding, including ICH and serious systemic bleeding. Mental status changes and a severe headache may indicate ICH. Signs of systemic bleeding include easy bruising; hematemesis; guaiac-positive stools; black, tarry stools; hematoma formation; hematuria; bleeding gums; and nosebleeds. Angioedema is a potential side effect that may cause airway obstruction.

Antiplatelet agents, anticoagulants, and invasive procedures such as insertion of a central line, placement of a nasogastric tube, and bladder catheterization should be avoided for 24 hours after infusion of alteplase to prevent bleeding complications. A CT scan should be obtained 24 hours after IV infusion of alteplase before initiating anticoagulants or antiplatelet agents.

Other Fibrinolytics Tenecteplase is a thrombolytic having more fibrin-specificity and a longer half-life than alteplase. It is administered as a single IV push injection due to these properties. Clinical trials that have been completed evaluating tenecteplase for acute ischemic stroke have compared different dosages and administration times. A meta-analysis of completed trials revealed no difference in outcome at 90 days between tenecteplase and alteplase.[24] The acute stroke guidelines state that tenecteplase 0.4 mg/kg IV bolus may be considered in patients with minor neurological impairment and no major intracranial occlusion.[12] Tenecteplase 0.25 mg/kg (maximum 25 mg) IV bolus may also be useful in place of alteplase in patients without contraindications to thrombolytics eligible for thrombectomy.[12] Fibrinolytic agents, other than alteplase and tenecteplase, and the defibrinogenating

Patient Encounter Part 2

In the emergency department, an IV line is placed, a physical and neurological examination is completed, and the patient is moved to the stroke unit. A head noncontrast CT scan is negative for hemorrhagic stroke and reveals a diffuse hypodensity on the left. The patient's BP on admission to the stroke unit is 188/112 mm Hg, glucose is 138 mg/dL (7.7 mmol/L), temperature is 37.1°C (98.8°F), and NIHSS score is 12. The patient denies other exclusions to IV alteplase. The neurologist is evaluating him for alteplase administration and endovascular therapy.

Identify acute treatment goals for the patient.

Is he a candidate for IV alteplase at this time?

What acute management would be appropriate for the patient in the stroke unit?

agents are not recommended for treatment unless associated with a clinical trial.[12]

Intra-arterial Fibrinolytics Early clinical trials evaluating intra-arterial (IA) fibrinolytics evaluated pro-urokinase (r-pro UK). A statistically significant benefit with treatment was found in one trial.[25] Pro-urokinase is not Food and Drug Administration (FDA)-approved for acute stroke treatment and is not available in the United States. Since embolectomy devices have advanced and are now the preferred endovascular therapy, the use of IA fibrinolytics without endovascular therapy is not recommended as first-line therapy in patients with acute ischemic stroke.[12]

▶ *Heparin*

Full-dose IV UFH has been previously used in acute stroke therapy; however, no adequately designed trials have been conducted to establish its efficacy and safety. Current acute ischemic stroke treatment guidelines do not recommend routine, urgent full-dose anticoagulation with UFH due to lack of a proven benefit in improving neurological function and the risk of intracranial bleeding.[12,26] The major complications of heparin include conversion of ischemic stroke into hemorrhagic stroke, bleeding, and thrombocytopenia. Occurrence of severe headache and mental status changes may indicate ICH. Signs of bleeding mirror those listed for alteplase therapy.

▶ *LMWHs and Heparinoids*

Full-dose LMWHs and heparinoids are not recommended in the treatment of acute ischemic stroke.[12,27] Studies with these agents have generally been negative, with no convincing evidence of improved outcomes after ischemic stroke. Increased risks of bleeding complications and hemorrhagic transformation have been observed.

▶ *Thrombin Inhibitors*

Several thrombin inhibitors have been approved for stroke prevention in patients with AF and may have a potential benefit in acute stroke treatment. Currently, use of these agents in acute stroke treatment is not well established, and it is recommended that their use be in conjunction with a clinical trial.[12] A clinical trial evaluated the use of dabigatran within 24 hours of stroke onset to prevent early stroke recurrence in patients without AF.[28] Argatroban was evaluated in patients receiving alteplase administered as a bolus within 1 hour of alteplase administration followed by an infusion for 48 hours. The study found an increased likelihood of a good outcome at 90 days.[29] Further clinical trials are needed to establish the role of these agents in the acute setting.

▶ *Antiplatelet Agents*

ASA use in acute ischemic stroke has been studied in two large randomized trials. Patients who received ASA within 48 hours of onset of acute ischemic stroke symptoms were less likely to suffer early recurrent stroke, death, and disability. **KEY CONCEPT** ASA therapy with an initial dose of 160 to 325 mg is recommended in most patients with acute ischemic stroke within 24 to 48 hours after stroke symptom onset. ASA dose may then be decreased to 75 to 100 mg daily to reduce bleeding complications. Administration should not replace other acute stroke treatments and should be delayed for 24 hours in patients receiving alteplase or tenecteplase. In minor stroke or TIA, ASA plus clopidogrel has been compared to ASA alone started within 24 hours of stroke onset in two large clinical trials.[30,31] A meta-analysis of these trials found that in patients with minor stroke or TIA, aspirin plus clopidogrel started within 24 hours of symptom onset and continued for 21 days reduced the risk of subsequent stroke.[32] The risk of moderate-to-severe bleeding is mitigated by discontinuing dual antiplatelet therapy at 21 days. The current stroke guidelines incorporated this treatment as a new recommendation.[12]

▶ *Nonpharmacologic Therapy*

Carotid Endarterectomy It is not well established whether carotid endarterectomy (CEA; removal of a thrombus from the carotid artery) is of value when performed emergently or urgently after stroke, meaning within the first 24 hours after symptom onset.[12] Trials have concluded that patients with TIA or mild-to-moderate stable stroke undergoing CEA within 48 hours may have an acceptable surgical risk. However, patients with unstable neurological status and more severe strokes demonstrated worse outcomes.[12,33] More research is needed to delineate the role of CEA in acute treatment.

Endovascular Treatment The current stroke guidelines include updated information and recommendations for endovascular treatment based on the results of clinical trials.[12] Clinical trials initially evaluated endovascular therapy with new-generation stent retrievers in patients meeting specific criteria within 6 hours of symptom onset. A meta-analysis of five clinical trials has demonstrated an improved outcome at 90 days in patients who received endovascular therapy compared to those not receiving endovascular therapy.[34] The majority of patients in these trials received IV alteplase initially followed by endovascular therapy. IV alteplase should not be withheld if indicated, even if endovascular treatments are being considered. Stent retrievers provide immediate restoration of blood flow through expansion of the stent at the site of occlusion and clot removal as the stent is removed. Criteria include a prestroke modified Rankin score of 0 to 1, IV alteplase use within 4.5 hours of symptom onset, age 18 years and older, causative occlusion of the internal carotid artery or proximal middle cerebral artery, NIHSS score of 6 or greater, Alberta Stroke Program Early CT (ASPECT) score 6 or greater, and treatment within 6 hours of symptom onset. Endovascular therapy using stent retrievers

Patient Encounter Part 3

The patient has received two doses of IV labetalol 20 mg over 1 to 2 minutes in the stroke unit. It is now 3.5 hours since his symptoms began. He is still experiencing weakness in his right arm and leg and continues to have facial drooping and dysarthria. His current BP in the stroke unit is 176/104 mm Hg. The neurologist has also requested additional diagnostic testing including a CT angiogram to assess whether he is a candidate for endovascular therapy. The CT angiogram reveals blockage in the first segment of the middle cerebral artery.

Is he a candidate for IV alteplase at this time? If so, what is the correct dosing for this patient?

Is he a candidate for endovascular therapy at this time?

plus standard care with IV alteplase, when appropriate, may improve outcomes in select patients with acute ischemic stroke due to large vessel occlusion, if administered within 6 hours of symptom onset. More rapid endovascular treatment has also shown better clinical outcomes.[12,34]

Subsequent to these initial trials, clinical trials have evaluated endovascular therapy implemented beyond 6 hours after stroke onset and in those patients with mild stroke.[35-37] In both trials comparing endovascular therapy more than 6 hours after symptom onset plus alteplase compared to alteplase alone, those receiving endovascular therapy had a higher rate of functional independence versus the alteplase only groups. Both of these trials found no significant difference in the rate of symptomatic ICH.[35,36] The decision regarding treatment in patients with large vessel occlusion and mild stroke based on NIHSS score and stroke symptoms has been difficult, as no consensus exists for this scenario. A meta-analysis evaluating five trials meeting criteria has been completed.[37] Results demonstrated that in patients with large vessel occlusion and NIHSS score less than or equal to 5, those patients who received either thrombectomy or IV alteplase experienced a higher rate of good and excellent outcomes at 90 days. These data suggest patients with minor stroke may benefit from treatment with endovascular therapy and that it may be a useful treatment in patients not eligible for IV alteplase. The stroke guidelines suggest that it is reasonable to maintain BP less than 180/105 mm Hg during and for 24 hours after endovascular therapy.[12]

Secondary Prevention Following an Ischemic Stroke

Secondary prevention is aimed at preventing another stroke in patients that have had an initial stroke and is an important component of treatment. Once the acute ischemic stroke has been managed, typically within the first 24 to 48 hours after symptom onset, the focus shifts to secondary prevention and developing plans to prevent another stroke and manage risk factors. Antiplatelet and anticoagulant agents should be held for 24 hours following alteplase administration.

▶ *Nonpharmacologic Therapy*

Carotid Endarterectomy The benefit of CEA for prevention of recurrent stroke in specific patients has been established.[38] CEA is recommended to prevent ipsilateral stroke in patients with symptomatic carotid artery stenosis of 70% or greater when the surgical risk is less than 6%. In patients with symptomatic stenosis of 50% to 69%, a moderate reduction in risk is seen in clinical trials. CEA is recommended when anesthesia risk is low based on patient factors including age, sex, and comorbidities, and surgical risk is less than 6%. CEA is not beneficial for symptomatic carotid stenosis less than 50% and should not be considered in these patients. Patients with asymptomatic carotid artery stenosis of 60% to 99% may benefit from CEA if surgical complication rates for stroke, MI, and death are less than 3%, and the patient has a life expectancy greater than 5 years. CEA is recommended within 14 days of the initial stroke.[39]

Carotid Artery Stenting Carotid artery stenting (CAS) has evolved as a less invasive procedure with shorter recovery times for appropriate patients. CAS is an alternative to CEA in high-risk surgical candidates with greater than 50% symptomatic carotid stenosis when performed by skilled clinicians with a surgical risk less than 6%.[39] Age is an important factor when deciding between CAS and CEA. Patients older than 70 years may have improved outcomes with CEA. In patients younger than 70 years, CEA and CAS have similar risks for stroke, MI, death, and ipsilateral stroke.[39] In asymptomatic patients with 60% to 99% stenosis, CAS may be considered when the surgical risk is less than 3%, and the patient's life expectancy exceeds 5 years.[39]

▶ *Pharmacologic Therapy*

Aspirin ASA is an option for initial therapy for secondary prevention of ischemic stroke due to its established efficacy. A wide range of doses have been used (50–1500 mg/day); however, current guidelines recommend an ASA dose of 50 to 325 mg daily as monotherapy.[40] Lower ASA doses are currently recommended to decrease the risk of bleeding complications.[40] Adverse effects of ASA include gastrointestinal (GI) intolerance, GI bleeding, and hypersensitivity reactions.

Clopidogrel Clopidogrel is slightly more effective than ASA and similar in efficacy to the combination of extended-release (ER) dipyridamole plus ASA.[41] Usual dose is 75 mg orally taken once daily. There have been 11 case reports of thrombotic thrombocytopenic purpura (TTP) occurring secondary to clopidogrel. Most occurred within the first 2 weeks of therapy; therefore, clinicians should be aware of the potential for development of TTP with clopidogrel. Proton pump inhibitors may decrease the effectiveness of clopidogrel. An H_2-blocker may be preferred in patients who require both acid suppression and clopidogrel. A meta-analysis found that patients who are carriers of cytochrome P450 (CYP) *2C19* loss-of-function alleles (*2, *3, and *8) have an increased risk of stroke and vascular events.[42] This results from a decrease in the active metabolite of clopidogrel, potentially requiring increased doses or use of an alternate agent such as ticagrelor. Use of ticagrelor requires further investigation before this could be recommended.[42] Clopidogrel is an option for initial monotherapy for secondary prevention of ischemic stroke and is considered first-line therapy in patients who also have peripheral arterial disease or are allergic to ASA.

Extended-Release Dipyridamole Plus Aspirin Combination therapy with ER dipyridamole plus ASA has been found to be more effective in preventing stroke than either agent alone.[40] Headache and diarrhea were common adverse effects of dipyridamole; bleeding was more common in all treatment groups that included ASA. A trial comparing the combination of ER dipyridamole plus ASA to clopidogrel found no difference in outcomes;

Patient Encounter Part 4

The patient received IV alteplase and mechanical thrombectomy 24 hours ago. He has been in the intensive care unit (ICU) for 24 hours, and the team is planning for transfer to the step-down unit.

What treatments would you recommend to reduce the risk of another stroke in the next 24 to 48 hours?

What treatments would you recommend at discharge to reduce the risk of another stroke?

however, adverse events occurred more frequently in the combination of ER dipyridamole plus ASA group. The currently available formulation is a combination product containing 25-mg ASA and 200-mg ER dipyridamole. This combination is an option for initial therapy for secondary stroke prevention but is not appropriate for patients who are intolerant to ASA.

Current Clinical Trials Clinical trials have been completed to evaluate other combinations of antiplatelet agents and to compare them against one another. Low-dose ASA plus clopidogrel combination therapy did not show a significant benefit in reducing recurrent stroke compared with either clopidogrel alone or aspirin alone. An increased risk of major bleeding was observed.[43,44] Trials have evaluated early initiation (within 24 hours) of the combination of ASA and clopidogrel and its effect in the months following a TIA or minor stroke.[30,31] In patients with minor stroke or TIA, combination therapy reduced the risk of recurrent stroke or TIA. Continuation beyond 21 days is not recommended due to an increased risk of hemorrhage and lack of benefits. Initiating this combination days to years after a minor stroke or TIA is also not recommended due to an increased bleeding risk.

Summary of Antiplatelet Therapy for Secondary Stroke Prevention KEY CONCEPT Current stroke treatment guidelines recommend ASA or combination therapy with ER dipyridamole plus ASA as initial antiplatelet therapy for the secondary prevention of stroke. Clopidogrel is another option for initial treatment and is recommended in patients unable to tolerate ASA and those with peripheral arterial disease.[40] Initial choice of agent should be individualized based on patient factors and cost. Therapeutic failure in this patient population is challenging because no data are available to guide a treatment decision. When a patient is on therapeutic doses of ASA, yet experiences a recurrent TIA or stroke, switching to either clopidogrel or the combination of ER dipyridamole and ASA is a reasonable option. If failure occurs on either clopidogrel or the combination of ASA and ER dipyridamole, switching to the alternate drug may be appropriate.

Oral Anticoagulants Recent clinical trials have not found oral anticoagulation to be better than antiplatelet therapy in those patients without AF or carotid stenosis. In patients without AF, antiplatelet therapy is recommended over oral anticoagulants for secondary prevention of stroke. On the other hand, patients with AF and a previous TIA or stroke have the highest risk of recurrent stroke. Long-term anticoagulation with warfarin or other newer agents is effective and therefore recommended in the primary and secondary prevention of cardioembolic stroke.[40] The newer oral anticoagulants have only been studied for stroke prevention in nonvalvular AF. The goal INR when monitoring warfarin for this indication is 2 to 3. Refer to Chapter 10, "Arrhythmias," for more information on stroke prevention in AF.

▶ *Blood Pressure Management*

Hypertension is a major risk factor for stroke, and BP control is an important strategy for secondary stroke prevention. Current stroke guidelines and the 2017 hypertension guidelines recommend initiation of antihypertensive treatment for untreated patients with TIA or stroke and an established BP of 140/90 mm Hg or greater. Patients previously treated with antihypertensives should be reinitiated on therapy several days after acute ischemic stroke. The optimal regimen to achieve the BP goal has not been established. Diuretics, either alone or in combination with an ACE-I, have been shown to be beneficial in reducing stroke recurrence.[9,40]

▶ *Other Recommendations*

Management of diabetes and lipids based on treatment guidelines, cessation of smoking, increased physical activity, and reducing alcohol use in heavy drinkers are additional recommendations for management of patients with previous stroke or TIA.[40] Statin therapy is recommended in patients with previous stroke or TIA, regardless of history of coronary heart disease. Table 12–5 provides drug and dosing recommendations for treatment of ischemic stroke.

Treatment of Acute Hemorrhagic Stroke

▶ *Supportive Measures*

Acute hemorrhagic stroke is considered to be a medical emergency due to ICH, SAH, or subdural hematoma. Initially, patients experiencing a hemorrhagic stroke should be transported to a neurointensive care unit. KEY CONCEPT There is no proven treatment for ICH. Management is based on neurointensive care treatment and prevention of complications. Treatment should be provided to manage the needs of the critically ill patient including management of increased ICP, seizures, infections, and prevention of rebleeding and delayed cerebral ischemia in patients with SAH. In those with severely depressed consciousness, rapid endotracheal intubation and mechanical ventilation may be necessary. BP is often elevated after hemorrhagic stroke; appropriate management is important to prevent rebleeding and expansion of the hematoma. In patients presenting with SBP greater than 220 mm Hg, BP lowering using continuous IV infusion is recommended.[9,45] When SBP is between 150 and 220 mm Hg, lowering of the SBP to less than 140 mm Hg does not improve outcomes and may cause harm compared to a less aggressive BP-lowering goal in the acute period.[9,46] BP can be controlled with IV boluses of labetalol 10 to 80 mg every 10 minutes up to a maximum of 300 mg or with IV infusions of labetalol (0.5–2 mg/min) or nicardipine (5–15 mg/hour). Deep vein thrombosis prophylaxis with intermittent compression stockings should be implemented early after admission. In those patients with SAH, once the aneurysm has been treated, heparin may be instituted. In ICH patients with lack of mobility after 1 to 4 days, heparin or LMWH may be started.[45,47]

▶ *Nonpharmacologic Therapy*

Patients with hemorrhagic stroke are evaluated for surgical treatment of SAH and ICH. In SAH, either clipping of the aneurysm or coil embolization is recommended within 72 hours after the initial event to prevent rebleeding. Coil embolization, also called coiling, is a minimally invasive procedure in which

Table 12–5

Recommendations for Pharmacotherapy of Ischemic Stroke

	Primary Agents	Alternatives
Acute treatment	Alteplase 0.9 mg/kg IV (maximum dose 90 mg); 10% as IV bolus, remainder infused over 1 hour in select patients within 4.5 hours of onset	Alteplase (various doses) intra-arterially within 6 hours after onset in select patients
	Tenecteplase 0.25 mg/kg IV bolus (maximum dose 25 mg); may choose over alteplase prior to thrombectomy	
	ASA 160–325 mg started within 48 hours of onset; hold for 24 hours if alteplase or tenecteplase given (may reduce dose to 50–100 mg daily after 48 hours)	If minor stroke or TIA, ASA 75 mg plus clopidogrel 75 mg daily started within 24 hours of onset × 21 days
Secondary prevention (noncardioembolic stroke)	ASA 50–325 mg daily ASA 25 mg + ER dipyridamole 200 mg twice daily	Clopidogrel 75 mg daily
Cardioembolic	Warfarin (INR 2–3) Apixaban 5 mg twice daily; decrease to 2.5 mg twice daily if patient has at least two of the following: age ≥ 80 years, weight ≤ 60 kg (132 lb) or serum creatinine ≥ 1.5 mg/dL (133 μmol/L) Rivaroxaban 20 mg daily with the evening meal; decrease to 15 mg daily with the evening meal if CrCl 15–50 mL/min (0.25–0.83 mL/s)	Edoxaban 60 mg once daily; decrease to 30 mg once daily if CrCl 15–30 mL/min (0.25–0.50 mL/s) Dabigatran 150 mg twice daily; decrease to 75 mg twice daily if CrCl 15–30 mL/min (0.25–0.50 mL/s)
All patients	BP control Statin therapy	

ASA, aspirin; BP, blood pressure; CrCl, creatinine clearance; ER, extended-release; INR, international normalized ratio; IV, intravenous; TIA, transient ischemic attack.

Table 12–6

Monitoring the Stroke Patient

Treatment	Parameter(s)	Monitoring Frequency	Comments
Ischemic Stroke			
All stroke patients	CT scan	Upon arrival	
	Neurological examination		
	BP	Every 5 minutes × 3	
Alteplase	CT scan	24 hours after alteplase infusion	
	BP	Every 15 minutes × 2 hours, every 30 minutes × 6 hours, every 1 hour × 16 hours; then every shift	
	Neurological function	Neurological examination every 15 minutes × 2 hours, every 30 minutes × 6 hours, every 1 hour × 16 hours; NIHSS 24 hours after alteplase infusion and at discharge	
	Bleeding	Clinical signs of bleeding every 2 hours × 24 hours	
ASA	Bleeding	Daily	
	Hb/Hct, platelets[a]		
Clopidogrel	Bleeding	Daily	
	Hb/Hct, platelets[a]		
ASA/ER dipyridamole	Headache, bleeding	Daily	
	Hb/Hct, platelets[a]		
Warfarin	Bleeding, INR, Hb/Hct[a]	INR daily × 3 days; weekly until stable; then monthly	
Oral anticoagulants	Bleeding	Each visit	
	Hb/Hct, renal and liver function	Yearly; if decreased renal function, every 3–6 months	
Hemorrhagic Stroke			
	BP, neurological function, ICP	Every 2 hours in ICU	May require treatments to lower systolic BP to < 180 mm Hg
Nimodipine for SAH	BP, neurological function, fluid status	Every 2 hours in ICU	

[a] Hb/Hct and platelets should be monitored at baseline and every 6 months for ASA, clopidogrel, ASA/ER dipyridamole, and warfarin treatment.

ASA, aspirin; BP, blood pressure; CT, computed tomography; ER, extended-release; Hb, hemoglobin; Hct, hematocrit; ICP, intracranial pressure; ICU, intensive care unit; INR, international normalized ratio; NIHSS, National Institutes of Health Stroke Scale; SAH, subarachnoid hemorrhage.

a platinum coil is threaded into the aneurysm. The flexible coil fills up the space to block blood flow into the aneurysm thereby preventing rebleeding. Surgical removal of the hematoma in patients with ICH is controversial because trials have not consistently shown improved outcomes. Minimally invasive clot removal techniques have been evaluated; however, these procedures are considered investigational because outcomes are not certain. Current guidelines note that surgical treatment of ICH is uncertain and is not recommended except in specific patient situations.[45]

▶ *Pharmacologic Therapy*

Calcium Antagonists Oral nimodipine is recommended in SAH to prevent delayed cerebral ischemia. It is recommended to begin oral nimodipine promptly after the initial event but no later than 96 hours following SAH. Delayed cerebral ischemia occurs 4 to 14 days after the initial aneurysm rupture and is a common cause of neurological deficits and death. Nimodipine 60 mg orally every 4 hours for 21 days following aneurysmal SAH reduces the risk of a poor outcome and delayed cerebral ischemia.

Hemostatic Therapy Current guidelines do not recommend treatment with recombinant factor VIIa due to an uncertain benefit and increased risk of thromboembolic events.[45] Tranexamic acid has been shown to reduce rebleeding in SAH and expansion of the hematoma in ICH. However, improved outcomes have not been established.[48]

OUTCOME EVALUATION

- Measure stroke outcomes based on neurological status and functioning of the patient after the acute event.
- Implement early rehabilitation which can reduce functional impairment after a stroke. Stroke rehabilitation guidelines have been endorsed by the American Heart Association and American Stroke Association. These guidelines recommend that patients receive care in a multidisciplinary setting or stroke unit, receive early assessment using the NIHSS, and that rehabilitation is started as soon as possible after the stroke. Other recommendations include screening for dysphagia (difficulty in swallowing) and aggressive secondary stroke prevention treatments.[49]
- Continued effort has been placed on stroke systems of care and developing mechanisms for more urgent assessment and treatment of suspected stroke.
- Table 12–6 provides monitoring guidelines for the acute stroke patient.

Patient Care Process

Collect Information:

- Assess signs and symptoms including time of symptom onset and time of arrival in the emergency department, obtaining information from patient or family members. Time the patient was last known to be well is used as the stroke onset time.
- Review results of completed prehospital stroke screening tests.
- Review the neurological and physical examination findings, including the NIHSS, evaluating for potential causes of stroke.
- Perform a comprehensive medication history, obtaining information from patient or family members.
- Determine the patient's baseline functional status.
- Determine the patient's risk factors for stroke.

Assess the Information:

- Determine if patient is experiencing an acute ischemic stroke.
- Determine if thrombolytic therapy is indicated based on inclusion and exclusion criteria.
- Review relevant laboratory tests (eg, BP, temperature, glucose, oxygen saturation).
- Assess the patient's weight.
- Review CT or MRI scan results to rule out hemorrhagic stroke.
- Review the results of other diagnostic tests (eg, ECG, Doppler studies).
- Evaluate the inclusion and exclusion criteria for fibrinolytic therapy.
- Evaluate patient for IV and endovascular treatment acutely.

Develop a Care Plan:

- Manage the patient's airway, breathing, and circulation (ABCs) initially in the acute phase of treatment.
- Transfer the patient to a stroke center if available.
- Begin IV alteplase if patient is within 4.5 hours of the onset of symptoms and meets inclusion and exclusion criteria.
- Hold other anticoagulants and antiplatelet agents for 24 hours after the infusion of alteplase.
- Begin antiplatelet therapy to prevent a recurrent stroke.
- Manage patient's stroke risk factors.

Implement the Care Plan:

- If fibrinolytic therapy is indicated, initiate treatment protocol for alteplase administration and follow recommended monitoring plan.
- Develop a plan for long-term management of risk factors to prevent a recurrent stroke.
- Educate the patient on risk factors and lifestyle factors to reduce the risk of stroke recurrence.
- Educate the patient on the importance of adherence to their medication regimen.

Follow-up: Monitor and Evaluate:

- Monitor the patient's BP and neurological status every 15 minutes × 2 hours, every 30 minutes × 6 hours, and then every hour for 24 hours after alteplase infusion.
- Obtain a follow-up CT scan 24 hours after the alteplase infusion.
- Evaluate functional status 24 hours after the alteplase infusion.
- Monitor patient's risk factors poststroke.

Abbreviations Introduced in This Chapter

ABCs	Airway, breathing, and circulation
ACE-I	Angiotensin-converting enzyme inhibitor
ADP	Adenosine diphosphate
AF	Atrial fibrillation
aPTT	Activated partial thromboplastin time
ARB	Angiotensin receptor blocker
ASA	Aspirin
ASCVD	Atherosclerotic cardiovascular disease
ASPECT	Alberta Stroke Program Early CT
AVM	Arteriovenous malformation
BP	Blood pressure
CAS	Carotid artery stent
CCB	Calcium channel blocker
CEA	Carotid endarterectomy
CNS	Central nervous system
CrCl	Creatinine clearance
CT	Computed tomography
CVD	Cardiovascular disease
CYP	Cytochrome P450
DBP	Diastolic blood pressure
ECG	Electrocardiogram
ECT	Ecarin clotting time
ER	Extended-release
FDA	Food and Drug Administration
GI	Gastrointestinal
Hb	Hemoglobin
Hct	Hematocrit
IA	Intra-arterial
ICH	Intracerebral hemorrhage
ICP	Intracranial pressure
ICU	Intensive care unit
INR	International normalized ratio
IV	Intravenous
LMWH	Low-molecular-weight heparin
MI	Myocardial infarction
MRI	Magnetic resonance imaging
NIHSS	National Institutes of Health Stroke Scale
NINDS	National Institute of Neurological Disorders and Stroke
PT	Prothrombin time
rt-PA	Alteplase
r-pro UK	Pro-urokinase
SAH	Subarachnoid hemorrhage
SBP	Systolic blood pressure
TIA	Transient ischemic attack
TTP	Thrombotic thrombocytopenic purpura
TT	Thrombin time
UFH	Unfractionated heparin
VTE	Venous thromboembolism

Dyslipidemia

Joel C. Marrs and Matthew D. Kostoff

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify the common types of lipid disorders.
2. Identify the statin-benefit groups and intensity of statin therapy according to the American College of Cardiology/American Heart Association.
3. Recommend appropriate therapeutic lifestyle changes (TLC) and pharmacotherapy interventions for dyslipidemia.
4. Determine a patient's atherosclerotic cardiovascular disease risk and corresponding treatment goals according to the National Lipid Association, American Association of Clinical Endocrinologist/American College of Endocrinology, and American Heart Association/American College of Cardiology.
5. Identify patients who are indicated for nonstatin therapy according to the American Heart Association/American College of Cardiology.
6. Describe components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for dyslipidemias.
7. Educate patients about the disease state, appropriate TLC, and drug therapy required for effective treatment.

INTRODUCTION

KEY CONCEPT Hypercholesterolemia, or dyslipidemia, plays a major role in atherosclerosis and plaque formation leading to coronary heart disease (CHD) as well as other forms of atherosclerotic cardiovascular disease (ASCVD), such as carotid and peripheral artery disease.[1] CHD is the leading cause of death in adults in the United States and most industrialized nations. It is also the chief cause of premature, permanent disability in the US workforce.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 92.8 million US adults have high cholesterol with a value of 200 mg/dL (5.17 mmol/L) or greater.[2] Further, one out of every three US adults has high low-density lipoprotein (LDL) cholesterol ($\geq$ 130 mg/dL [3.36 mmol/L]).[2] Elevated cholesterol values are a major risk factor for development of ASCVD. Annually, approximately 805,000 Americans experience a new heart attack or recurrent event.[2] Lowering cholesterol reduces atherosclerotic progression and mortality from CHD and stroke. Development of CHD is a lifelong process. Except in rare cases of severely elevated serum cholesterol levels, years of poor dietary habits, sedentary lifestyle, and life-habit risk factors (eg, smoking, overweight/obesity) contribute to the development of atherosclerosis.[3,4]

PATHOPHYSIOLOGY

Cholesterol and Lipoprotein Metabolism

Cholesterol, an essential substance manufactured by most cells in the body, is used to maintain cell wall integrity and for the biosynthesis of bile acids and steroid hormones. Cholesterol, triglycerides, and phospholipids circulate in the blood as lipoproteins. The major lipoproteins are chylomicrons, very low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), LDL, and high-density lipoprotein (HDL). Each lipoprotein has various proteins called apolipoproteins (Apos) embedded on the surface that serve four main purposes: (a) required for assembly and secretion of lipoproteins; (b) serve as major structural components of lipoproteins; (c) act as ligands for binding to receptors on cell surfaces; and (d) can be cofactors for inhibition of enzymes involved in the breakdown of triglycerides from chylomicrons and VLDL.[5]

A measured total cholesterol is the total cholesterol molecules in all these major lipoproteins. The estimated value of LDL cholesterol is found using the Friedewald equation (after fasting for 9–12 hours):

LDL cholesterol (mg/dL) = total cholesterol – (HDL cholesterol + triglycerides/5), when lipids are expressed in units of mg/dL;

or

LDL cholesterol (mmol/L) = total cholesterol – (HDL cholesterol + triglycerides/2.2), when lipids are expressed in units of mmol/L

Where triglycerides/5 or triglycerides/2.2 estimate VLDL cholesterol in units of mg/dL or mmol/L, respectively.

This formula becomes inaccurate if serum triglycerides are greater than 400 mg/dL (4.52 mmol/L), if chylomicrons are present, or the patient has familial dysbetalipoproteinemia. In each of these cases, LDL cholesterol must be directly measured, which can be done for any patient at most laboratoriess.[3] Non-HDL cholesterol is carried by all atherogenic Apos B-containing lipoproteins including VLDL, IDL, and LDL. It is calculated as:

$$\text{Non-HDL cholesterol} = \text{total cholesterol} - \text{HDL cholesterol}$$

Non-HDL cholesterol can be determined in a nonfasting state. More recently, some laboratories have transitioned to using the Martin-Hopkins equation to estimate LDL cholesterol instead of the Friedewald equation.[6] The Martin-Hopkins equation is calculated as:

$$\text{LDL cholesterol} = \text{total cholesterol} - \text{HDL cholesterol} - \text{triglyceride/adjustable factor}$$

The Martin-Hopkins equation has demonstrated improved estimation of LDL cholesterol compared to the Friedewald equation.

Cholesterol from the diet as well as from bile enters the small intestine and is emulsified by bile salts into micelles (Figure 13–1), which are microscopic particles of digested fat and cholesterol. These micelles interact with the duodenal enterocyte and jejunal enterocyte surfaces, and cholesterol is transported from the micelles into enterocytes by the Niemann-Pick C1 Like 1 (NPC1L1) transporter. Cholesterol within enterocytes is esterified and packaged into chylomicrons along with triglycerides, phospholipids, and Apos, which are then released into the lymphatic circulation. In the lymph and blood, chylomicrons are converted to chylomicron remnants. During this process, referred to as reverse cholesterol transport, chylomicrons also interact with HDL particles (Figure 13–2) and exchange triglyceride and cholesterol content (facilitated by cholesterol ester transfer protein, or CETP), and HDL particles acquire Apos A and C. Chylomicron remnant particles are then taken up by LDL-related protein (LRP).

In the liver, cholesterol and triglycerides are incorporated into VLDL along with phospholipids and Apo B-100 (Figure 13–3). VLDL loses its triglyceride content through interaction with lipoprotein lipase (LPL) to form VLDL remnant and IDL. IDL can be cleared from the circulation by hepatic LDL receptors or further converted to LDL (by further depletion of triglycerides) through the action of hepatic lipases (HLs). Approximately 50% of IDL is converted to LDL. LDL particles are cleared from the circulation primarily by hepatic LDL receptors by interaction with Apo B-100. They can also be taken up by extrahepatic tissues or enter the arterial wall, contributing to atherogenesis. Biosynthesis of cholesterol is directly regulated by the amount of cholesterol present in an individual. Therefore, higher ingestion of cholesterol through food consumption results in decreased production of endogenous cholesterol in the liver. In the liver, cholesterol is produced through the mevalonate pathway (Figure 13–3) where the production of mevalonate is the rate-limiting and irreversible step in cholesterol synthesis. 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) is converted to mevalonate by HMG-CoA reductase (site of action for statins).

Cholesterol is transported from the arterial wall or other extrahepatic tissues back to the liver by HDL (Figure 13–2). Triglyceride-rich HDL is hydrolyzed by HL, generating fatty acids (FA) and nascent (immature) HDL particles, or mature HDL can bind to scavenger receptors (SR-BI) on hepatocytes and transfer their cholesterol ester content for excretion in the bile.

A variety of genetic mutations can occur during lipoprotein synthesis and metabolism that cause lipid disorders. The major genetic disorders and their effect on serum lipids are presented in Table 13–1. Disorders that increase serum cholesterol are generally those that affect the number or affinity of LDL receptors and

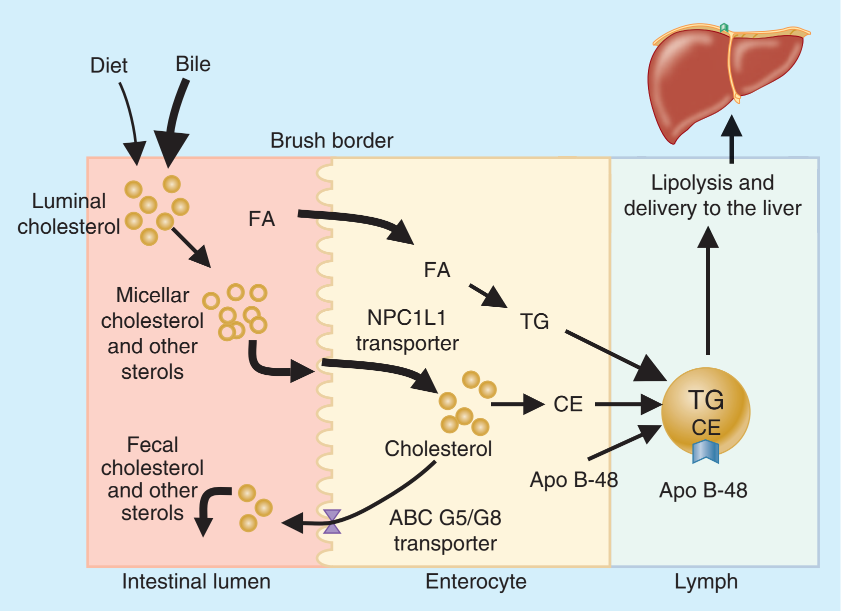

FIGURE 13–1. Intestinal cholesterol absorption and transport. Cholesterol from food and bile enters the gut lumen and is emulsified by bile acids into micelles. Micelles bind to the intestinal enterocytes, and cholesterol and other sterols are transported from the micelles into the enterocytes by a sterol transporter. Triglycerides synthesized by absorbed fatty acids, along with cholesterol and Apo B-48, are incorporated into chylomicrons. Chylomicrons are released into the lymphatic circulation and converted to chylomicron remnants (through loss of triglyceride) and then taken up by the hepatic LDL receptor-related protein (LRP). Table 13–1

Selected Characteristics of Primary Dyslipidemias

Disorder	Estimated Frequency	Metabolic Defect	Main Lipid Parameter
Autosomal dominant hypercholesterolemia			
Familial hypercholesterolemia homozygous	1/250,000–1/1 million	LDL-receptor negative	LDL-C > 500 mg/dL (12.93 mmol/L)
heterozygous	1/250–1/500	Reduction in LDL receptors	LDL-C 250–500 mg/dL (6.47–12.93 mmol/L)
Familial defective Apo B-100	1/1000	Single-nucleotide mutation	LDL-C 250–500 mg/dL (6.47–12.93 mmol/L)
PCSK9 gain-of-function mutations	Rare	Single-nucleotide mutation	LDL-C 250–500 mg/dL (6.47–12.93 mmol/L)
Polygenic hypercholesterolemia	Common	Metabolic and environmental	LDL-C 160–250 mg/dL (4.14–6.47 mmol/L)
Familial combined dyslipidemia	1/200–300	Overproduction of VLDL and/or LDL	LDL-C 250–350 mg/dL (6.47–9.05 mmol/L) TG 200–800 mg/dL (2.26–9.04 mmol/L)
Familial hyperapobetalipoproteinemia	5%	Increase Apo B production	Apo B > 125 mg/dL (1.25 g/L)
Familial dysbetalipoproteinemia (type III)	0.5%	Apo E2/2 phenotype	LDL-C 300–600 mg/dL (7.76–15.52 mmol/L)
Familial hypertriglyceridemia			
Type I	1/500,000–1/1 million	LPL-Apo CII system	TG > 1000 mg/dL (11.3 mmol/L)
Type IV	1/300	Unknown	TG 200–500 mg/dL (2.26–5.65 mmol/L)
Type V	1/205,000	Metabolic and environmental	TG > 1000 mg/dL (11.3 mmol/L)
Hypoalphalipoproteinemia	3%–5%	Defect in HDL catabolism	HDL-C < 35 mg/dL (0.91 mmol/L)

Apo, apolipoprotein; C, cholesterol; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; PCSK9, proprotein convertase subtilisin/kexin type 9; TG, triglyceride; VLDL, very low-density lipoprotein.

are known as familial hypercholesterolemia (FH). These patients commonly present with corneal arcus of the eye, xanthomas of extensor tendons of the hand and Achilles tendon, premature CHD (male < 45 years old and female < 55 years old), and/or have a first-degree relative with raised cholesterol and/or premature CHD (male first-degree relative < 55 years old and female first-degree relative < 65 years old). Elevations in triglycerides are generally associated with overproduction of triglyceride-rich VLDL, mutations in Apo E, or lack of LPL or Apo CII, which cause hyperchylomicronemia. Most individuals have mild-to-moderate elevations in cholesterol known as polygenic hypercholesterolemia, thought to be caused by various more subtle genetic

Clinical Presentation and Diagnosis

Physical Findings

- Dyslipidemia is usually asymptomatic.
- Corneal arcus of the eye and xanthomas may be seen in patients with genetic disorders that cause a marked increase in serum LDL cholesterol (> 250 mg/dL [6.47 mmol/L]).
- Those with severely elevated serum triglycerides (> 500 mg/dL [5.65 mmol/L]) and especially those with extremely elevated serum triglycerides (> 1000 mg/dL [11.3 mmol/L]) can develop pancreatitis (inflammation of the pancreas) and tuberoeruptive xanthomas.

Indications for Lipid Panel

- All adults more than 20 years of age should be screened at least every 5 years using a fasting blood sample to obtain a lipid profile (total cholesterol, non-HDL cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides). A nonfasting lipid profile can be used for risk assessment for most patients for primary and secondary prevention assessment. If the triglycerides are elevated in the nonfasting state, then it may be necessary to recheck a fasting lipid profile to assess LDL cholesterol, but non-HDL cholesterol can accurately be assessed irrespective of fasting state.
- Children between 2 and 20 years old should be screened for high cholesterol if their parents have premature CHD (male first-degree relatives < 55 years old and female first-degree relatives < 65 years old) or if one of their parents has a total cholesterol greater than 240 mg/dL (6.21 mmol/L). Early screening will help identify children at highest risk of developing CHD in whom early education and dietary intervention are warranted.

Lipid Panel

- Non-HDL cholesterol exceeding 100 mg/dL (2.59 mmol/L) or LDL cholesterol exceeding 70 mg/dL (1.81 mmol/L) should have an assessment of ASCVD risk if 40 to 75 years of age and a primary prevention patient without diabetes.
- Serum triglycerides exceeding 150 mg/dL (1.70 mmol/L) and serum HDL cholesterol less than 40 mg/dL (1.03 mmol/L) in men and less than 50 mg/dL (1.29 mmol/L) in women may increase risk of ASCVD and should be evaluated.

Indications for Other Tests

- Conditions that may produce lipid abnormalities (such as those listed in Table 13–2) should be screened for using appropriate tests. If present, these conditions should be properly addressed as they can be secondary causes for dyslipidemia.

Table 13–2

defects as well as environmental factors such as diet, sedentary lifestyle, and overweight/obesity.[3,4]

Pathophysiology of Clinical Atherosclerotic Cardiovascular Disease

Lipoproteins are the "root cause" of atherosclerosis. The process begins when lipoproteins migrate between the endothelial cells into the arterial wall where they are modified by oxidation (Figure 13–4). Oxidized lipoproteins promote endothelial dysfunction by disturbing the production of nitric oxide, an endogenous vasodilator that maintains vasomotor tone, as well as increasing expression of cell-adhesion molecules on vascular endothelial cells leading to recruitment of monocytes (a variety of white blood cells) into the intima (inner layer of the wall of an artery or vein). Monocytes differentiate into macrophages (large scavenger cells) and express SR-BI, allowing enhanced uptake of these oxidized lipoproteins. The macrophages continue to accumulate lipoproteins and ultimately develop into lipid-laden foam cells. Accumulation of foam cells leads to formation of a lipid-rich core, which marks the transition to a more complicated atherosclerotic plaque. Such plaques may result in ischemic heart disease and acute coronary syndromes, further discussed in Chapters 8 and 9, respectively. Aggressive lipid lowering can restore endothelial function, decrease cardiovascular disease (CVD) risk, and improve patient cardiovascular (CV) outcomes.[3,4]

TREATMENT

KEY CONCEPT The American Heart Association/American College of Cardiology (AHA/ACC), National Lipid Association (NLA), and American Association of Clinical Endocrinologists/American College of Endocrinology (AACE/ACE) guidelines emphasize that lifestyle therapies are an important element of risk reduction efforts in ASCVD prevention, whether or not pharmacotherapy is also used.[3,4,7,8] Therapeutic lifestyle changes (TLC) should be the first approach tried in all patients (Table 13–3), but pharmacotherapy should be instituted concurrently in higher-risk patients. TLC includes dietary restrictions as well as regular exercise and weight reduction if overweight or obese. Additionally, consumption of plant stanols/sterols and dietary fiber should be encouraged as they may reduce LDL cholesterol by 20% to 25%.

The rate-limiting enzyme in cholesterol biosynthesis is HMG-CoA reductase. Isolation of a specific inhibitor of this enzyme resulted in the first marketed statin called lovastatin.[9] By reducing cholesterol synthesis, statins were shown to upregulate the LDL receptor. Statins have now become the mainstay therapy for both familial and nonfamilial hypercholesterolemia.

In November 2018, the AHA and ACC released guidelines for treating high blood cholesterol to reduce risk of ASCVD in adults, which represented a reinforcement of the 2013 ACC/AHA guidelines.[3,4] Major changes in 2018 included reinforcement of statin-benefit groups, addition of LDL cholesterol thresholds and percent reduction in LDL cholesterol goals, and recommendations for specific nonstatin therapies in addition to statins in high- and very-high-risk patients to reduce ASCVD. The 2013 ACC/AHA guidelines shifted to a focus on statin-benefit groups versus other medical organizations recommending traditional cholesterol targets (eg, LDL goals, percent reduction in LDL). This approach was reinforced in 2018, with the exception of adding percent cholesterol goals and LDL cholesterol thresholds as highlighted in Table 13–4.[3,4,7,8] In this chapter, the 2013 ACC/AHA guideline,[3] the 2018 AHA/ACC guideline,[4] the NLA recommendations,[7] and the AACE/ACE guidelines[8] are reviewed.

ALGRAWANY

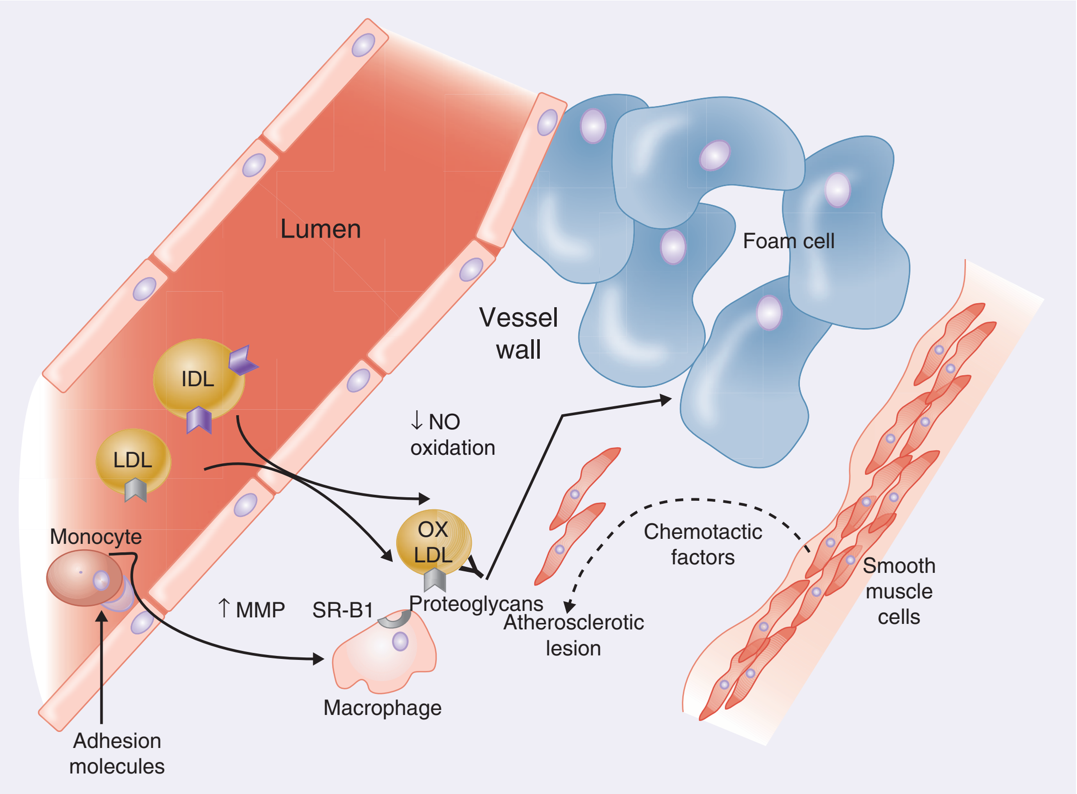

FIGURE 13–4. The process of atherogenesis. Atherosclerosis is initiated by the migration and retention of LDL and remnant lipoprotein particles into the vessel wall. These particles undergo oxidation and are taken up by macrophages in an unregulated fashion. The oxidized particles participate to induce endothelial cell dysfunction, leading to a reduced ability of the endothelium to dilate the artery which leads to a **prothrombotic state**. The unregulated uptake of cholesterol by macrophages leads to foam cell formation and the development of a blood clot–favoring fatty lipid core. The enlarging lipid core eventually causes an encroachment of the vessel lumen. Early in the process, smooth muscle cells are activated and recruited from the media to the intima, helping to produce a collagen matrix that covers the growing clot protecting it from circulating blood. Later, macrophages produce and secrete **matrix metalloproteinases** that degrade the collagen matrix, leading to unstable plaque that may cause a myocardial infarction. (IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; MMP, matrix metalloproteinases; NO, nitric oxide; OX, oxygen; SR-B1, scavenger receptors.)

Table 13–3

Essential Components of Therapeutic Lifestyle Changes

Component	Recommendation
Dietary cholesterol	< 200 mg/day (5.17 mmol/L)
Saturated fats	Total fat range should be 25%–35% of calories consumed for most cases < 7% of total calories and reduce intake of trans fatty acids
Therapeutic options for LDL-lowering plant stanols/sterols	2 g/day
Increased viscous (soluble) fiber	10–25 g/day
Total calories	Adjust caloric intake to maintain desirable body weight and prevent weight gain
Physical activity	≥ 150 min/week of moderate intensity physical activity or ≥ 75 min/week of vigorous-intensity physical activity

LDL, low-density lipoprotein.

The 2018 AHA/ACC guidelines identify four groups of adult patients targeted for statin treatment for both primary and secondary prevention (Figures 13–5 and 13–6), including:

- Established clinical ASCVD (secondary prevention).
- Primary prevention with elevation of LDL cholesterol levels 190 mg/dL (4.91 mmol/L) or higher.
- Primary prevention with diabetes mellitus (DM), age 40 to 75 years regardless of LDL cholesterol levels.
- Primary prevention without DM, age 40 to 75 years, with an estimated 10-year risk of 7.5% or greater, and LDL cholesterol levels 70 to 189 mg/dL (1.81–4.89 mmol/L).

If patients have established ASCVD or have LDL cholesterol levels 190 mg/dL (4.91 mmol/L) or greater, they are indicated for high-intensity statin and do not need their risk estimated with the pooled cohort equation (PCE) risk estimator. The pooled PCE risk estimator was developed to assist with decisions regarding initiation of statin therapy for primary prevention (http://tools.acc.org/ASCVD-Risk-Estimator-Plus/#!/calculate/estimate/). The PCE estimates the risk of having a nonfatal/fatal stroke or myocardial infarction over a 10-year period if the patient is between 40 and 79 years of age. The PCE should be used to evaluate primary prevention patients and not

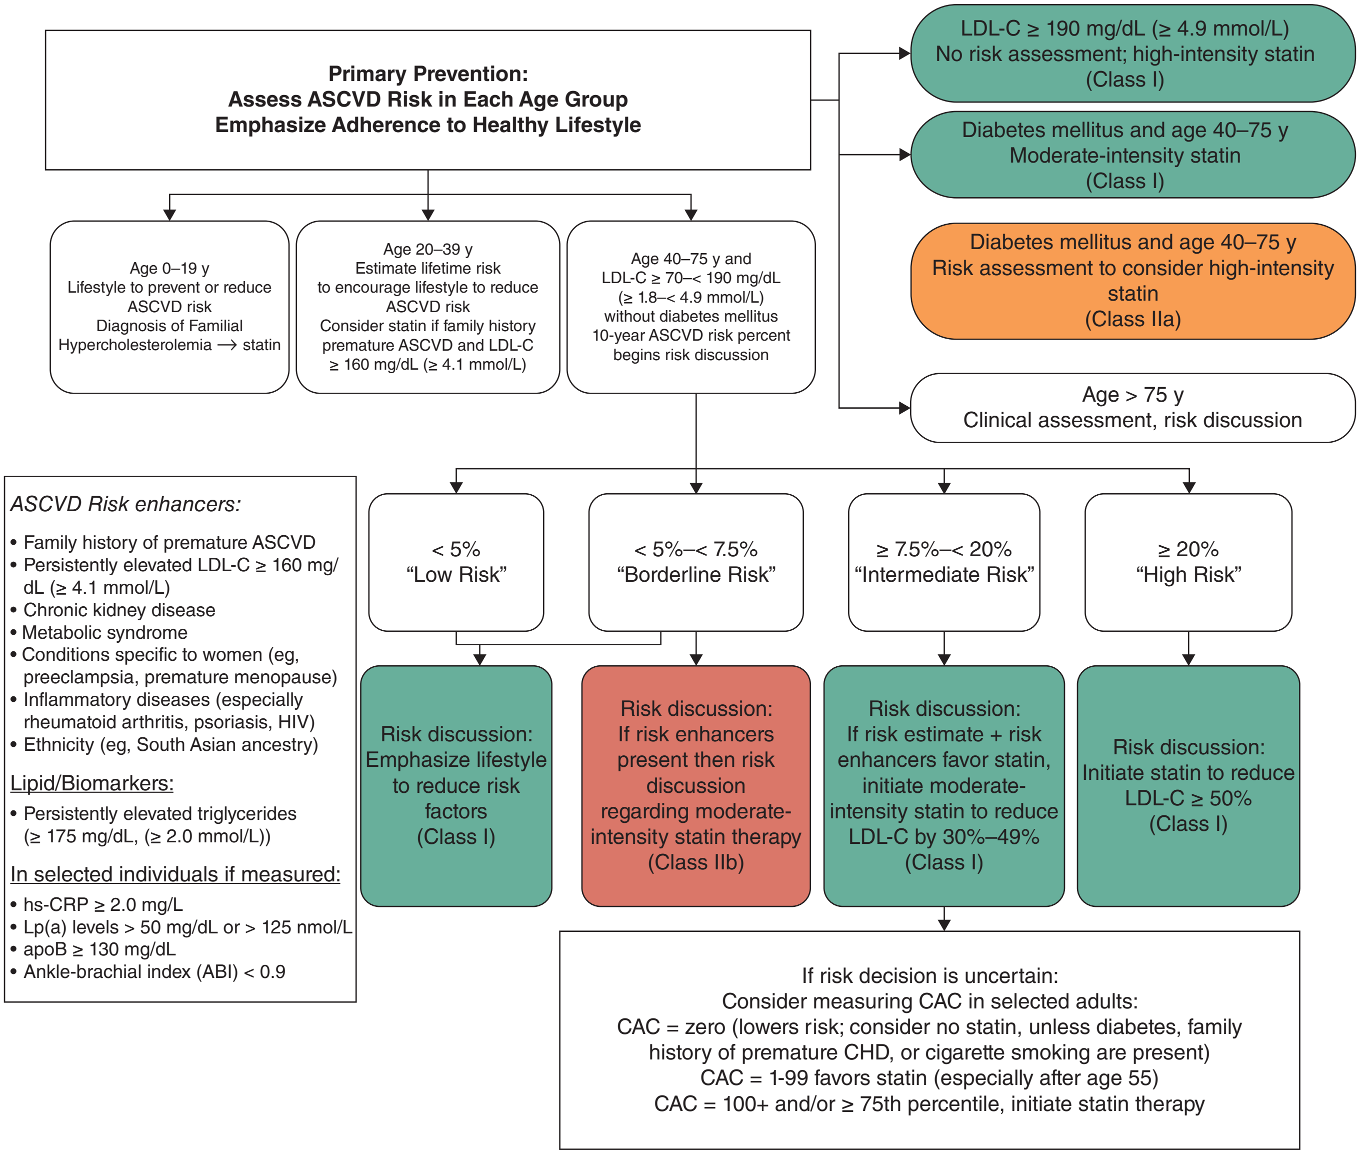
US Guidelines for Management of Dyslipidemias

Source	Fasting Lipid Panel Measurement for Risk Assessment	Recommended Lipoprotein Target of Therapy	Treatment Goals and Thresholds
2013 American College of Cardiology/American Heart Association: Blood Cholesterol Guideline for ASCVD Prevention[3]	Yes Used to evaluate for more severe forms and secondary dyslipidemias and to assess anticipated therapeutic response and adherence to statin therapy	No recommendation	No recommendation
National Lipid Association Recommendations for Patient-Centered Management of Dyslipidemia (2014)[7]	Fasting or nonfasting	Non-HDL-C and LDL-C Apo B (secondary target)	LDL-C: < 70 mg/dL (1.81 mmol/L) for very high-risk patients < 100 mg/dL (2.59 mmol/L) for high-risk, moderate-risk, and low-risk patients Non-HDL-C: < 100 mg/dL (2.59 mmol/L) for very high-risk patients < 130 mg/dL (3.36 mmol/L) for high-risk, moderate-risk, and low-risk patients Apo B: < 80 mg/dL (0.80 g/L) for very high-risk patients < 90 mg/dL (0.90 g/L) for high-risk, moderate-risk, and low-risk patients
American Association of Clinical Endocrinologists and American College of Endocrinology Guidelines for Management of Dyslipidemia and Prevention of Cardiovascular Disease (2020)[8]	Yes	Non-HDL-C and LDL-C and Apo B	LDL-C: < 55 mg/dL (1.42 mmol/L) for extreme-risk patients < 70 mg/dL (1.81 mmol/L) for very high-risk patients < 100 mg/dL (2.59 mmol/L) for high-risk and moderate-risk patients < 130 mg/dL (3.36 mmol/L) for low-risk patients Non-HDL-C: < 80 mg/dL (2.07 mmol/L) for extreme-risk patients < 100 mg/dL (2.59 mmol/L) for very high-risk patients < 130 mg/dL (3.36 mmol/L) for high-risk and moderate-risk patients < 160 mg/dL (4.14 mmol/L) for low-risk patients Apo B: < 70 mg/dL (0.70 g/L) for extreme-risk patients < 80 mg/dL (0.80 g/L) for very high-risk patients < 90 mg/dL (0.90 g/L) for high-risk and moderate-risk patients TG: <150 mg/dL (1.70 mmol/L) for all risk categories
2018 AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA Guideline on the Management of Blood Cholesterol[4]	Fasting or nonfasting	LDL-C and non-HDL-C	LDL-C and non-HDL-C: ≥ 50% reduction in LDL-C in patients with clinical ASCVD, consider adding nonstatin if LDL-C > 70 mg/dL (1.81 mmol/L) and non-HDL-C >100 mg/dL (2.59 mmol/L) if very high risk ≥ 50% reduction in LDL-C in patients with LDL-C ≥ 190 mg/dL (4.91 mmol/L), consider adding nonstatin if LDL > 100 mg/dL (2.59 mmol/L) ≥ 50% reduction in LDL-C in patients with diabetes and ASCVD risk factors ≥ 30% reduction in LDL-C in intermediate-risk patients with diabetes and ASCVD risk factors ≥ 30% reduction in LDL-C in intermediate-risk patients (ASCVD risk score ≥ 7.5% to < 20%)

Apo, apolipoprotein; ASCVD, atherosclerotic cardiovascular disease; LDL-C, low-density lipoprotein cholesterol; non-HDL-C, non–high-density lipoprotein cholesterol; TG, triglycerides.

secondary prevention patients. Specifically, it should be utilized in patients who are between the ages of 40 and 75 who have an LDL cholesterol between 70 and 189 mg/dL (1.81 and 4.89 mmol/L). The PCE estimate is then utilized to categorize patients into four risk groups which include low risk (< 5%), borderline risk (5%–7.4%), intermediate risk (7.5%–19.9%), and high risk (> 20%). It should be emphasized this risk estimator is part of the patient-clinician discussion regarding potential benefit of statin therapy and not the sole determinant for initiation of therapy. A fasting or nonfasting lipid panel should be used for initial calculation of the pooled cohort risk estimator. Clinical judgment, which includes risks and benefits, cost,



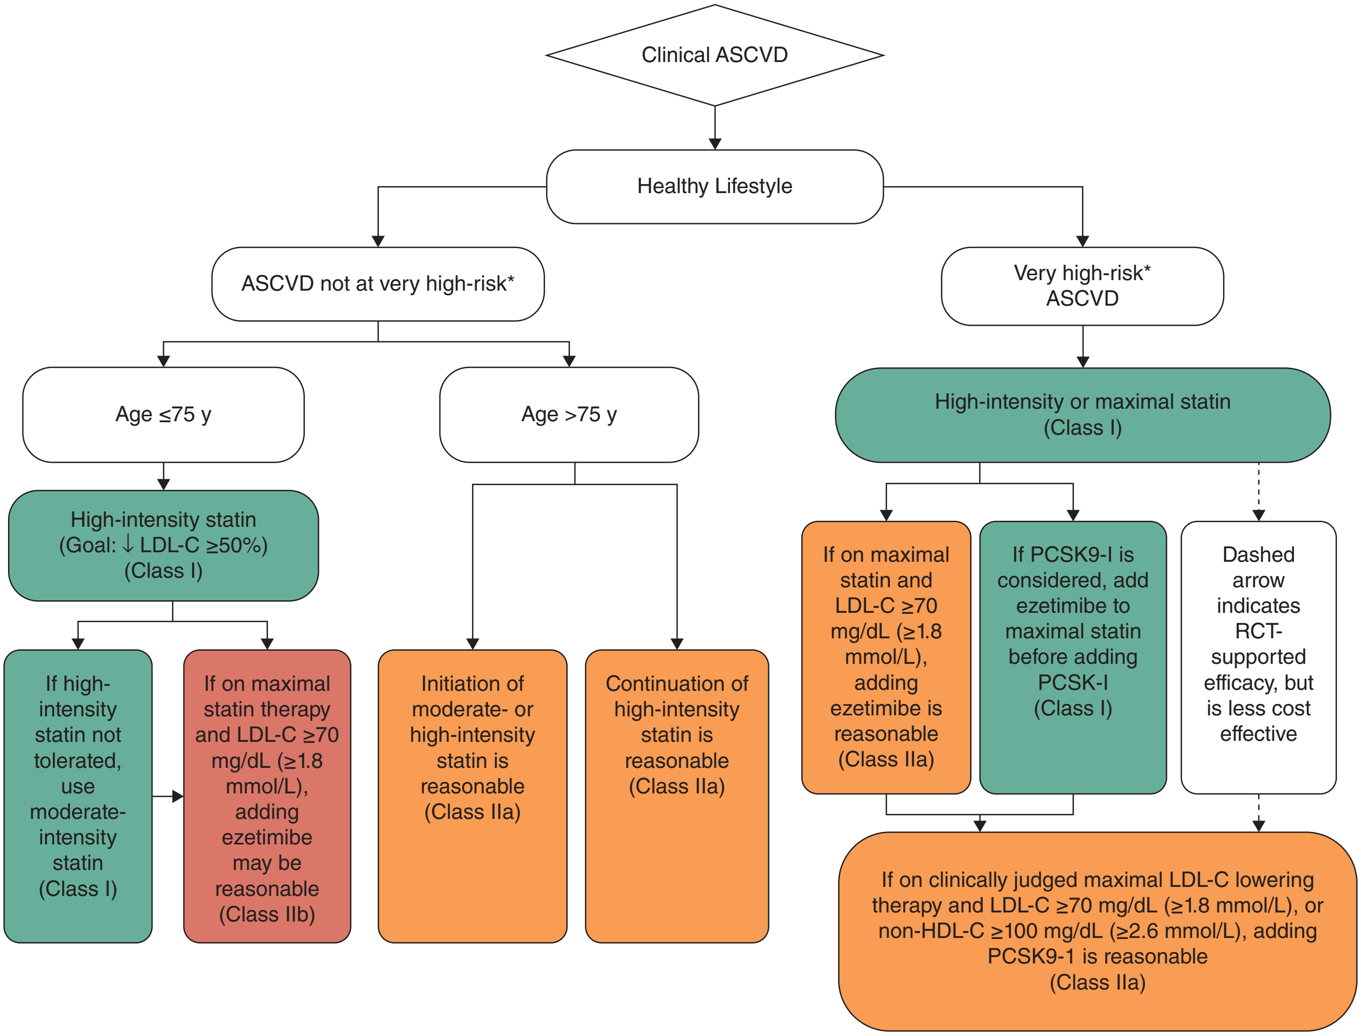
Primary Prevention:
Assess ASCVD Risk in Each Age Group
Emphasize Adherence to Healthy Lifestyle
Age 0–19 y
Lifestyle to prevent or reduce ASCVD risk
Diagnosis of Familial Hypercholesterolemia → statin
Age 20–39 y
Estimate lifetime risk to encourage lifestyle to reduce ASCVD risk
Consider statin if family history premature ASCVD and LDL-C ≥ 160 mg/dL (≥ 4.1 mmol/L)
Age 40–75 y and LDL-C ≥ 70–< 190 mg/dL (≥ 1.8–< 4.9 mmol/L) without diabetes mellitus
10-year ASCVD risk percent begins risk discussion
LDL-C ≥ 190 mg/dL (≥ 4.9 mmol/L)
No risk assessment; high-intensity statin
(Class I)
Diabetes mellitus and age 40–75 y
Moderate-intensity statin
(Class I)
Diabetes mellitus and age 40–75 y
Risk assessment to consider high-intensity statin
(Class IIa)
Age > 75 y
Clinical assessment, risk discussion
ASCVD Risk enhancers:
• Family history of premature ASCVD
• Persistently elevated LDL-C ≥ 160 mg/dL (≥ 4.1 mmol/L)
• Chronic kidney disease
• Metabolic syndrome
• Conditions specific to women (eg, preeclampsia, premature menopause)
• Inflammatory diseases (especially rheumatoid arthritis, psoriasis, HIV)
• Ethnicity (eg, South Asian ancestry)
Lipid/Biomarkers:
• Persistently elevated triglycerides (≥ 175 mg/dL, (≥ 2.0 mmol/L))
In selected individuals if measured:
• hs-CRP ≥ 2.0 mg/L
• Lp(a) levels > 50 mg/dL or > 125 nmol/L
• apoB ≥ 130 mg/dL
• Ankle-brachial index (ABI) < 0.9
< 5%
"Low Risk"
< 5%–< 7.5%
"Borderline Risk"
≥ 7.5%–< 20%
"Intermediate Risk"
≥ 20%
"High Risk"
Risk discussion:
Emphasize lifestyle to reduce risk factors
(Class I)
Risk discussion:
If risk enhancers present then risk discussion regarding moderate-intensity statin therapy
(Class IIb)
Risk discussion:
If risk estimate + risk enhancers favor statin, initiate moderate-intensity statin to reduce LDL-C by 30%–49%
(Class I)
Risk discussion:
Initiate statin to reduce LDL-C ≥ 50%
(Class I)
If risk decision is uncertain:
Consider measuring CAC in selected adults:
CAC = zero (lowers risk; consider no statin, unless diabetes, family history of premature CHD, or cigarette smoking are present)
CAC = 1-99 favors statin (especially after age 55)
CAC = 100+ and/or ≥ 75th percentile, initiate statin therapy

FIGURE 13–5. Summary of statin initiation recommendations for the treatment of blood cholesterol in patients for the primary prevention of clinical ASCVD. Colors correspond to class of recommendation. (apoB, apolipoprotein B; ASCVD, atherosclerotic cardiovascular disease; CAC, coronary artery calcium; CHD, coronary heart disease; HIV, human immunodeficiency virus; hs-CRP, high-sensitivity C-reactive protein; LDL-C, low-density lipoprotein cholesterol; Lp(a), lipoprotein (a); y, year.) (From Grundy SM, Stone NJ, Bailey AL, et al. 2018 AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA guideline on the management of blood cholesterol: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. J Am Coll Cardiol. 2019;73(24):e285–e350, with permission.)

and potential drug–drug interactions, must be exercised. This is especially important since the risk estimator has been shown to overestimate or underestimate risk in some patient populations. If initiation of statin therapy is uncertain based on quantitative risk assessment, additional ASCVD risk enhancers can be considered such as:

- LDL cholesterol 160 mg/dL (4.14 mmol/L) or higher.
- Persistently elevated triglycerides 175 mg/dL (2 mmol/L) or higher (three or more readings).
- Family history of premature ASCVD, chronic kidney disease, inflammatory disease, ethnicity (eg, South Asian ancestry).
- Apo B 130 mg/dL (1.3 g/L) or higher.
- Lipoprotein (a), or Lp(a), 50 mg/dL (0.5 g/L) or higher.
- High-sensitivity C-reactive protein (hs-CRP) of 2 mg/L or higher.
- Coronary artery calcium (CAC) score of 100 or higher.
- Ankle-brachial index (ABI) less than 0.9.
- Elevated lifetime ASCVD risk.

In adults 40 to 75 years of age without diabetes mellitus and with LDL cholesterol between 70 and 189 mg/dL (1.81 and 4.89 mmol/L) who fall into the intermediate-risk category (score of ≥ 7.5%–19.9%) the AHA/ACC guidelines recommend checking a CAC score to help with the decision about starting a statin or not.[4] The guidelines do not give specific



Clinical ASCVD
Healthy Lifestyle
ASCVD not at very high-risk*
Very high-risk* ASCVD
Age ≤75 y
Age >75 y
High-intensity or maximal statin (Class I)
High-intensity statin (Goal: ↓ LDL-C ≥50%) (Class I)
If high-intensity statin not tolerated, use moderate-intensity statin (Class I)
If on maximal statin therapy and LDL-C ≥70 mg/dL (≥1.8 mmol/L), adding ezetimibe may be reasonable (Class IIb)
Initiation of moderate- or high-intensity statin is reasonable (Class IIa)
Continuation of high-intensity statin is reasonable (Class IIa)
If on maximal statin and LDL-C ≥70 mg/dL (≥1.8 mmol/L), adding ezetimibe is reasonable (Class IIa)
If PCSK9-I is considered, add ezetimibe to maximal statin before adding PCSK-I (Class I)
Dashed arrow indicates RCT-supported efficacy, but is less cost effective
If on clinically judged maximal LDL-C lowering therapy and LDL-C ≥70 mg/dL (≥1.8 mmol/L), or non-HDL-C ≥100 mg/dL (≥2.6 mmol/L), adding PCSK9-1 is reasonable (Class IIa)

FIGURE 13–6. Summary of statin initiation recommendations for the treatment of blood cholesterol in patients with established clinical atherosclerotic cardiovascular disease (ASCVD). Colors correspond to class of recommendation. Clinical ASCVD consists of ACS, those with history of MI, stable or unstable angina or coronary or other arterial revascularization, stroke, transient ischemic attack (TIA), or peripheral artery disease (PAD) including aortic aneurysm, all of atherosclerotic origin. *Very high risk includes a history of multiple major ASCVD events or one major ASCVD event and multiple high-risk conditions. (ACS, acute coronary syndrome; LDL-C, low-density lipoprotein cholesterol; non-HDL-C, non-high-density lipoprotein cholesterol; MI, myocardial infarction; PCSK9-I, proprotein convertase subtilisin/kexin 9 inhibitor; RCT, randomized controlled trial; y, year.) (From Grundy SM, Stone NJ, Bailey AL, et al. 2018 AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA guideline on the management of blood cholesterol: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. J Am Coll Cardiol. 2019;73(24):e285–e350, with permission.)

recommendations about when to check the other risk-enhancing factors, but list them as options to help with the decision to initiate statin therapy based on a patient's individual risk.

Once the decision to initiate statin therapy is made, the dose intensity is based on the patient's specific statin-benefit group (Figures 13–5 and 13–6). High-intensity statin therapy on average lowers LDL cholesterol by approximately 50% or more and moderate-intensity statin therapy lowers LDL cholesterol approximately 30% to 49% (see Table 13–5). The 2013 ACC/AHA expert panel concluded they could not find evidence for or against titration of drug therapy to specific LDL cholesterol and/or non-HDL cholesterol goals, but thresholds for LDL cholesterol and percent LDL cholesterol goals were added to the 2018 guidelines.[3,4] A follow-up LDL cholesterol 4 to 12 weeks after initiating therapy is used to assess response (percent LDL cholesterol lowering from baseline) and statin adherence, and not for determining if specific LDL cholesterol concentrations have been achieved.

In 2014, the NLA issued its recommendation for patient-centered management of dyslipidemia and reaffirmed the importance of setting cholesterol goals for prevention of ASCVD.[7] The NLA emphasized that non-HDL cholesterol is a better primary target for modification than LDL cholesterol and is now considered a co-target with LDL cholesterol. Non-HDL cholesterol is preferred by the NLA as it has demonstrated greater accuracy than LDL cholesterol for predicting ASCVD events both on and off statin treatment and its lack of need for measurement in the fasting state and low cost. **KEY CONCEPT** The NLA recommendations for "desirable" cholesterol levels are presented in Table 13–6.

Table 13–5

High, Moderate, and Low-Intensity Statin Therapy as Indicated by the American Heart Association/American College of Cardiology (AHA/ACC) Guidelines[4]

	High Intensity	Moderate Intensity	Low Intensity
LDL-C Lowering[a]	≥ 50%	30%–49%	< 30%
Statins	**Atorvastatin (40[b])–80 mg** **Rosuvastatin 20 (40) mg**	**Atorvastatin 10** (20) **mg** **Rosuvastatin** (5) **10 mg** **Simvastatin 20–40 mg** **Pravastatin 40** (80) **mg** **Lovastatin 40** (80) **mg** Fluvastatin XL 80 mg **Fluvastatin 40 mg twice daily** Pitavastatin 1–4 mg	Simvastatin 10 mg **Pravastatin 10–20 mg** **Lovastatin 20 mg** Fluvastatin 20–40 mg

Boldface type indicates specific statins and doses that were evaluated in randomized controlled trials (RCTs).

[a] Low-density lipoprotein cholesterol (LDL-C) lowering that should occur with the dosage listed below each intensity.

[b] Evidence from one RCT only: down-titration if unable to tolerate atorvastatin 80 mg.

Table 13–6

National Lipid Association Classifications of Cholesterol and Triglyceride Levels in mg/dL (mmol/L)[7]

Lipids	
Non-HDL Cholesterol[a]	
< 130 (3.36)	Desirable
130–159 (3.36–4.12)	Above desirable
160–189 (4.13–4.90)	Borderline high
190–219 (4.91–5.68)	High
≥ 220 (5.69)	Very high
LDL Cholesterol	
< 100 (2.59)	Desirable
100–129 (2.59–3.35)	Above desirable
130–159 (3.36–4.12)	Borderline high
160–189 (4.13–4.90)	High
≥ 190 (4.91)	Very high
HDL Cholesterol	
< 40 (1.03) (men)	Low
< 50 (1.29) (women)	Low
Triglycerides	
< 150 (1.70)	Normal
150–199 (1.70–2.25)	Borderline high
200–499 (2.26–5.64)	High
≥ 500 (5.65)	Very high[b]

[a] Non-HDL-C = total cholesterol minus HDL cholesterol.

[b] Severe hypertriglyceridemia is another term used for very high triglycerides in pharmaceutical product labeling.

HDL, high-density lipoprotein; LDL, low-density lipoprotein; non-HDL, non–high-density lipoprotein.

In 2020, AACE/ACE updated their guidelines with continued emphasis on lifestyle recommendations.[8] They provide five different risk categories ranging from low risk to extreme risk. For each of these risk categories, treatment goals are provided for LDL cholesterol, non-HDL cholesterol, Apo B, and triglycerides. Their treatment goals for extreme risk patients go as low as an LDL cholesterol less than 55 mg/dL (1.42 mmol/L) and non-HDL cholesterol less than 80 mg/dL (2.07 mmol/L). The AACE/ACE also support measuring Lp(a) in higher-risk individuals and the use of icosapent ethyl to prevent ASCVD.

Recommendations for Treatment

▶ *Step 1: Screening and Classification of Initial Lipoprotein Lipid Levels*

Determine lipoprotein profile in either the fasting or nonfasting state. KEY CONCEPT The AHA/ACC recommends that either a fasting or nonfasting lipid panel can be performed. They specifically recommend a fasting lipid panel on a different day if a patient has ingested a high-fat meal in the preceding 8 hours, or if tested and the LDL cholesterol is less than 70 mg/dL (1.81 mmol/L), as the Friedewald calculated LDL cholesterol is less reliable. The NLA and AACE/ACE recommend that all adults older than 20 years are screened at least every 5 years to obtain a lipid profile (see Clinical Presentation and Diagnosis).[7,8] Children between 2 and 20 years old should be screened for high cholesterol if their parents have premature CHD or if one of their parents has total cholesterol greater than 240 mg/dL (6.21 mmol/L).

▶ *Step 2: Rule Out Secondary Causes of Dyslipidemia*

Certain secondary causes (drugs and diseases) can cause abnormalities in serum lipids and should be evaluated (Table 13–2). Every effort should be made to correct or control underlying diseases such as hypothyroidism and DM. Concurrent medications known to induce lipid abnormalities should be evaluated for discontinuation if alternative medications can be used prior to instituting long-term lipid-modifying therapy.[5,7]

▶ *Step 3: Identify Patients with Very High-Risk Conditions*

Individuals with established clinical ASCVD (Figure 13–6) or DM with greater or equal to two ASCVD risk factors (Table 13–7) or evidence of atherosclerosis-mediated end-organ damage are considered very high risk or extreme risk. NLA and AACE/ACE set non-HDL cholesterol and LDL cholesterol goals for very-high-risk patients at less than 100 mg/dL (2.59 mmol/L) and less than 70 mg/dL (1.81 mmol/L), respectively.[7,8] The 2020 AACE/ACE guidelines set non-HDL cholesterol and LDL cholesterol goals for extreme-risk patients (see Table 13–4) at less than 80 mg/dL (2.07 mmol/L) and less than 55 mg/dL (1.42 mmol/L), respectively.[8] AHA/ACC, NLA, and AACE/ACE recommend statin therapy as initial pharmacotherapy when non-HDL cholesterol or LDL cholesterol is equal to or above these targets/thresholds.[4,7,8] For patients with DM, consideration can be given to use at least moderate-to-high-intensity statin therapy, irrespective of baseline cholesterol levels. The 2018 AHA/ACC guidelines recommend nonstatin therapy (ezetimibe or proprotein convertase subtilisin/kexin 9 [PCSK9] inhibitors) in addition to maximum tolerated statin therapy in patients who are very high risk and continue to have an LDL cholesterol above the 70 mg/dL (1.81 mmol/L) threshold .[4]

Table 13–7

Risk Factors for Atherosclerotic Cardiovascular Disease (ASCVD) According to the National Lipid Association (NLA)[a,7]

Risk Factor	Definition
Age (years)	Male ≥ 45; female ≥ 55
Family history of premature CHD events[b]	Male first-degree relative at < 55 years Female first-degree relative at < 65 years
Hypertension[c]	SBP ≥ 140 mm Hg DBP ≥ 90 mm Hg
Low HDL cholesterol	< 40 mg/dL (1.03 mmol/L) in males < 50 mg/dL (1.29 mmol/L) in females
Cigarette smoking	Current

[a] Levels of non-HDL cholesterol and LDL cholesterol are not listed because these risk factors are used to assess risk category and treatment goals for atherogenic lipoprotein cholesterol levels. Diabetes is not listed because it is considered a high- or very high-risk condition for ASCVD risk assessment purposes.

[b] CHD is defined as myocardial infarction, coronary death, or a coronary revascularization procedure.

[c] Note, blood pressure values used by the NLA differ from the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCMA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults.

CHD, coronary heart disease; DBP, diastolic blood pressure; HDL, high-density lipoprotein; LDL, low-density lipoprotein; SBP, systolic blood pressure.

Table 13–8

Risk-Enhancing Factors for Clinician-Patient Risk Discussion According to American Heart Association/American College of Cardiology (AHA/ACC)[4]

Risk-Enhancing Factors

- **Family history of premature ASCVD** (male < 55 years; female, < 65 years)
- **Primary hypercholesterolemia** (LDL-C, 160–189 mg/dL [4.14–4.89 mmol/L); non–HDL-C 190–219 mg/dL [4.91–5.66 mmol/L])[a]
- **Metabolic syndrome**
- **Chronic kidney disease** (eGFR 15–59 mL/min/1.73 m^2 with or without albuminuria; not treated with dialysis or kidney transplantation)
- **Chronic inflammatory conditions** such as psoriasis, RA, or HIV/AIDS
- **History of premature menopause** (before age 40 years) and **history of pregnancy-associated conditions that increase later ASCVD risk** such as preeclampsia
- **High-risk race/ethnicities** (eg, South Asian ancestry)
- **Lipid/biomarkers**: Associated with increased ASCVD risk
  - Persistently[a] elevated, primary hypertriglyceridemia (≥ 175 mg/dL [1.98 mmol/L])
  - If measured:
    1. **Elevated high-sensitivity C-reactive protein** (≥ 2 mg/L)
    2. **Elevated Lp(a)**: A relative indication for its measurement is family history of premature ASCVD. An Lp(a) ≥ 50 mg/dL (0.5 g/L; 125 nmol/L) constitutes a risk-enhancing factor, especially at higher levels of Lp(a).
    3. **Elevated apoB** ≥ 130 mg/dL (1.3 g/L): A relative indication for its measurement would be triglycerides ≥ 200 mg/dL (2.26 mmol/L). ApoB level ≥ 130 mg/dL (1.3 g/L) corresponds to an LDL-C > 160 mg/dL (4.14 mmol/L) and constitutes a risk-enhancing factor.
    4. **ABI** < 0.9

[a] Optimally, three determinations.

ABI, ankle-brachial index; AIDS, acquired immunodeficiency syndrome; apoB, apolipoprotein B; ASCVD, atherosclerotic cardiovascular disease; eGFR, estimated glomerular filtration rate; HDL-C, high-density lipoprotein cholesterol; HIV, human immunodeficiency virus; LDL-C, low-density lipoprotein cholesterol; Lp(a), lipoprotein (a); RA, rheumatoid arthritis.

▶ *Step 4: Identify Patients with High-Risk Conditions*

The 2018 AHA/ACC guidelines set criteria for nonstatin therapy for patients with high residual risk after receiving maximum tolerated statin doses based on their statin-benefit group, described in Figure 13–6. The 2018 AHA/ACC guidelines have set a LDL cholesterol goal of a 50% reduction in those with established clinical ASCVD and recommend the addition of nonstatin therapy with either ezetimibe or a PCSK9 inhibitor when this goal and/or LDL cholesterol target of less than 70 mg/dL (1.81 mmol/L) are not achieved.[4] The NLA and AACE/ACE set non-HDL cholesterol and LDL cholesterol goals at less than 130 mg/dL (3.36 mmol/L) and less than 100 mg/dL (2.59 mmol/L) for high-risk primary prevention patients and at less than 100 mg/dL (2.59 mmol/L) and less than 70 mg/dL (1.81 mmol/L) for secondary prevention patients, respectively.[7,8] Pharmacotherapy can be considered when the desired LDL-cholesterol lowering is not achieved or LDL or non-HDL cholesterol is equal to or above the targets. If it is not possible to attain desirable LDL and non-HDL cholesterol levels in patients with severe hypercholesterolemia phenotype, a reduction of at least 50% is recommended.[4,7,8] For FH patients with multiple or poorly controlled other major ASCVD risk factors, clinicians may consider aiming for even lower levels of atherogenic cholesterol.[7,8]

▶ *Step 5: Identify Patients Without Established ASCVD and Need for Risk Assessment*

Individuals without clinical ASCVD should be screened for major ASCVD risk factors, and quantitative risk scoring should be obtained for adults 20 years or older (eg, pooled cohort equation ASCVD risk calculation). Consideration of additional risk-enhancing factors (Table 13–8) may also be useful for some patients if the patient or provider are uncertain about initiating a statin and want additional factors assessed to determine the best plan. If ASCVD risk score reaches the high-risk threshold (> 20%), assign patient to high-risk category. If risk-enhancing factors are present, consider assigning to the high-risk category. If no indication is present to assign to high risk, then patients should be considered low risk, borderline risk, or intermediate risk based on their ASCVD risk score and presence of risk-enhancing factors (Figure 13–5).

The NLA and AACE/ACE have established goals for non-HDL cholesterol and LDL cholesterol of less than 130 mg/dL (3.36 mmol/L) and less than 100 mg/dL (2.59 mmol/L), respectively, in patients considered high risk (eg, two or more CV risk factors and a 10%–20% estimated risk of ASCVD in 10 years).[7,8] Pharmacotherapy can be considered when non-HDL cholesterol or LDL cholesterol are equal to or above 160 mg/dL (4.14 mmol/L) and 130 mg/dL (3.36 mmol/L), respectively. For individuals with one or no major ASCVD risk factors, the NLA set goals for non-HDL cholesterol and LDL cholesterol at less than 130 mg/dL (3.36 mmol/L) and less than 100 mg/dL

(2.59 mmol/L), respectively. Pharmacotherapy can be considered when non-HDL cholesterol or LDL cholesterol are equal to or above 190 mg/dL (4.91 mmol/L) and 160 mg/dL (4.14 mmol/L), respectively. Consider assigning to a higher-risk category based on other known risk indicators, when present.

▶ *Step 6: Treatment of Elevated Triglycerides*

KEY CONCEPT Patients with severely elevated serum triglycerides exceeding 500 mg/dL (5.65 mmol/L) are at increased risk of pancreatitis, especially when levels are extremely elevated above 1000 mg/dL (11.3 mmol/L).[4,7,8] Reducing triglycerides in these individuals becomes the primary target for intervention. Reduction in fats and carbohydrates and abstaining from ethanol should be considered, and secondary causes (Table 13–2) should be assessed. Increase in exercise should be encouraged. Weight loss should also be encouraged if the individual is overweight. When pharmacotherapy is instituted, the goal is to reduce triglycerides to less than 150 mg/dL (1.70 mmol/L). Once triglycerides are less than 500 mg/dL (5.65 mmol/L), and the risk of pancreatitis is reduced, the primary focus of intervention should once again be on non-HDL and LDL cholesterol. Niacin, fibrates, and long-chain omega-3 fatty acids (OM3FA) are the most effective agents in patients with fasting triglyceride concentrations greater than 1000 mg/dL (11.3 mmol/L).[4,7,8] For patients with triglycerides 500 to 999 mg/dL (5.65–11.29 mmol/L), a triglyceride-lowering agent or a statin (if no history of pancreatitis) may be reasonable. Bile acid sequestrants should be avoided in patients with a triglyceride value of 300 mg/dL (3.39 mmol/L) or higher as they can increase triglycerides. Fibrate therapy needs to be used with caution in patients with renal dysfunction, and gemfibrozil should not be used in patients with stage 4 chronic kidney disease (CKD) or greater. Individuals with triglycerides between 200 and 499 mg/dL (2.26 and 5.64 mmol/L) have increased triglyceride-rich remnant lipoproteins and small-dense LDL particles, which are considered more atherogenic than large buoyant LDL particles. For patients with high triglycerides between 200 and 499 mg/dL (2.26 and 5.64 mmol/L), statins will generally be first line since they are most effective in reducing non-HDL and LDL-cholesterol levels. In 2019, the findings from the Reduction of Cardiovascular Events with Icosapent Ethyl–Intervention Trial (REDUCE-IT) results were published.[10] Based on the major CV event lowering seen in patients treated with icosapent ethyl, the Food and Drug Administration (FDA) approved this drug in December 2019 as adjunct to maximally tolerated statin therapy to reduce the risk of myocardial infarction (MI), stroke, coronary revascularization, and unstable angina requiring hospitalization in adult patients with triglyceride levels greater than or equal to 150 mg/dL (1.70 mmol/L) and established ASCVD or DM and two or more additional risk factors for CV disease (ie, male > 55 years of age or female > 65 years of age, tobacco smoker, hypertension, low HDL cholesterol, hs-CRP > 3 mg/L, renal dysfunction, retinopathy, albuminuria, ABI greater than 0.9).

Patient Encounter Part 1

A 60-year-old African American woman with hypertension, hypothyroidism, and type 2 diabetes mellitus has been referred for a follow-up of her cholesterol. Her current medication regimen includes lisinopril 40 mg daily, amlodipine 10 mg daily, hydrochlorothiazide 25 mg daily, metformin 1000 mg twice daily, and empagliflozin 10 mg daily. Her blood glucose is 150 mg/dL (8.3 mmol/L). Her laboratory test results are within normal limits. Her blood pressure today is 140/84 mm Hg with a heart rate of 70 beats/min. She is a nonsmoker. Her fasting lipid profile is total cholesterol 200 mg/dL (5.17 mmol/L), triglycerides 160 mg/dL (1.81 mmol/L), HDL cholesterol 46 mg/dL (1.19 mmol/L), non-HDL cholesterol 154 mg/dL (3.98 mmol/L), and LDL cholesterol 122 mg/dL (3.15 mmol/L).

What is your assessment of the patient's cholesterol results?

Should an assessment of her risk factors for ASCVD or an ASCVD risk score be conducted?

Does this patient have clinical ASCVD?

What treatment group does she fit according to AHA/ACC guidelines?

What additional information do you need to evaluate the patient?

Develop a care plan for the patient.

Pharmacotherapy

▶ *Statins (HMG-CoA Reductase Inhibitors)*

KEY CONCEPT Statins are very effective LDL-lowering medications and are proven to reduce the risk of CHD, stroke, and death. Thus, AHA/ACC, NLA, and AACE/ACE consider statins the preferred LDL-lowering medications.[4,7,8] Statins are effective in reducing ASCVD and in some cases, mortality. This effectiveness has been demonstrated in both male and female genders, the elderly, patients with DM and hypertension, those with or without preexisting ASCVD, and following an acute coronary syndrome.[11-16] Statins inhibit conversion of HMG-CoA to L-mevalonic acid and subsequently cholesterol (Figure 13–7). Statins lower LDL cholesterol levels by approximately 21% to 63% (Table 13–9), are moderately effective at reducing triglycerides, and modestly raise HDL cholesterol. Statins are routinely recommended to take in the evening as that is when the body produces the most cholesterol (most important for statins with shorter half-lives, but those with a long half-life [eg, atorvastatin, rosuvastatin] can be taken any time of day). Additionally, statins also inhibit other important by-products in the cholesterol biosynthetic pathway that affect intracellular transport, membrane trafficking, and gene transcription. This may explain some of the cholesterol-independent benefits (so-called pleiotropic effects) of statins such as reducing lipoprotein oxidation, enhancing endothelial synthesis of nitric oxide, and inhibiting thrombosis. These pleiotropic effects are thought to contribute to the early benefits of statins on CHD risk, while the decrease in serum lipids accounts for the later benefits.

KEY CONCEPT Statins are well tolerated, with less than 4% of patients in clinical trials discontinuing therapy due to adverse side effects (Table 13–10). Elevations in liver function tests (LFTs) and statin-associated muscle symptoms (SAMS) (including myalgia, myopathy, and rhabdomyolysis) are important adverse effects associated with statins. Liver toxicity, defined as LFT elevations greater than three times the upper limit of normal, is reported in less than 2% of patients. Incidence is higher at higher doses, but the progression to liver failure is exceedingly rare. LFTs should be obtained at baseline and as clinically indicated thereafter. Myalgia is defined as muscle aches or pains not associated with creatine kinase (CK) elevations. Myopathy, defined as unexplained muscle weakness or pain associated with CK elevations greater than 10 times the upper limit of normal, is reported to range

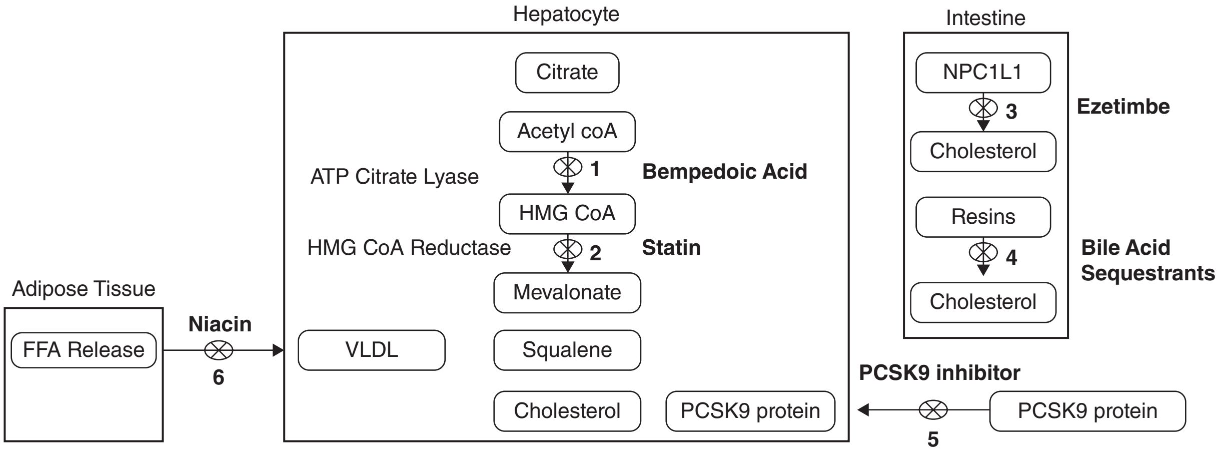


FIGURE 13–7. Mechanism of action for major lipid-lowering medication classes to target low-density lipoprotein. Bempedoic acid (1) inhibits ATP citrate lyase which blocks the synthesis of cholesterol in the hepatocyte resulting in reduced cholesterol production. Statins (2) inhibit HMG CoA reductase, which blocks the synthesis of cholesterol in the hepatocyte resulting in reduced cholesterol production. Ezetimibe (3) inhibits the action of the transporter NPC1L1, reducing intestinal absorption of dietary and biliary cholesterol, which reduces the delivery of chylomicron cholesterol to the hepatocyte via the portal circulation. Bile acid sequestrants (4) bind to bile acids in the gut, resulting in a resin–bile acid complex that is then excreted in the feces leading to hepatic cholesterol conversion to bile and an upregulation of LDL receptors. PCSK9 inhibitors (5) are monoclonal antibodies to PCSK9 and bind to PCSK9 within the circulation, resulting in less breakdown of the LDL receptor resulting in upregulation of LDL receptor expression by the hepatocyte. Niacin (6) inhibits FFA release from adipose tissue, which results in a reduction in VLDL leading to an overall reduction in LDL. (ATP, adenosine triphosphate; CoA, coenzyme A; FFA, free fatty acid; HMG-CoA, β-hydroxy β-methylglutaryl-CoA; LDL, low-density lipoprotein; NPC1L1, Niemann-Pick C1 Like 1; PCSK9, proprotein convertase subtilisin/kexin type 9; VLDL, very low-density lipoprotein.)

from 0% to less than 0.5% for the currently marketed statins at approved doses. Rhabdomyolysis, defined as muscle symptoms with marked elevation in CK of at least 40 times the upper limit of normal and creatinine elevation usually associated with myoglobinuria and brown urine, is very rare.[17,18] The risks associated with statin-induced myopathy include the following[17,18]:

- Small body frame and frailty.
- Multisystem disease (eg, CKD, especially due to DM).
- Perioperative periods.
- Multiple medications (see next bullet).
- Specific concomitant medications or consumptions (check specific statin package insert for warnings): fibrates (especially gemfibrozil, but other fibrates too), nicotinic acid (rarely), cyclosporine, azole antifungals, macrolide antibiotics, protease inhibitors, nefazodone, verapamil, amiodarone, large quantities of grapefruit juice (usually > 1 quart [about 950 mL] per day), and alcohol abuse (independently predisposes to myopathy).

The AHA scientific statement on statin safety and associated adverse events gives guidance on how to manage SAMS.[18] It is reasonable to check a baseline CK in patients at risk for myopathy. Follow-up CK should only be obtained in patients complaining of muscle pain, weakness, tenderness, or brown urine. Common secondary causes of muscle symptoms should be ruled out (eg, vitamin D deficiency, hypothyroidism, muscle disorders). If a patient presents with a CK elevation less than three times the upper limit of normal, they can continue their current statin dose and monitor for ongoing muscle symptoms. If their CK is greater than three times the upper limit of normal but less than 10 times, they can continue their statin therapy if mild symptoms and repeat a CK in 1 week. If the CK is decreasing or stable, they can be continued on their statin and continue to monitor for muscle symptoms, but if CK is increasing, then the statin should be stopped and the CK reassessed when the patient's symptoms have resolved. If CK is greater than 10 times the upper limit of normal, they should immediately have their statin stopped and be instructed to increase their fluid intake. If the CK is greater than 40 times the upper limit of normal, they would meet the definition of rhabdomyolysis and should immediately go to the hospital to be assessed as they are at a high risk of acute renal failure. Patient assessment for symptoms of myopathy should be done 6 to 12 weeks after starting or changing therapy and at each visit.

Some evidence suggests that statins increase the risk for development of DM. The FDA warns of increased blood sugar and glycosylated hemoglobin (HbA_{1c}) levels on statin labels. In addition, the FDA has added to statin labels that cognitive impairment, such as memory loss, forgetfulness and confusion, has been reported by some statin users. There have been some evaluations showing an association with cognitive impairment, but these symptoms appear to be reversible when stopping the statin, and one should always rule out other secondary causes. The FDA continues to believe the cardiovascular benefits of statins outweigh these small increased risks.

With the exception of pravastatin and pitavastatin, the other statins undergo biotransformation by the cytochrome P-450 (CYP) system with lovastatin and simvastatin having the highest risk of drug–drug interactions. Therefore, drugs known to inhibit statin metabolism should be used cautiously or avoided and are highlighted in an AHA scientific statement on statin–drug interactions.[19] Medications such as cyclosporine and gemfibrozil can inhibit drug transporters in the gut and liver that can increase statin concentrations. The time until maximum effect on lipids for statins is generally 4 to 6 weeks.

▶ *Cholesterol Absorption Inhibitors*

Ezetimibe blocks biliary and dietary cholesterol as well as phytosterol (plant sterol) absorption by interacting with the NPC1L1

Table 13–9

Effects of Lipid-Lowering Drugs on Serum Lipids at FDA-Approved Doses

Lipid-Lowering Drug	LDL Cholesterol	HDL Cholesterol	Triglycerides	Total Cholesterol
Statins				
Atorvastatin	–26% to –60%	+5% to +13%	–17% to –53%	–25% to –45%
Fluvastatin	–22% to –36%	+3% to +11%	–12% to –25%	–16% to –27%
Fluvastatin ER	–33% to –35%	+7% to +11%	–19% to –25%	–25%
Lovastatin	–21% to –42%	+2% to +10%	–6% to –27%	–16% to –34%
Pitavastatin	–31% to –45%	+1% to +8%	–13% to –22%	–23% to –31%
Pravastatin	–22% to –34%	+2% to +12%	–15% to –24%	–16% to –25%
Rosuvastatin	–45% to –63%	+8% to +14%	–10% to –35%	–33% to –46%
Simvastatin	–26% to –47%	+8% to +16%	–12% to –34%	–19% to –36%
Cholesterol Absorption Inhibitor				
Ezetimibe	–18%	+1% to +2%	–7% to –9%	–12% to –13%
Bile Acid Sequestrants				
Cholestyramine	–15% to –30%	+3% to +5%	May increase in patients with elevated triglycerides	–10% to –25%
Colesevelam	–15% to –18%	+3% to +5%		–70% to –10%
Colestipol	–15% to –30%	+3% to +5%		–10% to 25%
Nicotinic Acid				
Niacin ER	–5% to –17%	+14% to +26%	–11% to –38%	–3% to –12%
Niacin IR	–5% to –25%	+15% to +39%	–20% to –60%	–3% to –25%
Fibric Acid Derivatives				
Fenofibrate	–31% to +45%	+9% to +23%	–23% to –54%	–9% to –22%
Gemfibrozil	–30% to +30%	+10% to +30%	–20% to –60%	–2% to –16%
Omega-3-Fatty Acids				
Omega-3 ethyl esters	+45%	+9%	–45%	–10%
Icosapent ethyl	–5%	–4%	–27%	–7%
Microsomal Transfer Protein Inhibitors				
Lomitapide	–40%	–7%	–45%	–36%
Antisense Oligonucleotide				
Mipomersen	–25%	+15%	–18%	–21%
Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors				
Alirocumab	–48% to –71%			–46% to –59%
Evolocumab	–48% to –71%			–46% to –59%
Adenosine Triphosphate Citrate Lyase (ACL) Inhibitors				
Bempedoic Acid	–15% to –25%	–5%		–11%

ER, extended-release; FDA, Food and Drug Administration; HDL, high-density lipoprotein; IR, immediate-release; LDL, low-density lipoprotein.

transporter (Figure 13–2 and Figure 13–7).^{5} Less cholesterol is delivered to the liver, which leads to an upregulation of LDL receptors. This causes a reduction in serum cholesterol and a compensatory increase in cholesterol biosynthesis. Because statins inhibit cholesterol biosynthesis, this compensatory increase by ezetimibe can be blocked when coadministered with a statin.

KEY CONCEPT Ezetimibe reduces LDL cholesterol by an average of 18%. However, larger reductions can be seen in some individuals, presumably due to higher absorption of cholesterol. These individuals appear to have a blunted response to statin therapy. Ezetimibe lowers triglycerides by 7% to 9% and modestly increases HDL cholesterol (see Table 13–9).

Ezetimibe is contraindicated in patients with active liver disease or unexplained persistent elevations in LFTs. Since statins are the standard of care, a placebo-controlled randomized trial of the effects of ezetimibe monotherapy on CHD morbidity and mortality has never been conducted. Ezetimibe combined with simvastatin was associated with a reduced incidence of ischemic cardiovascular events in low-risk patients with mild-to-moderate

Patient Encounter 2, Part 1

A 52-year-old man presents to your clinic for a physical examination. He states that he was diagnosed with peripheral artery disease 2 years ago, and he tries to take his medications every day. He has not had his cholesterol evaluated in the last 2 years. He reports having claudication pain about one to two times a month. His family has no history of cardiovascular disease. Both his parents are alive. He is married with three children. He is a former smoker who quit 2 years ago. He exercises regularly (three times a week most weeks riding his bike). He has not eaten yet this morning.

Does this patient have clinical ASCVD?

Can the patient be evaluated today for LDL cholesterol?

Should an assessment of his risk factors for ASCVD or an ASCVD risk score be conducted?

What additional information do you need to evaluate the patient?

Table 13–10

Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Statins			
Atorvastatin	10-, 20-, 40-, 80-mg tablets	10–80 mg once daily (at any time of day). Dose adjustment in patients with renal dysfunction is not necessary	Most frequent side effects are constipation, abdominal pain, diarrhea, and nausea. Statins should be dose reduced and/or discontinued promptly if serum transaminase levels (liver function tests) rise to three times upper limit of normal or if patient develops signs or symptoms of myopathy. Dose equivalence should be considered when switching HMG-CoA reductase inhibitors
Fluvastatin	20-, 40-mg capsules; 80-mg extended-release tablets	20–40 mg/day as a single dose (evening) or 40 mg twice daily; 80-mg extended-release once daily. Dose adjustments for mild-to-moderate renal impairment are not necessary	
Lovastatin	10-, 20-, 40-mg tablets	10–80 mg/day as a single dose (with evening meal) or divided twice daily with food; 20–60 mg/day as a single dose. In patients with severe renal insufficiency (creatinine clearance < 30 mL/min [0.5 mL/s]), dosage increases above 20 mg/day should be carefully considered and, if deemed necessary, implemented cautiously	
Pravastatin	10-, 20-, 40-, 80-mg tablets	10–80 mg/day as a single dose at bedtime. In patients with a history of significant renal or hepatic dysfunction, a starting dose of 10 mg daily is recommended	
Pitavastatin	1-, 2-, 4-mg tablets	1–4 mg/day as a single dose can be taken with or without food, at any time of day. Moderate renal impairment (glomerular filtration rate 30–60 mL/min/1.73 m^2 [0.29–0.58 mL/s/m^2]) and end-stage renal disease on hemodialysis: Starting dose of 1 mg once daily and maximum dose of 2 mg once daily	
Rosuvastatin	5-, 10-, 20-, 40-mg tablets	5–40 mg/day (at any time of day); 40 mg reserved for those who do not achieve LDL cholesterol goal on 20 mg. In patients with history of significant renal dysfunction or Asian, starting dose of 5 mg daily is recommended	
Simvastatin	5-, 10-, 20-, 40-, 80-mg tablets	5–40 mg/day as a single dose in the evening, or divided. Recommended starting dose for patients at high risk of CHD is 40 mg/day. In patients with mild-to-moderate renal insufficiency, dosage adjustment is not necessary. However, caution should be exercised in patients with severe renal insufficiency; such patients should be started at 5 mg/day and be closely monitored. Due to increased risk of myopathy, including rhabdomyolysis, use of the 80-mg dose should be restricted to patients who have been taking simvastatin 80 mg chronically (eg, for 12 months or more) without evidence of muscle toxicity.	
Cholesterol Absorption Inhibitors			
Ezetimibe	10-mg tablets	10 mg once daily. No dosage adjustment is necessary in patients with renal or mild hepatic insufficiency	Overall incidence of adverse events reported with ezetimibe alone was similar to that reported with placebo and generally similar between ezetimibe with a statin and statin alone. The frequency of increased transaminases was slightly higher in patients receiving ezetimibe plus a statin compared with those receiving statin monotherapy (1.3% vs 0.4%)
Bile Acid Sequestrants			
Cholestyramine	4-g packets	4–24 g/day in two or more divided doses	Main side effects are nausea, constipation, bloating, and flatulence, although these may be less with colesevelam. Increasing fluid and dietary fiber intake may relieve constipation and bloating. Impairs absorption of fat-soluble vitamins
Colesevelam	625-mg tablets	3750 mg/day as a single dose or divided twice daily, with meals	
	3.75-g oral suspension packet	One packet once a day with meals	
Colestipol	5-g packets	5–30 g/day as a single dose or divided	
	1-g tablets	2–16 g/day as a single dose or divided	

(Continued)

Table 13–10

Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs (*Continued*)

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Nicotinic Acid (Prescription Products)			
Niacin ER	250-, 500-, 750-, 1000-mg extended-release tablets	1000–2000 mg once daily at bedtime. Use with caution in patients with renal impairment	Side effects include flushing, itching, gastric distress, headache, hepatotoxicity, hyperglycemia, and hyperuricemia
Niacin IR	250-, 500-mg tablets	1–6 g/day in two to three divided doses. Do not exceed 6 g daily	
Fibric Acid Derivatives			
Fenofibrate	54-, 160-mg tablets[a]	54–160 mg/day; the dosage should be minimized in severe renal impairment	Most common side effects are nausea, diarrhea, abdominal pain, and rash. Increased risk of rhabdomyolysis when given with a statin. Fibric acids are associated with gallstones, myositis, and hepatitis
Gemfibrozil	600-mg tablets	1200 mg/day in two doses, 30 minutes before meals; should be avoided in hepatic or severe renal impairment	
Omega-3-Fatty Acids			
Omega-3 ethyl esters	1-g capsule containing at least 0.9 g of OM3FA ethyl ester (EPA~0.465 g and DHA ~0.375 g)	4 g/day taken as single 4-g dose (four capsules) or two 2-g doses (two capsules twice daily)	All products are obtained from oil of fish. Should be used with caution in patients with known hypersensitivity to fish and/or shellfish. Side effects of Lovaza/Omtryg include: • Eructation, 4% • Dyspepsia, 3% • Taste perversion, 4% Side effects of Vascepa include: • Arthralgia, 2.3%
Icosapent ethyl	0.5-, 1-g capsule containing 1 g of icosapent ethyl	2 g twice daily with meals	
Microsomal Transfer Protein Inhibitors			
Lomitapide	5-,10-, 20-, 30-, 40-, and 60-mg capsules	5 mg once daily. Titrate dose based on acceptable safety/tolerability: increase to 10 mg daily after at least 2 weeks; and then, at a minimum of 4-week intervals, to 20 mg, 40 mg, and up to the maximum recommended dose of 60 mg daily	Gastrointestinal side effects and elevation in liver enzymes and hepatic fat are common
Antisense Oligonucleotide			
Mipomersen	200-mg subcutaneous injection	200 mg once weekly as a subcutaneous injection	Injection site reactions, hepatic fat, and liver enzyme elevations are common
Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors			
Alirocumab	75- or 150-mg subcutaneous injection	75–150 mg once every 2 week subcutaneous injection or 300 mg once every month subcutaneous injection	Injection site reactions, nasopharyngitis, influenza, upper respiratory tract infections, urinary tract infection, elevation in liver enzymes
Evolocumab	140- or 420-mg subcutaneous injection	140 mg once every 2 week subcutaneous injection or 420 mg once every month subcutaneous injection	Injection site reactions, nasopharyngitis, influenza, upper respiratory tract infections, urinary tract infection, back pain
Adenosine Triphosphate Citrate Lyase (ACL) Inhibitors			
Bempedoic acid	180-mg tablets	180 mg once daily. No dosage adjustment for patients with renal or hepatic insufficiency provided in labeling	Hyperuricemia
Combination Products			
Ezetimibe and simvastatin	10 mg/10 mg, 10 mg/20 mg, 10 mg/40 mg, 10 mg/80 mg	Dosage range is 10/10 mg/day through 10/40 mg/day. Recommended usual starting dose is 10/10 or 10/20 mg/day. Initiation of therapy with 10/10 mg/day may be considered for patients requiring less aggressive LDL cholesterol reductions. Due to increased risk of myopathy, including rhabdomyolysis, use of the 10/80-mg dose of Vytorin should be restricted to patients who have been taking Vytorin 10/80 mg chronically (eg, for 12 months or more) without evidence of muscle toxicity	See previous entries for each drug (ezetimibe and simvastatin)
Bempedoic acid and ezetimibe	180 mg/10 mg	180 mg/10 mg once daily	See previous entries for each drug (bempedoic acid and ezetimibe)

[a] Dose strengths vary depending on brand.

CHD, coronary heart disease; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; ER, extended-release; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IR, immediate-release; LDL, low-density lipoprotein; OM3FA, omega-3 fatty acid.

asymptomatic aortic stenosis compared with placebo,[20] as well as reduced incidence of major atherosclerotic events in a wide range of patients with advanced CKD.[21] Ezetimibe combined with simvastatin was shown to further reduce ASCVD events in patients who have suffered a recent MI compared to simvastatin alone.[22] Additionally, ezetimibe combined with bempedoic acid has been shown to be safe and effective at lowering LDL cholesterol. Ezetimibe is primarily used in combination with a statin when adequate reductions in atherogenic cholesterol are not achieved (Figure 13–6) or in those patients who are intolerant to statin therapy. The time until maximum effect on lipids for ezetimibe is generally 2 weeks.

▶ *Bile Acid Sequestrants*

Cholestyramine, colestipol, and colesevelam are the oral bile acid–binding resins or sequestrants (BAS) currently available in the United States. Resins are highly charged molecules that bind to bile acids in the gut (Figure 13–7). The resin–bile acid complex is then excreted in the feces. The loss of bile causes a compensatory conversion of hepatic cholesterol to bile, reducing hepatocellular stores of cholesterol and resulting in an upregulation of LDL receptors which then results in a decrease in serum cholesterol. Resins have been shown to reduce CHD events in patients without CHD.[23]

KEY CONCEPT Resins are moderately effective in lowering LDL cholesterol but do not lower triglycerides. Moreover, in patients with elevated triglycerides, the use of a resin may increase triglycerides. This may be due to a compensatory increase in HMG-CoA reductase activity which increases secretion of VLDL. The increase in HMG-CoA reductase activity can be blocked with a statin, resulting in enhanced reductions in serum lipids. Resins reduce LDL cholesterol from 15% to 30%, with a modest increase in HDL cholesterol (3%–5%) (Table 13–9). Resins are most often used as adjuncts to statins in patients who require additional lowering of atherogenic cholesterol and are an option to add to statins if ezetimibe and PCSK9 inhibitors are not an option, per the 2018 AHA/ACC guidelines.[4] Additionally, they are an option to lower LDL cholesterol in patients who are completely statin intolerant or cannot tolerate a moderate or high dose of statin and need further LDL-cholesterol lowering. Since these drugs are not absorbed, adverse effects are limited to the gastrointestinal (GI) tract (Table 13–10). About 20% of patients taking cholestyramine or colestipol report constipation and symptoms such as flatulence and bloating. A large number of patients stop therapy because of the GI effects. Resins should be started at the lowest dose and escalated slowly over weeks to months as tolerated until the desired response is obtained. Patients should be instructed to prepare the powder formulations in 6 to 8 ounces (approximately 180–240 mL) of noncarbonated fluids, usually juice (enhances palatability) or water. Fluid intake should be increased to minimize constipation. Colesevelam is better tolerated with fewer GI side effects, although it is more expensive.[24] Colesevelam also has an indication for improvement of glycemic control in type 2 DM. All resins have the potential to prevent absorption of other drugs such as digoxin, warfarin, thyroxine, thiazides, β-blockers, fat-soluble vitamins, and folic acid. Potential drug interactions can be avoided by taking a resin either 1 hour before or 4 hours after these other agents. The time until maximum effect on lipids for resins is generally 2 to 4 weeks.

▶ *Adenosine Triphosphate Citrate Lyase Inhibitors*

Bempedoic acid decreases LDL cholesterol by its adenosine triphosphate citrate lyase (ACL) inhibition in the liver (Figure 13–7). By inhibiting ACL, an enzyme upstream of HMG-CoA reductase, bempedoic acid decreases conversion of mitochondrial-derived citrate to cytosolic acetyl-CoA carboxylase, creating less substrate for cholesterol and FA synthesis.[25]

KEY CONCEPT Bempedoic acid reduces LDL cholesterol by an average of 15% to 25% and up to 38% when combined with ezetimibe. In 2020, the FDA-approved bempedoic acid and the combination of bempedoic acid with ezetimibe for treatment of adults with heterozygous familial hypercholesterolemia (HeFH) or established ASCVD who require additional LDL-cholesterol lowering after maximally tolerated statin therapy.[26] Overall, bempedoic acid has demonstrated good tolerance in clinical trials, and the only noted adverse event seen has been increases in uric acid. The ongoing Cholesterol Lowering via Bempedoic Acid, an ACL-Inhibiting Regimen (CLEAR) Outcomes trial aims to evaluate whether bempedoic acid can reduce CV events in patients with statin intolerance, but the trial is not set to conclude for another few years.[27,28]

▶ *Niacin*

Niacin (vitamin B_3) has broad applications in the treatment of lipid disorders when used at doses higher than those used as a nutritional supplement. Niacin inhibits FA release from adipose tissue and FA and triglyceride production in liver cells. This results in a reduction in the number of VLDL particles secreted (Figure 13–3), which leads to an overall reduction in LDL cholesterol and a decrease in the number of small dense LDL particles (Figure 13–7). Niacin also reduces the uptake of HDL-Apo A1 particles and increases uptake of cholesterol esters by the liver, thus improving the efficiency of reverse cholesterol transport between HDL particles and vascular tissue (Figure 13–3). Niacin is indicated for patients with elevated triglycerides, low HDL cholesterol, and elevated LDL cholesterol.[7,8]

Several different niacin formulations are available: immediate-release (IR), sustained-release (SR), and extended-release (ER).[29] These formulations differ in terms of dissolution and absorption rates, metabolism, efficacy, and side effects. Limitations of niacin IR and SR are flushing and hepatotoxicity, respectively. These differences appear related to the dissolution and absorption rates of niacin formulations and their subsequent metabolism. Niacin IR is available by prescription (Niacor) as well as a dietary supplement, which is not regulated by the FDA.[29] Currently, all SR products are available only as dietary supplements.

Niacin ER (Niaspan) was developed as a once-daily formulation to be taken at bedtime, with the goal of reducing the incidence of flushing without increasing the risk of hepatotoxicity. Niaspan is the only long-acting niacin product approved by the FDA for dyslipidemia.

Niacin use is limited by cutaneous reactions such as flushing and pruritus of the face and body. The use of aspirin or a nonsteroidal anti-inflammatory drug (NSAID) 30 minutes prior to taking niacin can help alleviate these reactions because they are mediated by an increase in prostaglandin D2.[7,8] In addition, taking niacin with food and avoiding hot liquids or alcohol at the time niacin is taken is helpful in minimizing flushing and pruritus. Lastly, slow titration of the niacin dose to minimize and/or prevent flushing (eg, 500 mg/day to 1000 mg/day over 8 weeks).

In general, niacin reduces LDL cholesterol from 5% to 25%, reduces triglycerides by 11% to 60%, and increases HDL cholesterol by 14% to 39% (Table 13–9). Niacin monotherapy has been shown to reduce CHD events and total mortality, as well as the progression of atherosclerosis when combined with a statin.[29,30] However, a trial that tested the effects of adding niacin ER or placebo in patients with CHD optimally treated (LDL cholesterol approximately 70 mg/dL [1.81 mmol/L]) on a statin was stopped earlier than planned because no apparent benefits by adding niacin ER were found. Moreover, a small and unexplained increase in ischemic stroke in the niacin ER group was seen.[31] Another trial also found no benefit by the addition of niacin ER plus an anti-flush medication (laropiprant).[32] These two trials have resulted in ambiguity in the role of niacin in lipid management. However, niacin is still a useful agent in the management of high triglycerides.

Niacin should be instituted at the lowest dose and gradually titrated to a maximum dose of 2 g daily for ER and SR products and no more than 6 g daily for IR products. FDA-approved niacin products are preferred because of product consistency. Moreover, niacin products labeled as "no flush" do not contain nicotinic acid and therefore have no therapeutic role in the treatment of lipid disorders.[29] The time until maximum effect on lipids for niacins is generally 3 to 5 weeks.

▶ Fibrates

KEY CONCEPT The predominant effects of fibrates are a decrease in triglyceride levels by 20% to 60% and an increase in HDL cholesterol levels by 9% to 30% (Table 13–9). The effect on LDL cholesterol is less predictable. In patients with high triglycerides, however, LDL cholesterol may increase. Fibrates increase the size and reduce the density of LDL particles much like niacin. **KEY CONCEPT** Fibrates are the most effective triglyceride-lowering drugs and are used primarily in patients with elevated triglycerides and low HDL cholesterol.

Fibrates work by activating peroxisome proliferator-activated receptor-alpha (PPAR-α), a nuclear receptor involved in cellular function. This results in a reduction in triglyceride-rich lipoproteins (VLDL and IDL) and an increase in HDL.

Clinical trials of fibrate therapy in patients with elevated cholesterol and no history of CHD demonstrated a reduction in CHD incidence, although less than the reduction attained with statin therapy.[33] In addition, a large study of men with CHD, low HDL cholesterol, low LDL cholesterol, and elevated triglycerides demonstrated a 24% reduction in risk of death from CHD, nonfatal MI, and stroke with gemfibrozil.[33] LDL-lowering therapy with statins should be the primary target if non-HDL and LDL cholesterol are elevated. Evidence of a reduction in CHD risk among patients with established CHD has not been demonstrated with fenofibrate.

The fibric acid derivatives are generally well tolerated. The most common adverse effects include dyspepsia, abdominal pain, diarrhea, flatulence, rash, muscle pain, and fatigue (Table 13–10). Myopathy and rhabdomyolysis can occur, and the risk appears to increase with renal insufficiency or concurrent statin therapy. If a fibrate is used with a statin, fenofibrate is preferred because it appears to inhibit the glucuronidation of the statins less than gemfibrozil.[33] A CK level should be checked before therapy is started and if symptoms occur. Fibrates should be avoided with severe renal dysfunction (estimated glomerular filtration rate [eGFR] < 30 mL/min/1.73 m^2). Baseline renal function should be assessed and then periodically reassessed in patients with renal dysfunction. Of note, fenofibrate can reversibly increase serum creatinine levels. Liver dysfunction has been reported, and LFTs should be monitored. Fibrates increase cholesterol in the bile and have caused gallbladder and bile duct disorders, such as cholelithiasis and cholecystitis. Unlike niacin, these agents do not increase glucose or uric acid levels. Fibrates are contraindicated in patients with gallbladder disease, liver dysfunction, or severe kidney dysfunction. Risk of bleeding is increased in patients taking both a fibrate and warfarin, specifically with gemfibrozil based on a CYP 2C9 interaction which can result in an increase in a patient's international normalized ratio (INR) if adding gemfibrozil to warfarin therapy. Increased INR monitoring is suggested after initiation of gemfibrozil in patients currently taking warfarin. The time until maximum effect on lipids is generally 2 weeks for fenofibrate and 3 to 4 weeks for gemfibrozil.

▶ Omega-3 Fatty Acids

Omega-3 fatty acids (OM3FA) (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]), the predominant long-chain FA in the oil of cold-water fish, lower triglycerides by as much as 45% (Table 13–9) when taken in large amounts (2–4 g). Long-chain OM3FA may be useful for patients with high triglycerides despite diet and weight loss, alcohol restriction, and fibrate therapy. This effect may be modulated through reduction in hepatic synthesis and release of VLDL triglycerides, increased β-oxidation of FA, and enhanced triglyceride clearance from triglyceride-rich lipoproteins. EPA and DHA both have the ability to lower triglycerides, but DHA also leads to increases in LDL cholesterol whereas EPA does not increase. Long-chain OM3FA have other cardiac effects such as reduced platelet aggregation and antiarrhythmic properties. The current AHA Scientific Statement on fish consumption, fish oil, OM3FA, and cardiovascular disease recommends an increased intake of OM3FA in the diet.[34]

Prescription-grade long-chain OM3FA ethyl esters and free FA formulations are FDA approved at a dose of 2 to 4 g daily for the treatment of elevated triglycerides (≥ 500 mg/dL [5.65 mmol/L]). Based on the REDUCE-IT, a multicenter, randomized, double-blind, placebo-controlled trial in patients with clinical ASCVD or with DM and additional CV risk factors, icosapent ethyl has demonstrated the ability to lower CV events in patients on maximum tolerated statins with fasting triglycerides from 135 to 499 mg/dL (1.53–5.64 mmol/L) and an LDL cholesterol from 41 to 100 mg/dL (1.06–2.59 mmol/L).[10] The positive CV outcomes seen with icosapent ethyl have not been demonstrated with other prescription OM3FA products (eg, omega-3 acid ethyl esters). One hypothesis is that icosapent ethyl only contains EPA and thus does not increase LDL cholesterol like the omega-2 acid ethyl ester products which contain both EPA and DHA and can increase LDL cholesterol. As previously stated, the FDA approved icosapent ethyl as adjunct to maximally tolerated statin therapy to reduce the risk of MI, stroke, coronary revascularization, and unstable angina requiring hospitalization in adult patients with triglyceride levels greater than or equal to 150 mg/dL (1.70 mmol/L) and established ASCVD or DM and two or more additional risk factors for CV disease (ie, male > 55 years of age or female > 65 years of age, tobacco smoker, hypertension, low HDL cholesterol, hs-CRP > 3 mg/L, renal dysfunction, retinopathy, albuminuria, ABI < 0.9).

Use of high-quality OM3FA free of contaminants such as mercury and organic pollutants should be encouraged when using these agents. Common side effects associated with long-chain OM3FA are dyspepsia and eructation (Table 13–10). Patients taking anticoagulant or antiplatelet agents should be monitored more closely when consuming these products because excessive amounts of long-chain OM3FA (eg, > 3 g daily) may lead to bleeding and may increase risk of hemorrhagic stroke.

▶ Microsomal Triglyceride Transport Inhibitors

Lomitapide is an oral inhibitor of microsomal triglyceride transfer protein, thereby inhibiting the normal transfer of triglycerides to Apo B in the lumen of the endoplasmic reticulum and preventing the assembly of Apo B–containing lipoproteins in enterocytes and hepatocytes.[7,8] Lomitapide reduces LDL cholesterol levels on average by 40% (Table 13–9) in homozygous FH patients on maximum tolerated lipid-lowering therapy and LDL apheresis. However, given its mechanism of action, GI side effects and elevation in liver enzymes and hepatic fat are common (Table 13–10). Because of the risk of hepatotoxicity, lomitapide is available only through the Risk Evaluation and Mitigation Strategy (REMS) program and is currently FDA approved for the management of patients with homozygous FH. Gastrointestinal side effects are managed by strict adherence to a low-fat diet (< 20% of total calories from fat) and gradual dose escalation based on acceptable safety and tolerability. Lomitapide is primarily metabolized by CYP 3A4. Lomitapide interacts with numerous agents such as strong and moderate CYP 3A4 inhibitors and 3A4 inducers. Lomitapide is classified as pregnancy category X.

▶ *Antisense Oligonucleotide Inhibitor of Apo B-100 Synthesis*

Mipomersen is a once-weekly subcutaneous injectable antisense inhibitor of Apo B synthesis. When given in combination with maximum tolerated doses of lipid-lowering therapy, it can reduce LDL cholesterol by an additional 25% in homozygous FH patients (Table 13–9).[7,8] Injection site reactions, flu-like symptoms, hepatic fat, and liver enzyme elevations are common (Table 13–10). Because of the risk of hepatotoxicity similar to lomitapide, mipomersen is available only through a REMS program. Mipomersen is not a substrate for CYP metabolism and is metabolized by endonucleases and exonucleases. Therefore, mipomersen has minimal clinically relevant drug–drug interactions. Mipomersen is pregnancy category B.

▶ *Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors*

Alirocumab and evolocumab are subcutaneous injectable human monoclonal antibodies that bind to PCSK9. PCSK9 binds to the LDL receptors on hepatocyte surfaces to promote low-density lipoprotein receptor (LDLR) degradation (Figure 13–7). LDLR is the primary receptor that clears circulating LDL; therefore, the decrease in LDLR levels by PCSK9 results in higher blood levels of LDL. By inhibiting the binding of PCSK9 to LDLR, these agents increase the number of LDLRs available to clear LDL, thereby lowering LDL levels. In clinical trials, these agents have produced an additional 48% to 71% decrease in LDL levels when used in combination with statin therapy, compared with statin monotherapy (Table 13–9). Both medications are FDA approved for heterozygous FH or ASCVD as an adjunct to diet and maximally tolerated statin therapy, when additional LDL lowering is required.[4,7,8] Evolocumab is also indicated as an adjunct in homozygous FH.[4,7,8] The results of the CV outcomes study for evolocumab demonstrated CV event lowering.[35] Alirocumab's CV outcome trial demonstrated a reduction in major adverse cardiovascular events in post-acute coronary syndrome patients who were taking maximally tolerated statins compared to placebo.[36,37] Both the evolocumab and alirocumab CV outcome studies demonstrated a reduction in the primary CV composite endpoint on top of statin therapy. These findings drove the 2018 AHA/ACC guidelines to include PCSK9 inhibitors as nonstatin therapy that is recommended to be added to maximum tolerated statin therapy in the very-high-risk ASCVD population (Figure 13–6). The 2018 AHA/ACC guidelines additionally recommend adding ezetimibe to maximum tolerated statin therapy prior to adding PCSK9 inhibitors as a more cost-effective approach.

Combination Pharmacotherapy

A large proportion of the US population remains at high risk for future CV events despite treatment with statin therapy. Reasons for high residual risk include inadequate starting doses, lack of dose escalation, and high baseline risk warranting lower treatment targets. In addition, if lack of response is seen, patient adherence and adverse events should be assessed. Moreover, patients with concomitant elevations in triglycerides may need combination drug therapy to reach their non-HDL cholesterol goal. **KEY CONCEPT** Combination drug therapy is an effective means to achieve greater reductions in non-HDL and LDL cholesterol (statin plus ezetimibe or PCSK9 inhibitor) as well as lowering serum triglycerides (statin plus long-chain OM3FA or fibrate).

▶ *Combination Therapy for Elevated LDL Cholesterol*

For patients who do not achieve their non-HDL and LDL cholesterol goals with statin monotherapy and lifestyle modifications, including those unable to tolerate high doses due to adverse effects, combination therapy may be appropriate. The 2018 AHA/ACC guidelines describe the first-line and second-line add-on therapies to statins for both primary and secondary prevention of

Patient Encounter 2, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Diagnosed with peripheral artery disease 2 years ago (most recent right ABI = 0.67 and left ABI = 0.60).

FH: Both parents are still living; no known cardiovascular disease in family.

SH: Works in an office setting and exercises three times a week (rides bike about 5 miles each time). Drinks alcohol (three beers about three to four times a week)

Meds: Losartan 100 mg once daily, amlodipine 10 mg once daily, aspirin 81 mg daily, atorvastatin 80 mg once daily

ROS: No chest pain, shortness of breath, or dizziness today in clinic

PE:

VS: BP 140/86 mm Hg, pulse 88 beats/min, RR 18 breaths/min, T 98.8°F (37.1°C)

CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended; positive for bowel sounds, no hepatosplenomegaly or abdominal aortic aneurysm

Exts: Right ABI 0.67 and Left ABI 0.60

Neck: No carotid and basilar bruits

EENT: Within normal limits

Labs: Total cholesterol 220 mg/dL (5.69 mmol/L), triglycerides 230 mg/dL (2.60 mmol/L), HDL cholesterol 42 mg/dL (1.09 mmol/L), non-HDL cholesterol 178 mg/dL (4.60 mmol/L), LDL cholesterol 132 mg/dL (3.41 mmol/L) (baseline pre-statin LDL cholesterol 175 mg/dL [4.53 mmol/l]), and glucose 115 mg/dL (6.4 mmol/L); all other labs within normal limits

Given this additional information, what is your assessment of the patient's ASCVD risk?

Identify your treatment goals for the patient based on the AHA/ACC guidelines.

What nonpharmacologic and pharmacologic alternatives are available for the patient?

Should his children be screened for high cholesterol and why?

Develop a care plan for the patient.

ASCVD (Figure 13–6). First-line add-on therapies include ezetimibe or PCSK9 inhibitors. Second-line add-on therapies include BAS. Bempedoic acid is not mentioned in the guidelines since it was just recently FDA approved. Ezetimibe, PCSK9 inhibitors, and BAS combine effectively with statins to augment further cholesterol reduction, with the largest LDL cholesterol and non-HDL cholesterol reductions seen with PCSK9 inhibitors combined with statins. Adverse events are similar to those of each product taken separately. The time until maximum effect on lipids for the combinations of statins plus ezetimibe, PCSK9 inhibitors, BAS, or bempedoic acid is generally 4 weeks.

Some patients, in particular those with genetic forms of hypercholesterolemia such as FH (Table 13–1), require three or more drugs to manage their disorder. It is recommended that patients with FH obtain a minimum of greater than or equal to 50% reduction in LDL cholesterol.[4,7,8]

▶ Combination Therapy for Elevated Cholesterol and Triglyceridemia with or without Low HDL Cholesterol

Fibrates are the most effective triglyceride-lowering agents and also raise HDL cholesterol levels. Combination therapy with a fibrate, particularly gemfibrozil, and a statin has been found to increase the risk for myopathy. Therefore, more frequent monitoring, thorough patient education, and consideration of factors that increase risk as reviewed previously should be considered.

KEY CONCEPT The evidence of reducing non-HDL and LDL cholesterol while substantially raising HDL cholesterol (statin plus niacin or fibrate) to reduce the risk of CHD-related events to a greater

Patient Care Process

Collect Information:

- Obtain fasting cholesterol profile.
- Obtain vital signs and physical examination findings.
- Obtain a thorough history of prescription, nonprescription, and natural drug product use.
- Obtain history of lipid-lowering therapy use (current and past).
- Obtain a family history for premature heart disease.
- Obtain a smoking history.
- Obtain a medical history for other comorbidities that may increase ASCVD risk or adverse drug reactions to the lipid-lowering therapy.
- Obtain history of current diet and exercise regimen/pattern.

Assess the Information:

- Assess any abnormal lipid levels (Table 13–6).
- Assess lifestyle factors including diet and exercise habits.
- Assess if patient fits any of the groups who would benefit from lipid-lowering therapy (Figures 13–5 and 13–6).
- Assess major risk factors for ASCVD (Table 13–8). Assign patient to risk category based on AHA/ACC patient benefit groups or NLA/AACE risk categories previously described (eg, Figure 13–6 and Tables 13–7 and 13–8).
- Assess if taking any medications that may contribute to abnormal lipid levels or increase risk of adverse drug reactions (eg, drug interactions) (Table 13–2).
- Assess concomitant diseases that may contribute to abnormal lipid levels (Table 13–2).
- Assess treatments for cholesterol the patient has used in the past (if any). If already receiving pharmacotherapy for dyslipidemia, assess efficacy, safety, and adherence. Are there any significant drug interactions?

Develop a Care Plan:

- Determine treatment goal for percent LDL cholesterol lowering, non-HDL cholesterol, and LDL cholesterol based on risk category (Figures 13–5 and 13–6).
- Discuss importance of family screening if patient has FH.
- Select TLCs and educate patient on importance of TLCs and regular physical activity (Table 13–3).
- Consider starting pharmacotherapy in patients based on their risk category for ASCVD (Figures 13–5 and 13–6). Consider potential disease and drug interactions that may affect choice or intensity of pharmacotherapy (Table 13–10).
- For patients with ASCVD or DM, consideration should be given to use of moderate- or high-intensity statin therapy (Table 13–5), irrespective of baseline cholesterol levels.
- Determine patient's prescription coverage.

Implement the Care Plan:

- Provide patient education and address concerns associated with ASCVD, hyperlipidemia, drug therapy, and therapy adherence.
- Educate patient on TLC interventions (eg, exercise, diet modifications).
- Start pharmacotherapy concordant with statin-benefit group or overall ASCVD risk in collaboration with healthcare team.
- Develop a follow-up plan for the patient to assess efficacy and safety.
- Stress the importance of medication adherence to the patient.
- Address any patient concerns about dyslipidemia and its management.

Follow-up: Monitor and Evaluate:

- Follow-up at regular intervals (4–12 weeks after initiation/titration and then every 3–12 months thereafter) to assess cholesterol levels for attaining goals for dyslipidemia and monitoring of side effects (Table 13–10).
- Review medication adherence.
- Review physical examination, laboratory tests, and results of other diagnostic tests to assess changes in clinical status.
- For patients with FH, if it is not possible to attain desirable cholesterol levels, a reduction of at least 50% is recommended.
- Intensify TLC for those patients above cholesterol targets.
- Titrate therapy or add additional drug as needed.

degree than statin monotherapy remains in question. A trial found the combination of fenofibrate and simvastatin did not reduce the overall rate of fatal cardiovascular events, nonfatal MI, or nonfatal stroke, as compared with simvastatin alone.[38] However, in a prespecified subgroup analysis, incremental benefits of adding a fenofibrate to simvastatin therapy were noted in patients with triglycerides greater than or equal to 204 mg/dL (2.31 mmol/L) and HDL cholesterol less than or equal to 34 mg/dL (0.88 mmol/L).[38]

Compared with monotherapy, combination therapy may reduce patient adherence through increased side effects and increased costs. When used appropriately and with proper precautions, however, combination therapy is effective in normalizing lipid abnormalities, particularly in patients who cannot tolerate adequate doses of statin therapy for more severe forms of dyslipidemia.

OUTCOME EVALUATION

- **KEY CONCEPT** The successful outcome in cholesterol management is to reduce cholesterol and triglycerides in an effort to alter the natural course of atherosclerosis and decrease future cardiovascular events and pancreatitis.
- Use an adequate trial of TLC in all patients, but institute pharmacotherapy concurrently in higher-risk patients.
- For patients in whom lipid-lowering drug therapy is indicated, statin treatment is the primary modality for reducing ASCVD risk because of its ability to substantially reduce non-HDL and LDL cholesterol, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, availability of inexpensive generics, and low risk of side effects.
- Use an individualized patient monitoring plan in an effort to promote medication safety, minimize side effects, maintain treatment adherence, and achieve lipid goals.
- Lipid goals should be assessed by determining if the patient has achieved their target LDL cholesterol reduction based on their statin benefit group (eg, clinical ASCVD patient on a high-intensity statin should achieve at least a 50% reduction in LDL cholesterol; if baseline LDL cholesterol values are not available to calculate percent reduction, then achieving an LDL cholesterol of less than 70 mg/dL [1.81 mmol/L] or a non-HDL cholesterol of less than 100 mg/dL [2.59 mmol/L] are additional targets).

Abbreviations Introduced in This Chapter

AACE	American Association of Clinical Endocrinologists
ABI	Ankle-brachial index
ACC	American College of Cardiology
ACE	American College of Endocrinology
ACL	Adenosine triphosphate citrate lyase
AHA	American Heart Association
AIDS	Acquired immunodeficiency syndrome
Apo	Apolipoprotein
ASCVD	Atherosclerotic cardiovascular disease
BAS	Bile acid sequestrant
C	Cholesterol
CAC	Coronary artery calcium
CETP	Cholesterol ester transfer protein
CHD	Coronary heart disease
CK	Creatine kinase
CKD	Chronic kidney disease
CLEAR	Cholesterol Lowering via Bempedoic Acid, an ACL-Inhibiting Regimen
CVD	Cardiovascular disease
CV	Cardiovascular
CYP	Cytochrome P-450
DBP	Diastolic blood pressure
DHA	Docosahexaenoic acid
DM	Diabetes mellitus
eGFR	Estimated glomerular filtration rate
EPA	Eicosapentaenoic acid
ER	Extended-release
FA	Fatty acid
FDA	Food and Drug Administration
FH	Familial hypercholesterolemia
GI	Gastrointestinal
HbA_{1c}	Glycosylated hemoglobin
HDL	High-density lipoprotein
HeFH	Heterozygous familial hypercholesterolemia
HIV	Human immunodeficiency virus
HL	Hepatic lipase
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A
hs-CRP	High-sensitivity C-reactive protein
IDL	Intermediate-density lipoprotein
INR	International normalized ratio
IR	Immediate-release
LDL	Low-density lipoprotein
LDLR	Low-density lipoprotein receptor
LFT	Liver function test
Lp(a)	Lipoprotein (a)
LPL	Lipoprotein lipase
LRP	LDL-related protein
MI	Myocardial infarction
NLA	National Lipid Association
NPC1L1	Niemann-Pick C1 Like 1
NSAID	Nonsteroidal anti-inflammatory drug
OM3FA	Omega-3 fatty acid
PPAR-α	Peroxisome proliferator-activated receptor-alpha
PCE	Pooled cohort equation
PCSK9	Proprotein convertase subtilisin/kexin 9
RA	Rheumatoid arthritis
RCT	Randomized controlled trial
REDUCE-IT	Reduction of Cardiovascular Events with Icosapent Ethyl–Intervention Trial
REMS	Risk evaluation and mitigation strategy
SAMS	Statin-associated muscle symptoms
SBP	Systolic blood pressure
SR	Sustained-release
SR-BI	Scavenger receptor class B type I
TG	Triglycerides
TLC	Therapeutic lifestyle changes
VLDL	Very-low-density lipoprotein

14 Circulatory Shock Syndromes

Bradley A. Boucher and G. Christopher Wood

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the most common conditions resulting in the following circulatory shock syndromes: hypovolemic, cardiogenic, and obstructive.
2. Describe the major hemodynamic and metabolic abnormalities that occur in patients with circulatory shock.
3. Describe the clinical presentation including signs, symptoms, and laboratory test measurements for the typical circulatory shock patient.
4. Prepare a treatment plan with clearly defined outcome criteria for hypovolemic, cardiogenic, and obstructive shock patients, including fluid management, pharmacologic therapy, and/or surgical/mechanical interventions.
5. Compare and contrast relative advantages and disadvantages of crystalloids, colloids, and blood products in treating hypovolemic shock.
6. Formulate a stepwise monitoring strategy for patients with hypovolemic, cardiogenic, and obstructive shock.

INTRODUCTION

The primary function of the circulatory system is to supply oxygen and vital metabolic compounds to cells throughout the body, as well as remove metabolic waste products. Circulatory shock is a life-threatening condition whereby this principal function is compromised, resulting in inadequate cellular oxygen utilization.[1,2] While septic shock also has a cardiovascular component to its manifestation, it will not be addressed in this chapter based on its unique presentation involving the systemic inflammatory response. Instead, this shock state is addressed as a component of Chapter 84, "Sepsis and Septic Shock" within this textbook. Furthermore, less common shock states such as anaphylactic and neurogenic shock will not be addressed in this chapter. **KEY CONCEPT** When circulatory shock is caused by a severe loss of blood volume or body water, it is called hypovolemic shock. Cardiogenic shock can be thought of as "pump failure." It most often follows an acute myocardial infarction and less commonly, end-stage heart failure, advanced valvular disease, or cardiac arrhythmias.[2,3] Obstructive shock limits adequate heart functioning mechanically, usually due to a massive pulmonary embolism, cardiac tamponade, tension pneumothorax, or abdominal compartment syndrome.[4] These three shock states share the commonality of decreased blood flow.[5] Rapid and effective restoration of circulatory homeostasis using fluids and/or blood products, pharmacologic agents, and/or surgical/mechanical interventions is imperative to prevent complications of untreated shock and, ultimately, death following circulatory shock.

ETIOLOGY AND EPIDEMIOLOGY

The most common type of shock is septic shock, accounting for over 60% of cases in a large shock trial. In this same trial, cardiogenic, hypovolemic, and obstructive shock accounted for 16%, 16%, and 2% of enrolled patients, respectively.[6] The prognosis of shock patients depends on several variables, including type, severity, duration, underlying etiology, preexisting organ dysfunction, and reversibility.[5] For example, overall mortality rates may approach 50% in cardiogenic shock patients,[7] while hypovolemic shock due to hemorrhage is a major factor in trauma deaths, with an estimated 1.9 million deaths per year worldwide.[8]

Practitioners must have a good understanding of cardiovascular physiology to diagnose, treat, and monitor circulatory problems in critically ill patients. The interrelationships among the major hemodynamic variables are depicted in Figure 14–1.[9] These variables include mean arterial pressure (MAP), cardiac output (CO), systemic vascular resistance (SVR), heart rate (HR), stroke volume (SV), left ventricular size, afterload, myocardial contractility, and preload. Although an oversimplification, Figure 14–1 is beneficial in conceptualizing where the major abnormalities occur in patients with hypovolemic and cardiogenic shock as well as predicting the body's compensatory responses.

Hypovolemic shock is caused by a loss of intravascular volume either by hemorrhage or fluid loss (eg, dehydration). There is a profound deficit in preload, defined as the volume in the left ventricle at the end of diastole. Decreased preload results in subsequent decreases in SV, CO, and, eventually, MAP. As such, restoration of preload becomes an overarching goal in management of hypovolemic shock. Cardiogenic shock is primarily a result of diminished myocardial contractility leading to decreased SV and CO with an increase in preload due to inadequate left ventricular emptying. Obstructive shock interferes mechanically with the heart's capacity to function resembling heart failure resulting in a lowered CO and MAP.[4] This is due to decreased left ventricular filling secondary to these mechanical forces resulting in a reduction in preload, SV, and CO.

FIGURE 14–1. Hemodynamic relationships among key cardiovascular parameters (A). Solid lines represent a direct relationship; the broken line represents an inverse relationship. In (B), the alterations typically observed in hypovolemic shock are highlighted with arrows depicting the likely direction of the alteration. The alterations typically observed in cardiogenic shock are highlighted in (C). In (D), the alterations resulting from obstructive shock are highlighted. In this latter instance, the reduction in preload is secondary to mechanical interference with mechanical filling. (Panel A from Braunwald E. Regulation of the circulation. I. N Engl J Med. 1974;290:1124–1129, with permission.)

Table 14–1

Circulatory Shock Manifestations on Major Organs

Heart
- Myocardial ischemia
- Dysrhythmias

Brain
- Restlessness, confusion, obtundation
- Global cerebral ischemia

Liver
- Release of liver enzymes
- Biliary stasis

Lungs
- Pulmonary edema
- ARDS

Kidneys
- **Oliguria**
- Decreased glomerular filtration
- Acute kidney injury

GI tract
- Stress-related mucosal disease
- Bacterial translocation

Hematologic
- Thrombocytopenia
- Coagulopathies

ARDS, acute respiratory distress syndrome; GI, gastrointestinal.

PATHOPHYSIOLOGY

KEY CONCEPT Regardless of etiology, the most distinctive clinical manifestations of circulatory shock are arterial hypotension, clinical signs of hypoperfusion, and metabolic acidosis.[2] Metabolic acidosis is a consequence of an accumulation of lactic acid resulting from tissue hypoxia and anaerobic metabolism. Prolonged tissue hypoxia sets in motion a downward spiral of events leading to organ dysfunction and eventual failure if untreated. Table 14–1 describes the effects of shock on the body's major organs. Relative failure of more than one organ is referred to as multiple organ dysfunction syndrome (MODS). Primary or secondary involvement of the heart is particularly devastating considering its central role in oxygen delivery and the potential for myocardial dysfunction to perpetuate the shock state. Preexisting organ dysfunction and buildup of inflammatory mediators can also exacerbate effects of circulatory shock to the point of irreversibility.[7] For example, heart failure can lead to pulmonary edema, further aggravating gas exchange in the lungs, and, ultimately, tissue hypoxia. Thus, circulatory shock must be treated aggressively to avoid MODS.

Hypovolemic Shock

The total amount of water in a typical 70 kg (154 lb) adult is approximately 42 L (Figure 14–2). About 28 of the 42 L are inside the cells of the body (intracellular fluid); the remaining 14 L are in the extracellular fluid space (fluid outside of cells, ie, interstitial fluid and plasma). Circulating blood volume for a normal adult is roughly 5 L (70 mL/kg) and composed of 2 L of red blood cell fluid (intracellular) and 3 L of plasma (extracellular). Diminished intravascular volume results from severe external or internal bleeding, profound fluid losses from gastrointestinal (GI) sources such as diarrhea or vomiting, or urinary losses such as diuretic use, diabetic ketoacidosis, or diabetes insipidus (Table 14–2).[1,10] Other sources of intravascular fluid loss can occur through damaged skin, as seen with burns, or via capillary leak into the interstitial space or peritoneal cavity, as seen with peripheral edema or ascites. This latter phenomenon is often referred to as "third spacing" because fluid accumulates in the interstitial space disproportionately to the intracellular and extracellular fluid spaces. Regional ischemia may also develop as blood flow is naturally shunted from organs such as the GI tract or the kidneys to vital organs such as the heart and brain.

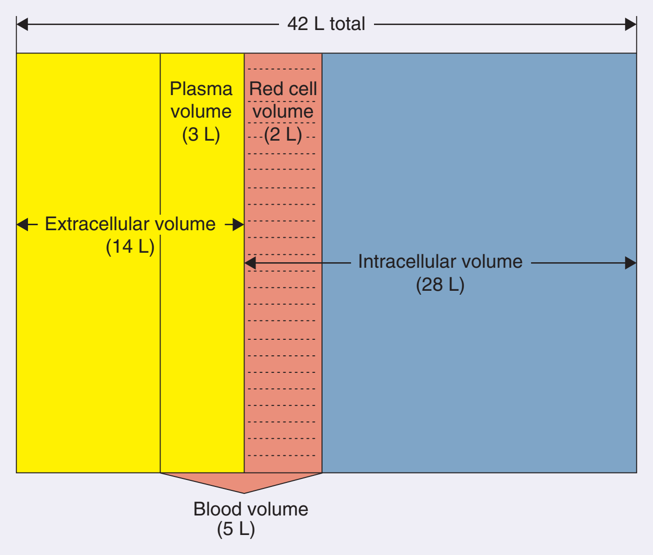

FIGURE 14–2. Distribution of body fluids showing the extracellular fluid volume, intracellular body fluid volume, and total body fluids in a 70 kg (154 lb) adult. Extracellular volume (ECV; yellow section of figure) comprises 14 L of total body fluid (42 L). Plasma volume makes up approximately 3 L of the 14 L of ECV. Intracellular volume (blue section of figure) accounts for the remaining 28 L of total body fluids, with roughly 2 L located within the red blood cells. Blood volume (~5 L) is also depicted and made up of primarily red blood cells and plasma (red section of figure). (From Guyton AC, Hall JE. Textbook of Medical Physiology, 8th ed. Philadelphia, PA: Saunders, 1991:275, with permission.)

Hypovolemic shock symptoms begin to occur with decreases in intravascular volume in excess of 1500 to 2000 mL (about 3–4 pints), or 30% to 40% of the circulating blood volume in adults.[8] Decreases in preload result in decreases in SV. Initially, CO may be partially maintained by compensatory tachycardia. Similarly, reflex increases in SVR, and myocardial contractility may diminish arterial hypotension. Regardless, rapid losses (eg, minutes) undoubtedly have more profound effects than losses

Table 14–2

Major Hypovolemic Shock Etiologies[1,2,10]

Clinical Presentation and Diagnosis

General

Patients will be in acute distress, although symptoms and signs will vary depending on the severity of the circulatory shock

Symptoms

- Thirst
- Weakness
- Light-headedness
- Substernal chest pain; may be radiating to shoulder, back, jaw*
- Nausea

Signs

- Hypotension, arterial systolic blood pressure (SBP) less than 90 mm Hg or fall in SBP greater than 40 mm Hg
- Tachycardia
- Tachypnea
- Hypothermia
- Oliguria
- Dark, yellow-colored urine
- Skin color: pale to ashen; may be cyanotic in severe cases
- Skin temperature: cool to cold
- Mental status: confusion to coma
- **Pulmonary artery (PA) catheter** measurements: decreased CO, decreased SV, increased SVR, low **pulmonary artery occlusion pressure** (PAOP) (hypovolemic shock), high PAOP (cardiogenic shock, obstructive shock)
- Electrocardiogram (ECG) changes, arrhythmias*
- Pulmonary edema on chest X-ray*
- Bibasilar rales*
- Vomiting
- Diaphoresis*
- Organ dysfunction (see Table 14–2)

Laboratory Tests

- Increased serum lactate
- Decreased arterial pH
- Decreased hemoglobin/hematocrit (hemorrhagic hypovolemic shock)
- Hypernatremia (hypovolemic shock), hyponatremia (cardiogenic shock)
- Elevated serum creatinine (SCr)
- Elevated blood urea nitrogen
- Hyperglycemia
- Elevated troponin*

*Specific to cardiogenic shock.

over a longer period (eg, hours). This neurohumoral response to hypovolemia is mediated by the sympathetic nervous system in an attempt to preserve perfusion to vital organs such as the heart and brain. Two major endpoints of this response are to conserve water to maximize intravascular volume and improve tissue perfusion by increasing MAP and CO (oxygen delivery). The body attempts to maximize its fluid status by decreasing water and sodium excretion through the release of antidiuretic hormone (ADH), aldosterone, and cortisol. MAP is maintained by peripheral vasoconstriction mediated by catecholamine release and the renin–angiotensin system.[1] CO is augmented by catecholamine release and fluid retention.[1] Unfortunately, the increased sympathetic drive may become detrimental as tissue ischemia occurs with inconsistent microcirculatory flow.[1] The decrease in CO results in a diminished delivery of oxygen to tissues within the body and activation of an acute inflammatory response.[4,8] Oxygen delivery can be further compromised by inadequate blood hemoglobin levels due to hemorrhage and/or diminished hemoglobin saturation due to impaired ventilation. Decreased delivery of oxygen and other vital nutrients results in diminished production of the energy substrate adenosine triphosphate (ATP). Lactic acid is then produced as a by-product of anaerobic metabolism within tissues throughout the body. Lactic acidosis is a key indicator that inadequate tissue perfusion has occurred.[2]

Cardiogenic Shock

Cardiogenic shock is primarily a result of ventricular failure most commonly following an acute myocardial infarction or acute decompensated heart failure.[7] Valvular heart diseases and dysrhythmias can also lead to cardiogenic shock.[1] Readers are directed to Chapter 9, "Acute Coronary Syndromes" (ACS), and Chapter 7, "Heart Failure," for a more detailed description of the pathophysiology and postresuscitation management for these two conditions, including mechanical circulatory support and reperfusion therapy for ACS patients.[7,11] While both hypovolemic and cardiogenic shocks share a reduction in CO and MAP, one major difference is the effect on preload. Whereas hypovolemic shock will be associated with decreased preload, cardiogenic shock patients will generally have increased preload due to diminished ventricular emptying. Inappropriate compensatory fluid retention can also occur due to diminished renal blood flow.

Obstructive Shock

In obstructive shock, physical forces result in compression of the heart chambers or the great vessels. This results in diminished contraction of the heart and/or ventricular filling.[2] These compressive forces are generally a consequence of pericardial tamponade, tension pneumothorax, massive pulmonary emboli, or aortic dissection. Management of these conditions is therefore targeted at reducing the compressive forces through surgical intervention in the case of pericardial tamponade,[12] tension pneumothorax,[13] aortic dissection, and potentially thrombolytic therapy following a pulmonary embolus (see Chapter 11, "Venous Thromboembolism").

TREATMENT

Desired Outcomes

KEY CONCEPT The major goals in treating circulatory shock are to restore effective circulating blood volume and manage the underlying cause of shock. By optimizing the delivery of oxygen and metabolic substrates, such as glucose and electrolytes, to the tissues throughout the body, organ function will be restored and the body will return to homeostasis. This is evidenced by a return to the patient's baseline vital signs, relative normalization of laboratory test results, and alleviation of other signs and symptoms of circulatory shock previously summarized.

General Approach to Therapy

Securing an adequate airway and ventilation is imperative in circulatory shock patients consistent with the "VIP Rule" of resuscitation: Ventilate (oxygen administration), Infuse (fluid resuscitation if needed), and Pump (administration of a vasoactive and/or inotropic agent).[2,4] Any compromise in ventilation only exacerbates the tissue hypoxia occurring secondary to inadequate perfusion. Thus, sedation, endotracheal intubation, and mechanical ventilation should occur early in the resuscitation of the patient (see Figures 14–3 and 14–4). Additionally, intravenous (IV) access is essential for administration of fluids and/or medications. A peripheral IV or central venous catheter should be placed. Central venous access may be preferred in patients requiring rapid or large volumes of fluid and/or blood products, especially for hypovolemic shock. Placement of an arterial catheter is advantageous to allow for accurate and continuous monitoring of MAP, as well as arterial blood gas (ABG) sampling. A bladder catheter should be inserted for ongoing monitoring of urine output. Baseline laboratory tests that should be done immediately include complete blood cell count (CBC) with differential, serum chemistry profile, liver enzymes, prothrombin and partial thromboplastin times, serum lactate, and troponin if ACS is suspected. A urinalysis and an ABG should also be obtained, and ongoing ECG monitoring should be performed. In addition to restoring circulating blood volume, it is necessary to prevent further losses from the vascular space. For patients in hemorrhagic hypovolemic shock, identifying the source of bleeding and achievement of hemostasis is imperative to successfully resuscitate the patient. Frequently, surgical intervention is required to achieve hemostasis. A chest X-ray should also be obtained in patients suspected of cardiogenic or obstructive shock, as well as performance of echocardiography of the heart.[3] Ultrasonography may also be beneficial diagnostically in patients in hemorrhagic shock.[8]

Upon stabilization, central venous catheters that typically reside in the superior vena cava may be used to monitor central venous pressure (CVP). Measurement of CVP allows more specific hemodynamic monitoring than is available from noninvasive measurements such as vital signs, cardiac rhythm, and urine output.[7] Alternatively, a pulmonary artery (PA) catheter may be indicated based on the need for even more extensive cardiovascular monitoring. Key measured parameters obtained from a PA catheter are pulmonary artery occlusion pressure (PAOP), a measure of left ventricular preload, and CO. Based on CO values and simultaneous measurement of HR and MAP, left ventricular SV and SVR can be calculated. Placement of a PA catheter should be reserved for patients at high risk of death due to severity of the circulatory shock or patients with cardiogenic shock. Noteworthy, however, is that central venous catheters are less expensive than PA catheters and have been associated with comparable survival in selected critically ill patient subsets.[14]

Patient Encounter Part 1

A 63-year-old woman is admitted to the trauma center after being struck by a car as a pedestrian. She has bilateral open femur fractures and an unstable pelvis, and a bedside sonogram (focused assessment for sonography in trauma or FAST) shows intra-abdominal bleeding. She is awake but confused and not cooperating fully with her care due to pain. Her initial blood pressure (BP) is 68/40 mm Hg and HR is 112. She is tachypneic (RR 23) and oxygen saturation (SaO_2) is 90% (0.90).

Is this patient in shock? If so, what type of shock does the patient have and what is the cause?

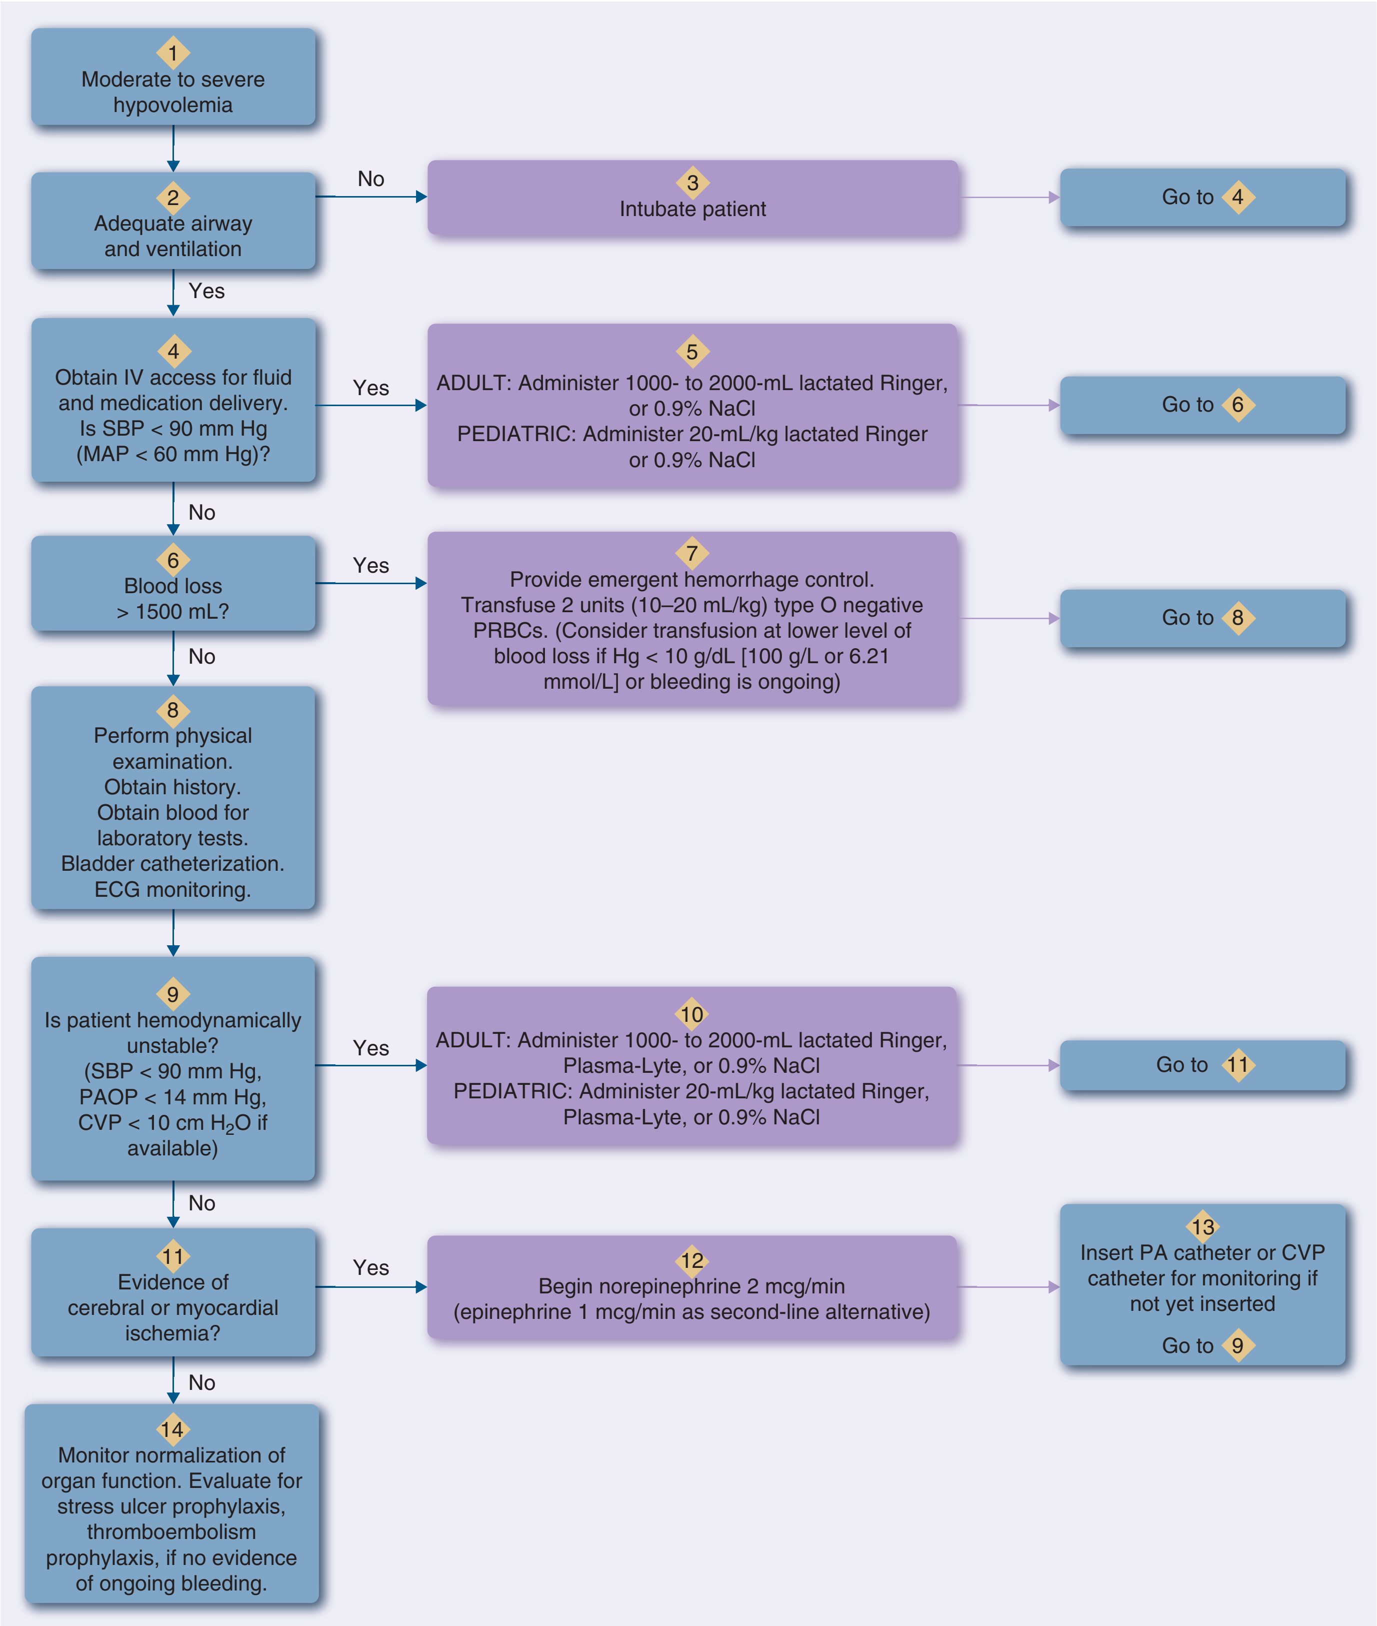
Describe ways the patient can be stabilized for a full assessment.

Describe the first nonpharmacologic steps in treating the patient.

▶ *Fluid Therapy*

The use of fluids is the cornerstone of managing hypovolemic shock.[1,5] KEY CONCEPT Three major therapeutic options are available to clinicians for restoring circulating blood volume: crystalloids (electrolyte-based solutions), colloids (large molecular weight solutions), and blood products.[15] Crystalloid and colloid fluids are first-line therapy in all types of hypovolemic shock. Blood products should be reserved for patients in hemorrhagic shock or in patients with severe preexisting anemia. Vasopressors may be required in patients who are not initially responsive to IV fluids or blood products alone. The aggressiveness of fluid resuscitation (rate and volume) is driven by the severity of the hypovolemic shock and the underlying cause. Warming of all fluids to 37°C (98.6°F) prior to administration is an important consideration to prevent hypothermia, arrhythmias, and coagulopathy because these complications will have a negative impact on resuscitation effort success.[16]

Crystalloids Isotonic crystalloid solutions are fluids with (a) electrolyte composition that approximates plasma known as balanced solutions (eg, lactated Ringer's [LR] solution or Plasma-Lyte) or (b) a total calculated osmolality similar to that of plasma (280–295 mOsm/kg or mmol/kg), such as 0.9% sodium chloride (also known as normal saline [NS] or 0.9% NaCl) (Table 14–3).[15,17] Thus, conventional crystalloids distribute in normal proportions throughout the extracellular fluid space upon administration. In other words, expansion of the intravascular space only increases by roughly 200 to 250 mL for every liter of isotonic crystalloid fluid administered.[18] Hypertonic crystalloid solutions such as 3% NaCl or 7.5% NaCl have osmolalities substantially higher than plasma. Hypertonic sodium solutions increase the osmolality of the intravascular and interstitial fluid compared with the intracellular fluid. Therefore, hypertonic crystalloid fluids result in a relatively larger volume expansion of the intravascular space due to the volume of fluid administered and osmotic drawing of intracellular fluid into the intravascular and interstitial spaces. By comparison with conventional crystalloids, administration of 250 mL of 7.5% sodium chloride results in an intravascular space increase of 500 mL.[18] Crystalloids are generally advocated as the initial resuscitation fluid in hypovolemic shock because of their availability, low cost, and equivalent outcomes compared with colloids. A reasonable initial volume of an isotonic crystalloid (0.9% NaCl, LR, or Plasma-Lyte) in adult patients is 1000 to 2000 mL administered over the first hour of therapy.[4] Ongoing external or internal bleeding requires more aggressive resuscitation with fluid and blood products. KEY CONCEPT In the absence of ongoing blood loss, administration of 4000 to 6000 mL of isotonic crystalloid normally reestablishes baseline vital signs in adult hypovolemic shock patients.[19] Selected populations with high



1
Moderate to severe hypovolemia
2
Adequate airway and ventilation
No
3
Intubate patient
Go to 4
Yes
4
Obtain IV access for fluid and medication delivery. Is SBP < 90 mm Hg (MAP < 60 mm Hg)?
Yes
5
ADULT: Administer 1000- to 2000-mL lactated Ringer, or 0.9% NaCl
PEDIATRIC: Administer 20-mL/kg lactated Ringer or 0.9% NaCl
Go to 6
No
6
Blood loss > 1500 mL?
Yes
7
Provide emergent hemorrhage control. Transfuse 2 units (10–20 mL/kg) type O negative PRBCs. (Consider transfusion at lower level of blood loss if Hg < 10 g/dL [100 g/L or 6.21 mmol/L] or bleeding is ongoing)
Go to 8
No
8
Perform physical examination. Obtain history. Obtain blood for laboratory tests. Bladder catheterization. ECG monitoring.
9
Is patient hemodynamically unstable? (SBP < 90 mm Hg, PAOP < 14 mm Hg, CVP < 10 cm H2O if available)
Yes
10
ADULT: Administer 1000- to 2000-mL lactated Ringer, Plasma-Lyte, or 0.9% NaCl
PEDIATRIC: Administer 20-mL/kg lactated Ringer, Plasma-Lyte, or 0.9% NaCl
Go to 11
No
11
Evidence of cerebral or myocardial ischemia?
Yes
12
Begin norepinephrine 2 mcg/min (epinephrine 1 mcg/min as second-line alternative)
13
Insert PA catheter or CVP catheter for monitoring if not yet inserted
Go to 9
No
14
Monitor normalization of organ function. Evaluate for stress ulcer prophylaxis, thromboembolism prophylaxis, if no evidence of ongoing bleeding.

FIGURE 14–3. Treatment algorithm for the management of moderate-to-severe hypovolemia. (balanced solution: lactated Ringer's solution, Plasma-Lyte. CVP, central venous pressure; ECG, electrocardiogram; Hg, hemoglobin; H_2O, water; IV, intravenous; MAP, mean arterial pressure; NaCl, sodium chloride or normal saline; PA, pulmonary artery; PAOP, pulmonary artery occlusion pressure; PRBCs, packed red blood cells; SBP, systolic blood pressure.) Hemoglobin concentration of 10 g/dL is equivalent to 100 g/L or 6.2 mmol/L.

Plasma-Lyte A	140	98	5	3			27 mEq/L (27 mmol/L) Acetate 23 mEq/L (23 mmol/L) Gluconate	7.4	294
Plasma-Lyte 148	140	98	5	3			27 mEq/L (27 mmol/L) Acetate	5.5	294
Hetastarch (Hextend)	143	124	3	0.9	5	28	Hetastarch 6 g/dL (60 g/L)	5.9	307
Hetastarch (Hespan)	154	154					Hetastarch 6 g/dL (60 g/L)	5.5	310
Pentastarch	154	154					Pentastarch 10 g/dL (100 g/L)	5.0	326
5% Albumin	145	145					Albumin 5 g/dL (50 g/L)	6.9	300
25% Albumin	145	145					Albumin 25 g/dL (250 g/L)	6.9	258
5% PPF	130–160	130–160	0.25				Plasma proteins 5 g/dL (50 g/L) (88% albumin)	6.7–7.3	294
Dextran 40	154	154					Dextran 10 g/dL (100 g/L) (avg molecular weight 40 kDa)	5–5.5	310
Dextran 70	154	154					Dextran 6 g/dL (60 g/L) (avg molecular weight 70 kDa)	3.5–7	287
Dextran 75	154	154					Dextran 6 g/dL (60 g/L) (avg molecular weight 75 kDa)	5.5	308

[a] For these values, mEq/L = mmol/L (eg, 154 mEq/L Na = 154 mmol/L).

[b] For these values, mEq/L × 0.5 = mmol/L (eg, 0.9 mEq/L Mg = 0.45 mmol/L Mg).

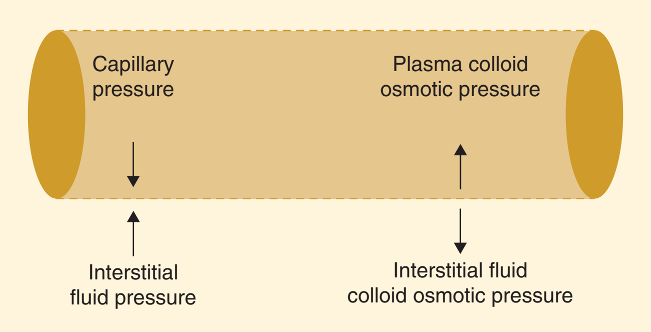
[c] For this value, mOsm/kg = mmol/kg (eg, 308 mOsm/kg = 308 mmol/kg).

avg, average; Ca, calcium; Cl, chloride; K, potassium; kDa, kilodalton; Mg, magnesium; Na, sodium; NaCl, sodium chloride or normal saline; PPF, plasma protein fraction.

insensible losses of volume, such as burn patients, may require more aggressive fluid resuscitation.[4] In hemorrhagic shock patients, approximately three to four times the shed blood volume of isotonic crystalloids is needed for effective resuscitation. Nevertheless, individualization of therapy is critical with well-defined endpoints to avoid excessive administration of crystalloids based on studies in trauma patients.[20]

Side effects from crystalloids primarily involve fluid overload and electrolyte disturbances of sodium, potassium, and chloride.[1] Dilution of coagulation factors can also occur with overzealous administration of crystalloids resulting in a dilutional coagulopathy, especially in patients with active bleeding.[8] The combination of coagulopathy, hypothermia, and acidosis is a particularly deadly combination known as the "lethal triad."[8] Two clinically significant differences between LR solution and NS are that the former contains potassium and has a lower sodium content (130 vs 154 mEq/L or mmol/L). Therefore, LR solution has a greater potential than NS to cause hyponatremia and/or hyperkalemia. Alternatively, NS can cause hypernatremia, hypokalemia, metabolic acidosis, and hyperchloremia. Hyperchloremia is a particularly concerning adverse effect due to the potential risk for acute kidney injury in critically ill patients.[21] Thus, based on the buffering capacity, lower chloride content, and respective side-effect profiles, balanced crystalloid solutions may be preferred compared with NS by some authorities.[22–24] However, improvements in outcomes have not been consistently documented with balanced crystalloid solutions compared to NS. Additionally, there is no clear association between NS containing a higher chloride content and acute kidney injury.[21,25] Nevertheless, there is a growing consensus in selecting balanced crystalloid solutions over NS.

Colloids Administration of exogenous colloids increases the intravascular colloid osmotic pressure (also referred to as oncotic pressure; see Figure 14–5). The effects of colloids on intravascular volume are a consequence of their relatively large molecular size (> 30 kDa), limiting their passage across the capillary membrane in large amounts. Alternately stated, colloids can be



Capillary pressure
Plasma colloid osmotic pressure
Interstitial fluid pressure
Interstitial fluid colloid osmotic pressure

FIGURE 14–5. Operative forces at the capillary membrane tend to move fluid either outward or inward through the capillary membrane. In hypovolemic shock, one therapeutic strategy is the administration of colloids that can sustain and/or draw fluid from the interstitial space by increasing the plasma colloid osmotic pressure. (From Guyton AC, Hall JE. Textbook of Medical Physiology, 8th ed. Philadelphia, PA: Saunders, 1991:174, with permission.)

conceptualized as "sponges" drawing fluid into the intravascular space from the interstitial space. In the case of isooncotic colloids (5% albumin, 6% hetastarch, and dextran products), initial expansion of the intravascular space is approximately 50% of the volume of colloid administered, accounting for some "leakage" of the colloid from the intravascular space.[18]

KEY CONCEPT Thus, in contrast to isotonic crystalloid solutions that distribute throughout the extracellular fluid space, the volume of isooncotic colloids administered remains relatively confined to the intravascular space. In the case of hyperoncotic solutions such as 25% albumin, fluid is pulled from the interstitial space into the vasculature, resulting in an increase in the intravascular volume that is much greater than the original volume of the 25% albumin that was administered. Although theoretically attractive, hyperoncotic solutions should not be used for hypovolemic shock because the expansion of the intravascular space is at the expense of depleting the interstitial space. Exogenous colloids available in the United States include 5% albumin, 25% albumin, 5% plasma protein fraction (PPF), 6% hetastarch, 10% pentastarch, 10% dextran 40, 6% dextran 70, and 6% dextran 75 (see Table 14–3). The first three products are derived from pooled human plasma. Hetastarch and pentastarch are semisynthetic hydroxyethyl starches derived from amylopectin. The dextran products are semisynthetic glucose polymers that vary in terms of the average molecular weight of the polymers. Superiority of one colloid solution over another in terms of efficacy has not been clearly established.[26]

For decades within the critical care literature, a controversy known as the "colloid versus crystalloid debate" raged over the relative merits of these two types of resuscitation fluids. Based on previous data, there does not appear to be a clear-cut overall advantage relative to mortality for either crystalloids or colloids in critically ill patients.[27] This was confirmed in a large study known as the CRISTAL (Colloids Versus Crystalloids for the Resuscitation of the Critically Ill) Randomized Trial published in 2013.[28] Thus, most clinicians today prefer using crystalloids based on their availability and inexpensive cost compared with colloids. However, in addition to these factors, a shift in this debate has recently taken place focused on adverse events.

Generally, the major adverse effects associated with colloids are fluid overload, dilutional coagulopathy, and anaphylactoid/anaphylactic reactions.[18] Because of direct effects on the coagulation system with the hydroxyethyl starch and dextran products, they should be avoided in hemorrhagic shock patients. Further, hetastarch has been associated with an increased risk of acute kidney injury in several recent clinical trials. As such, hydroxyethyl starch products are no longer recommended.[29] Despite these general limitations, there is a paradigm shift in a subset of hypovolemic shock patients, that is, traumatic hemorrhagic shock, to minimize crystalloids, increase the use of blood products and plasma, and accept lower MAP values (permissive hypotension). Collectively, this approach is referred to as damage control resuscitation (DCR).[16,30]

Blood Products **KEY CONCEPT** Blood products are indicated in hypovolemic shock patients who have sustained blood losses from hemorrhage exceeding 1500 mL. This, in fact, is the only setting in which freshly procured whole blood is administered. In virtually all other settings, blood products are given as the individual components of whole blood units, such as packed red blood cells (PRBCs), fresh-frozen plasma (FFP), platelets, cryoprecipitate, and prothrombin complex concentrates (PCC). This includes ongoing resuscitation of hemorrhagic shock. In patients with documented coagulopathies, FFP should be administered to replace lost or diluted clotting factors. Platelets are indicated for patients with severe thrombocytopenia ($< 20–50 \times 10^3/\text{mm}^3$ or $20–50 \times 10^9/\text{L}$).[19] Use of viscoelastic testing may also be a valuable tool for assessing coagulation defects and guiding blood product administration.[31] Type O negative blood or "universal donor blood" is given in emergent cases of hemorrhagic shock. Thereafter, blood that has been typed and cross-matched with the recipient's blood is given.

▶ *Pharmacologic Therapy*

Inotropes Positive inotropes are medications that increase the contractility of the heart and the cornerstone of therapy for patients in cardiogenic shock.[32] A detailed discussion of these agents can be found in Chapter 7, "Heart Failure." Dobutamine and dopamine are inotropes that stimulate the β_1 adrenergic receptors in the heart (see Table 14–4). This stimulation activates cyclic adenosine monophosphate (cAMP), thereby enhancing calcium influx into the myocardial cells resulting in increased contractility. Dobutamine is the gold standard of therapy in cardiogenic shock following an acute myocardial infarction or in patients with decompensated heart failure. Dopamine is less commonly used due to its variable effects on contractility and vasoconstriction depending on dose. Milrinone is a phosphodiesterase inhibitor that also increases cAMP, resulting in increased contractility. While milrinone has utility in the management of heart failure patients, in general, it is rarely used for cardiogenic shock because its vasodilating properties may exacerbate hypotension present in these patients.

Vasopressors Vasopressor is the term used to describe any pharmacologic agent that can induce arterial vasoconstriction through stimulation of the α_1-adrenergic receptors or vasopressin receptors (V_1).[33] **KEY CONCEPT** Use of vasopressors may be warranted as a temporary measure in patients with profound hypotension or evidence of organ dysfunction in the early stages of circulatory shock.[2,7,34] Vasopressors are typically used concurrently with fluid administration in hypovolemic shock if fluids alone have not resulted in adequate restoration of MAP and/or tissue perfusion.[35] Vasopressors are also commonly used with inotropes to support BP and CO in patients with cardiogenic shock. The risk of using vasopressors in cardiogenic shock patients is diminishing CO secondary to impeding ventricular emptying, that is,

Table 14–4

Inotropic and Vasopressor Drugs[1,7]

		Adrenergic Effects			
Drug	**Usual IV Dose**	**α1**	**β1**	**Dopaminergic**	**Potential to Cause Arrhythmias**
Dobutamine[a]	2.5–20 mcg/kg/min	+	+++	0	+++
Dopamine	5–10 mcg/kg/min	+	++	++	++
	10–20 mcg/kg/min[b]	+++	++	++	+++
Norepinephrine	0.01–0.4 mcg/kg/min	+++	++	0	++
Epinephrine	0.01–0.5 mcg/kg/min	++	+++	0	+++
Phenylephrine	0.1–10 mcg/kg/min	++++	0	0	0
Vasopressin[c]	0.02–0.04 U/min	0	0	0	0

[a] Mild vasodilation may occur as a result of β_2 adrenergic receptor stimulation.

[b] Adrenergic effects dose dependent with β_1 effects predominating at lower dosages (1–3 mcg/min) with α_1 effects at higher dosages.

[c] Stimulate vasopressin (V_1) receptors in vascular smooth muscle.

IV, intravenous

0 = No effect

+ = Low

++ = Moderate

+++ = High

++++ = Very high

increased arterial resistance. Table 14–4 lists those vasopressors recommended for use in the management of hypovolemic shock.[1] Although vasopressor therapy may improve the hemodynamic profile in shock patients, data are lacking that they improve mortality.[7,35] Regardless, norepinephrine is considered preferable to dopamine secondary to increased incidence of arrhythmias associated with dopamine in treatment of shock patients if vasopressors are required.[35,36] As such, norepinephrine is generally considered the first-line vasopressor therapy for patients.[2,7,36] Epinephrine should be considered a second-line vasopressor in patients with shock because of its association with tachyarrhythmias, impaired abdominal organ (splanchnic) circulation, and hypoglycemia.[2] Vasopressin is yet another second-line agent. Its mechanism of action is through stimulation of the V_1 within the vascular smooth muscle. If used, generally vasopressin is combined with norepinephrine at a fixed rate, although limited data is available relative to its role in circulatory shock.[7,11] Another vasopressor, angiotensin II, is an active form of the endogenous

Patient Encounter Part 2

PMH: (Per family member) Diabetes, hypertension, hyperlipidemia, heart failure, atrial fibrillation

Meds: (Per family member) "Blood thinner," "heart meds," and insulin

SH: None

FH: Father died of myocardial infarction, mother has diabetes

PE:

VS: BP 65/42 mm Hg, P 125 beats/min, RR 25 breaths/min, T 36.0°C (96.8°F), Ht 5′5″ (165 cm), Wt 80 kg (176 lb), urine output: none since bladder catheterization 10 minutes ago

Neuro: Was in pain upon entering the trauma center. Now calmer but still confused after one-time doses of hydromorphone and midazolam.

Cardiovascular: Heart sounds and ECG normal except for tachycardia

Pulmonary: Normal breath sounds

Abd: Tender, negative bowel sounds

Extremities: Open fractures of both femurs with soft tissue damage and moderate bleeding.

Pertinent labs: pH 7.19, partial pressure of arterial carbon dioxide ($PaCO_2$) 34 mm Hg (4.52 kPa), partial pressure of arterial oxygen (PaO_2) 70 mm Hg (9.31 kPa), Na 145 mEq/L (mmol/L), Cl 104 mEq/L (mmol/L), bicarbonate (HCO_3) 16 mEq/L (mmol/L), K 5.0 mEq/L (mmol/L), Mg 2.8 mg/dL (1.15 mmol/L), lactate 6 mEq/L (mmol/L), serum glucose 218 mg/dL (12.1 mmol/L), SCr 1.5 mg/dL (133 mcmol/L), Hct 28% (0.28), Hgb 9.3 g/dL (93 g/L; 5.8 mmol/L), International Normalized Ratio (INR) 2.78

What signs and symptoms of hypovolemic shock are present in this patient?

What laboratory abnormalities related to hypovolemic shock are present in this patient and why?

Describe treatment goals for the patient in the next hour.

Develop a pharmacologic and fluid therapy plan for initial therapy. Defend your selections compared to alternative agents.

Discuss the role in therapy for blood products, sodium bicarbonate, and hemostatic agents in the patient at this time.

Describe treatment goals for the patient in the next 24 hours.

vasoconstrictor angiotensin and became available in 2017.[33] However, its use to date has been almost exclusively in patients with septic shock refractory to first-line therapies.

Vasopressors are almost exclusively administered as continuous infusions because of their very short duration of action and the need for close titration of their dose-related effects. Starting doses should be at the lower end of the dosing range followed by rapid titration upward if needed to maintain adequate MAP. Monitoring of end-organ function such as adequate urine output should also be used to monitor therapy. Once MAP is restored, vasopressors should be weaned and discontinued as soon as possible to avoid any adverse effects.[2] The most significant systemic adverse events associated with vasopressors are excessive vasoconstriction resulting in decreased organ perfusion and tachyarrhythmias as well as extremity ischemia (see Table 14–4). Vasopressors should be administered via central venous catheter to minimize the risk of local tissue necrosis that can occur with extravasation.

Hemostatic Agents Several systemic pharmacologic agents have been used historically in patients with severe bleeding, such as the prothrombin complex concentrates and recombinant activated factor VII. Off-label use of this latter drug has fallen into disfavor due to uncertain efficacy, safety concerns, and high acquisition cost. In recent years, the greatest interest has shifted instead to use of the antifibrinolytic drug, tranexamic acid. Two large studies of tranexamic acid in trauma patients with or at risk of significant bleeding as well as patients with traumatic brain injury demonstrated a decrease in mortality compared with placebo.[37,38] As such, several guidelines recommend use of tranexamic acid within 3 hours of injury (1 g IV over 10 minutes, then 1 g over 8 hours) as an adjunctive agent in the management of bleeding trauma patients.[39]

Patient Encounter Part 3

Twenty-four hours after the initial fluid bolus, the patient's vital signs are BP 92/64 mm Hg, P 95 beats/min, RR 22 breaths/min, urine output: averaging 35 mL/hour for the last 24 hours. Pertinent new data: lactate 3.0 mEq/L (mmol/L), SCr 1.9 mg/dL (168 mcmol/L), serum glucose 197 mg/dL (10.9 mmol/L), SaO_2 92% (0.92; on mechanical ventilation), INR 1.9. Pulmonary artery catheter readings: Cardiac index (CI) 1.9 L/min/m^2 (0.032 L/s/m^2), PAOP 23 mm Hg.

Assess the patient's condition compared to 24 hours ago.

Develop a plan for additional therapy, if any, that you recommend at this time.

Outline a plan for monitoring the patient over the next 24 hours.

What cultural beliefs, norms, or values should be considered when treating patients with hemorrhagic shock?

Supportive Care Measures

Lactic acidosis, which typically accompanies hypovolemic shock as a consequence of tissue hypoxia, is best treated by reversal of the underlying cause. Administration of alkalizing agents such as sodium bicarbonate has not been demonstrated to have any beneficial effects and may actually worsen intracellular acidosis.[40,41] However, this is based on limited retrospective data in a variety of patients with lactic acidosis. Because GI ischemia is a common complication of circulatory shock, most patients with circulatory shock will meet criteria for initiation of stress ulcer prophylaxis to begin once the patient is stabilized.[42] The most common agents

Patient Care Process

Collect Information

- Conduct medical history to determine the cause of shock to guide pharmacologic and nonpharmacologic therapy.
- Obtain pertinent laboratory tests (electrolytes, CBC, coagulation tests, ABG, serum lactate, liver function tests, and possibly troponin) to help determine circulatory shock etiology, severity, and organ dysfunction.

Assess the Information:

- Assess airway/ventilation status to determine the need for supplemental oxygen/mechanical ventilation.
- Assess vital signs and urine output at least every 15 minutes (continuously if possible) to determine shock severity and response to therapy.
- Determine adequacy of current blood product therapy (if applicable).
- Determine adequacy of current vasopressor/inotropic therapy (if applicable).

Develop a Care Plan

- Assure venous access to deliver fluid resuscitation.
- Determine fluid to be used including rate of administration in hypovolemic shock patients.
- Determine if blood products are needed.
- Ascertain need for continued vasopressor therapy and/or inotropic therapy.
- Consider using tranexamic acid within 3 hours of injury in bleeding trauma patients.

Implement the Care Plan

- Start aggressive crystalloid IV fluid therapy if SBP is less than 90 mm Hg (MAP < 60 mm Hg) in hypovolemic shock patients.
- If required (see Figure 14–3), transfuse PRBCs and provide emergent control of ongoing hemorrhaging.
- Begin vasopressor and/or inotropic therapy if there is evidence of cerebral or myocardial insufficiency.
- Use the resulting data to optimize therapy if a PA catheter is placed.
- Avoid electrolyte disturbances and adverse drug events.

Follow-Up: Monitor and Evaluate:

- Determine if appropriate treatment goals for the first hour and first 24 hours of therapy have been met (see Outcome Evaluation).
- Determine if the underlying cause of circulatory shock has been addressed (eg, control of bleeding or GI fluid losses, etc).
- Ascertain if supportive care measures such as prophylaxis for stress ulcers and venous thromboembolism are indicated.

used for stress ulcer prophylaxis are the histamine$_2$-receptor antagonists and proton pump inhibitors. Prevention of thromboembolic events is another secondary consideration in hypovolemic shock patients. This can be accomplished with the use of external devices such as sequential compression devices and/or antithrombotic therapy such as the low molecular weight heparin products or unfractionated heparin. Sequential compression devices are preferred in any hypovolemic shock patient at risk of ongoing bleeding.

OUTCOME EVALUATION

KEY CONCEPT Successful treatment of circulatory shock is measured by the restoration of MAP to baseline values and reversal of associated organ dysfunction. The likelihood of a successful resuscitation is directly related to the expediency of treatment. Therapy goals include:

- Arterial SBP greater than 90 mm Hg (MAP > 60–75 mm Hg) within 1 hour.
- Organ dysfunction reversal evident by increased urine output to greater than 0.5 mL/kg/hour (1.0 mL/kg/hour in pediatrics), return of mental status to baseline, and normalization of skin color and temperature over the first 24 hours.
- HR should begin to decrease reciprocally to increases in the MAP restoration within minutes to hours.
- Normalization of most laboratory measurements expected within hours to days following fluid resuscitation. Specifically, normalization of base deficit and serum lactate is recommended within 24 hours and may be associated with decreased mortality.
- Achievement of PAOP to a goal pressure of 14 to 18 mm Hg occurs (alternatively, CVP 8–12 mm Hg).

Abbreviations Introduced in this Chapter

ABG	Arterial blood gas
ACS	Acute coronary syndrome
ADH	Antidiuretic hormone
ARDS	Acute respiratory distress syndrome
ATP	Adenosine triphosphate
BP	Blood pressure
Ca	Calcium
cAMP	Cyclic adenosine monophosphate
CBC	Complete blood count
CI	Cardiac index
Cl	Chloride
CO	Cardiac output
CRISTAL	Colloids Versus Crystalloids for the Resuscitation of the Critically Ill trial
CVP	Central venous pressure
DCR	Damage control resuscitation
ECG	Electrocardiogram
FAST	Focused assessment for sonography in trauma
FFP	Fresh-frozen plasma
GI	Gastrointestinal
HCO_3	Bicarbonate
Hct	Hematocrit
HR	Heart rate
INR	International normalized ratio
IV	Intravenous
K	Potassium
kDa	Kilodalton
LR	Lactated Ringer
MAP	Mean arterial pressure
Mg	Magnesium
MODS	Multiple organ dysfunction syndrome
Na	Sodium
NaCl	Sodium chloride (normal saline)
NS	Normal saline
PA	Pulmonary artery
$PaCO_2$	Partial pressure of arterial carbon dioxide
PaO_2	Partial pressure of arterial oxygen
PAOP	Pulmonary artery occlusion pressure
PCC	Prothrombin complex concentrate
PPF	Plasma protein fraction
PRBCs	Packed red blood cells
SaO_2	Oxygen saturation
SBP	Systolic blood pressure
SCr	Serum creatinine
SV	Stroke volume
SVR	Systemic vascular resistance
V_1	Vasopressin receptor
VIP	Ventilate, infuse, pump

Asthma

Lori Wilken and Amanda Eades

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology and clinical presentation of acute and chronic asthma.
2. List the treatment goals for asthma.
3. Identify environmental factors associated with worsening asthma control.
4. Discuss the factors to consider when choosing an inhaled drug delivery device for a patient.
5. Recommend an asthma medication regimen for an adult patient based on symptoms.
6. Compare the preferred asthma reliever and controller regimens for children, adolescents, and adults.
7. Describe the purpose of an individualized asthma action plan.

INTRODUCTION

KEY CONCEPT Asthma is a disorder of the airways characterized by chronic airway inflammation, bronchial hyperresponsiveness, and airflow obstruction. Patients with asthma typically present with respiratory symptoms such as wheezing, shortness of breath, chest tightness, and cough. These symptoms vary over time and in intensity, and worsening is often triggered by factors such as exercise, allergen exposure, change in weather, or respiratory infections.[1] Severity of chronic asthma ranges from mild intermittent symptoms to severe and disabling disease. Despite variability in the severity of chronic asthma, all patients with asthma are at risk of acute severe exacerbations that may be life threatening. International guidelines emphasize the importance of treating underlying airway inflammation to control asthma and reduce asthma-associated risks.[1–5]

EPIDEMIOLOGY AND ETIOLOGY

KEY CONCEPT Asthma is the most prevalent chronic disease of childhood, and it causes significant morbidity and mortality in both adults and children. About 262 million adults and children worldwide have asthma.[6] In the United States, asthma affects 8% of adults (20 million) and 7% of children (5.1 million).[7] Asthma is the primary diagnosis for 9.8 million physician office visits, 1.6 million emergency department visits, and 3524 deaths annually.[7] In 2019, 41.2% of persons with asthma reported having one or more asthma attacks, indicating that nearly half of patients with asthma are not optimally controlled.[8]

Asthma is also a significant economic burden. Annual per-person medical costs have been estimated to exceed $3000, with cost of medications amounting for about 56% of total medical expenditures. The total cost of asthma is estimated to be $81.9 billion, with 61% for medical costs and nearly 39% attributable to absenteeism and mortality.[9]

It is believed that asthma originates primarily early in life and involves a complex interaction of genetic and environmental factors such as allergens, occupational sensitizers, infections, exposure to tobacco smoke, air pollution, diet, and stress.[10] Host factors that increase risk of developing asthma include genes, obesity, sex, and early growth characteristics including younger gestational age, lower birth weight, and greater infant weight gain.

PATHOPHYSIOLOGY

KEY CONCEPT Asthma is characterized by airway narrowing and inflammation primarily in medium-sized bronchi. A key pathophysiologic feature is airway hyperresponsiveness, which is exaggerated narrowing of the airways in response to a trigger or allergen such as cold air, strong odors, pollen, or dust. Airway narrowing results from contraction of airway smooth muscle, increased mucus secretion, airway edema, and remodeling.[1]

In recent years, the discovery of various asthma endotypes, or subtypes of asthma defined by a distinct pathobiological mechanism, has helped clinicians individualize treatment regimens to address a patient's specific pathophysiology within a very heterogeneous disease.[1] Two distinct molecular endotypes have emerged involving a $CD4^+$ T helper 2 (Th2) cell response: Th2 high and Th2 low inflammations.

Th2 high inflammation asthma includes early-onset allergic asthma, adult-onset eosinophilic nonallergic asthma, and exercise-induced asthma.[11] In early-onset allergic asthma, environmental allergens trigger the asthma; it commonly presents in childhood and is associated with family history of allergic disease such as eczema, allergic rhinitis, or food or drug allergy.[1] Airway inflammation is initiated by an inhaled allergen or trigger such as dust, pollen, or animal dander inducing a Th2 response. This leads to B-cell production of antigen-specific immunoglobulin E (IgE), proinflammatory cytokines (eg, interleukin-5), and chemokines that recruit and activate eosinophils, neutrophils, and alveolar macrophages.[2] Further exposure to the antigen results in cross-linking of cell-bound IgE in mast cells and basophils, causing release of preformed inflammatory mediators such as histamine, cysteinyl leukotrienes, and prostaglandin D_2.[1] Patients with Th2 high asthma typically respond well to inhaled corticosteroids (ICS), monoclonal antibodies to IgE, and Th2-targeted therapeutics.

Adult-onset eosinophilic nonallergic asthma develops in adulthood and has a severe onset with high levels of eosinophils in sputum and peripheral blood. These patients often have chronic sinusitis, nasal polyps, and asthma that is exacerbated by aspirin (aspirin-exacerbated respiratory disease, AERD). ICS and IL-5 monoclonal antibodies are used to treat this endotype.

Patients with nonallergic, Th2 low asthma have severe, adult-onset asthma. The sputum shows a high percentage of neutrophils instead of eosinophils. Th2 low asthma is commonly triggered by viral respiratory infections, air pollution, and cigarette smoke. Obesity is also thought to worsen this type of asthma. Patients in this subset of asthma often demonstrate severe disease with a poor response to ICS therapy.

CLINICAL PRESENTATION AND DIAGNOSIS

See accompanying box for the clinical presentation and diagnosis of asthma. Diagnosis is based on a detailed medical history, physical examination of the upper respiratory tract and skin, and measurement of expiratory airflow. The clinician determines if episodic symptoms of airflow obstruction are present, whether airflow obstruction is at least partially reversible, and that alternative diagnoses are excluded. Full pulmonary function tests should be performed at baseline in patients 5 years or older to rule out

Clinical Presentation and Diagnosis of Asthma

General Findings

Asthma presentation ranges from normal pulmonary function with symptoms only during acute exacerbations to significantly decreased pulmonary function with continuous symptoms of daily coughing, wheezing, and shortness of breath.

- Acute asthma can present rapidly (within 3–6 hours), but deterioration more commonly occurs over a longer period, even days or weeks. Acute asthma can be life threatening.
- Family history, social history, precipitating factors, history of exacerbations, and development of symptoms are important components of an asthma diagnosis.

Symptoms

- Patients usually complain of wheezing, shortness of breath, coughing (usually worse at night), and chest tightness.
- Patients may be anxious and agitated. In acute severe asthma, patients may be unable to communicate in complete sentences.
- Mental status changes (eg, confusion, irritability, agitation) may indicate impending respiratory failure.
- The presence of precipitating factors (eg, smoke, mold, or viral illness) worsens symptoms.
- Symptoms usually have a pattern (eg, worse at night, seasonal symptoms).

Physical Exam

Vital signs may reflect **tachypnea**, **tachycardia**, and **hypoxemia**.

- On inspection, there may be hyperexpansion of the thorax and use of accessory muscles.
- Auscultation of the lungs may detect end-expiratory **wheezes** in mild exacerbations or wheezing throughout inspiration and expiration in severe exacerbations.
- **Bradycardia** and absence of wheezing may indicate impending respiratory failure.
- In acute asthma, patients may present with **pulsus paradoxus**, diaphoresis, and cyanosis.

Laboratory Tests

- Spirometry may demonstrate airway limitation and excessive airway variability.
  - Airway limitation is demonstrated by a decrease in the FEV_1/FVC (**forced expiratory volume in the first second**/forced vital capacity) less than 80% (0.80) and a decrease in the FEV_1 to less than 80% (0.80) of the predicted value.
  - Excessive airway variability is seen with:
    a. A positive bronchodilator test, defined as an increase in greater than 200 mL and 12% (0.12) in the FEV_1 from baseline, 10 to 15 minutes after 200 to 400 mcg inhaled albuterol or equivalent. For children, a positive test is defined as increase in the FEV_1 greater than 12% (0.12) of the predicted value.
    b. Excessive variability in twice-daily PEF over 2 weeks: average daily diurnal PEF variability >10% (0.10) for adults and >13% (0.13) for children.
    c. Significant increase in lung function after 4 weeks of anti-inflammatory treatment.
    d. Positive exercise challenge test: fall in FEV_1 greater than 10% (0.10) and more than 200 mL from baseline for adults, and greater than 12% (0.12) predicted for children.
    e. Positive bronchial challenge test: after administration of methacholine or histamine, a decrease in the FEV_1 of 20% (0.20) at specified doses.
- A white blood cell count with differential may show an elevated absolute eosinophil count.
- Elevated serum immunoglobulin E (IgE) levels may be present.
- **Immunoassays** are serologic tests used to detect allergies in patients that may have sensitivities to molds, dust mites, pollen, and other triggers that worsen asthma control. The test is used when skin testing is not available or cannot be used because it is a less sensitive test than skin testing.

Other Diagnostic Tests

- Arterial blood gases (to evaluate PCo_2) should be obtained for patients in severe distress, suspected hypoventilation, or when PEF or FEV_1 is at least 30% less than the percent predicted after initial treatment.
- **Pulse oximetry** is performed at each visit to assess for hypoxemia.
- FeNO changes from baseline may indicate inflammation or a response to an ICS. A normal value in adults is less than 25 parts per billion (ppb).

other disorders. Spirometry is the preferred method of measuring expiratory airflow for diagnosing asthma in persons older than 5 years; however, peak expiratory flow (PEF) meters may be used in the absence of a spirometer. The medical history and physical examination alone are not reliable for characterizing the status of lung impairment or excluding other diagnoses. Spirometry may be normal when the patient is asymptomatic. In this situation, methacholine bronchoprovocation test is used to clinically evaluate airway hyperresponsiveness. Diagnostic tests to confirm allergic asthma include allergy testing for environmental allergens, a white blood cell count to look for increased eosinophils, blood IgE antibody level, and occasionally measurements of fractional concentration of exhaled nitric oxide (FeNO).

Chronic Asthma

KEY CONCEPT Patients with chronic asthma should be assessed based on current symptom control as well as future risk of adverse outcomes. Asthma control considers the frequency and severity of symptoms, use of short-acting β_2-agonists (SABA) for quick relief of symptoms, and impact on normal activity and quality of life. Future risk refers to the potential for future severe exacerbations and asthma-related death, progressive loss of lung function (adults) or reduced lung growth (children), and the occurrence of drug-related adverse effects.[4] Asthma severity is determined by the level of treatment needed to achieve control of asthma symptoms.

Acute Asthma

In acute asthma, symptoms of wheezing, coughing, and shortness of breath increase. Most exacerbations can be treated at home, while some require hospitalization. The severity of the asthma exacerbation does not depend upon the classification of the patient's chronic asthma. Patients with intermittent asthma can have life-threatening acute exacerbations.

TREATMENT

Desired Outcomes

The goals of treatment for asthma are directed at maintaining long-term control of symptoms while minimizing adverse effects.[1–5] Treatment goals are to: (a) achieve good control of asthma symptoms, (b) maintain normal or near-normal pulmonary function, (c) maintain normal activity levels, (d) meet patients' and families' expectations of satisfaction with asthma care, (e) prevent exacerbations of asthma and the need for emergency department visits or hospitalizations, (f) prevent progressive loss of lung function, (g) provide optimal medications with minimal or no adverse effects, and (h) minimize risk of asthma-related death.

Nonpharmacologic Therapy

Incorporating nonpharmacologic care and education is important for patients with asthma. Patient education begins at the time of diagnosis and should meet the individual patient's needs. Asthma management improves when patients are empowered to assume an active role in their asthma management and provided with the knowledge and skills to do so.[1] It is also vital that all individuals with asthma be assessed for sensitivity to common allergens known to worsen asthma. This assessment should include a detailed history of symptoms when exposed to allergens and/or skin testing for sensitivity. For those who are proven to have sensitivity to allergens or other environmental triggers, mitigation interventions may improve asthma control[12] (Table 15–1).

Table 15–1

Nonpharmacologic Interventions to Improve Symptom Control in Patients With Asthma

Tobacco use[1]
- Strongly encourage smokers to quit
- Advise parents/caregivers of children with asthma to not smoke and not allow smoking in rooms or cars that children use

Physical activity[1]
- If EIB, use a SABA or ICS–formoterol 5–20 minutes prior to physical activity
- Encourage stretching and warm-up exercises prior to physical activity

Occupational exposures[1]
- Ask patients with adult-onset asthma about work history and other exposures
- Record when work-related exposures and symptoms occur, when bronchodilator is needed, and peak airflow at work vs. home
- Use respiratory protective devices such as air-purifying masks to help protect against noxious occupational inhalants
- Identify and eliminate occupational sensitizers and remove sensitized patients from further exposure, if possible

Medications[1]
- Ask about asthma before prescribing NSAIDs and advise patients to stop NSAIDs if asthma worsens after use
- If β-blockers are indicated, choose cardioselective agents (eg, atenolol). Asthma is not an absolute contraindication to β-blocker use, but consider the risk vs. benefit

Indoor allergens[12]
- Mold: Dehumidifiers, removal of dampness in homes, and mold abatement
- Rodents and/or cockroaches: Abatement and measures to block infestation
- Dust mites: Dust-mite impermeable pillow and mattress covers, HEPA filter-equipped vacuum cleaner, carpet and curtain removal, and cleaning products

Diet[1]
- Avoid foods for which there is a confirmed allergy
- Encourage weight reduction if overweight or obese
- Avoid foods containing sulfites if they cause symptoms (eg, beer, wine, shrimp, dried fruit, processed potatoes)

Vaccinations[13,14]
- Administer yearly influenza vaccine to patients with moderate-to-severe asthma
- Follow CDC recommendations for administering the pneumococcal and COVID-19 vaccines

Emotional stress[1]
- Identify goals and strategies (eg, relaxation, breathing exercises) to deal with emotional stress if it worsens asthma

Weather conditions[1]
- Avoid strenuous outdoor activities during unfavorable weather conditions
- Cover the nose and mouth with a scarf on cold or windy days

Outdoor allergens[1]
- When pollen counts are high, remain indoors and keep windows and doors closed
- If time is spent outdoors, shower afterward to remove allergens on the skin
- Avoid being outdoors in areas of high pollution

CDC, Centers for Disease Control and Prevention; EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; NSAID, nonsteroidal anti-inflammatory drug; SABA, short-acting β_2 agonist.

Patient Encounter Part 1

HPI: A 36-year-old woman presents to the clinic for a yearly check-up. She has no acute health complaints other than symptoms of seasonal allergies (sneezing, runny nose, watery eyes). She takes loratadine 10 mg as needed for allergy symptoms and fluticasone nasal spray as needed for rhinitis. She reports having mild allergy symptoms year around, but symptoms are worst in the spring months. The patient has a history of asthma and has been prescribed an albuterol inhaler to use as needed for asthma symptoms. She cannot recall exactly how often she has used her albuterol inhaler in the past month but estimates "maybe 4 or 5 times. I usually need it about once a week." She remembers needing it after she participated in a walkathon event stating, "I finished the walk, but I thought I was going to pass-out afterwards." She also recalls needing to use albuterol when she was helping her mother clean out her basement and states, "That day I thought I was going to end up in the emergency room again." She says she self-treated with several puffs of albuterol and took some prednisone she had in her cabinet. Otherwise, she attributes the need for her inhaler to outdoor allergens. She denies any nighttime awakenings due to asthma symptoms.

PMH:

- Mild, intermittent asthma diagnosed during childhood; has never been hospitalized or intubated. She has had one emergency department visit in the past year for an asthma exacerbation. She was treated with albuterol/ipratropium inhalation solution and discharged with a prednisone burst.
- Allergic rhinitis
- Nasal polyps
- Obesity

Family History: Has a sister who also has asthma. No other notable family history

Social History: Denies tobacco use; socially drinks (1–2 glasses of wine on the weekends); lives in a smoke-free home, but her mother smokes heavily; denies having any pets; patient is self-employed (owns a pastry shop in her town); home has hardwood floors throughout. She enjoys walking when it is nice outside, but it aggravates her asthma.

Allergies: Pollen, ragweed, trees, grass, roaches, mold, sulfites, dogs, and cats. No known medication allergies.

What environmental factors may affect the patient's asthma control?

What nonpharmacologic recommendations might decrease the patient's risk of future exacerbations?

What aspects of the patient's past medical history are relevant?

Pharmacologic Therapy

Treatment of chronic asthma involves avoidance of triggers known to precipitate or worsen asthma and use of long-term control and quick-relief medications. Long-term control medications include ICS, inhaled long-acting β_2-agonists (LABAs), oral leukotriene receptor antagonists (LTRAs), inhaled long-acting muscarinic antagonists (LAMA), and biologic agents. Quick-relief medications include SABAs, ICS–formoterol, short-acting muscarinic antagonists (SAMAs), and short bursts of systemic corticosteroids.

▶ *Drug Delivery Devices*

KEY CONCEPT Direct airway administration of asthma medications through inhalation is the most efficient route and minimizes systemic adverse effects. Inhaled asthma medications are available in metered-dose inhalers (MDIs), dry powder inhalers (DPIs), slow mist inhalers (SMIs), breath-actuated inhalers (BAI), and inhalation solutions for nebulization. Poor inhaler technique is common with inhaler devices and results in increased oropharyngeal deposition, leading to decreased efficacy and increased adverse effects. Use of a spacer is recommended with an MDI inhaler to decrease the need for coordination of actuation with inhalation, decrease oropharyngeal deposition, and increase pulmonary drug delivery.[15,16] A spacer with a face mask may be used in younger patients who are unable to hold their breath after inhalation. A spacer with a face mask is not recommended for most adults because the mask results in fewer drug particles being delivered to the lungs. Using an MDI with a spacer also has faster medication delivery and is as effective as administration by nebulization. Although DPIs and BAIs have the benefit of not requiring coordination of breath with the actuation of the inhaler, patients must demonstrate the ability to breathe quickly and deeply for the drug particles to deposit in the lungs rather than in the mouth and throat. This technique for DPI and BAI limits their use in younger patients. Selection of the appropriate inhalation device depends on patient characteristics and medication accessibility.

▶ *Maintenance Medications*

Inhaled Corticosteroids KEY CONCEPT All adults and adolescents with persistent asthma should receive an ICS-containing treatment to control symptoms and reduce future risk of severe exacerbations.[1] It is recommended that patients who present with asthma symptoms at least 2 days each month be initiated on either daily low-dose ICS therapy along with a SABA as needed, or low-dose ICS–formoterol to use as needed.

Corticosteroids are the most potent anti-inflammatory agents available for asthma treatment and are available in inhaled, oral, and injectable dosage forms. They decrease airway inflammation, attenuate airway hyperresponsiveness, and minimize mucus production and secretion. Corticosteroids also improve the response to β_2-agonists. ICS are more effective than LTRAs in improving lung function and preventing emergency department visits and hospitalizations due to asthma exacerbations.[1,4] The primary advantage of using ICS instead of systemic corticosteroids is targeted drug delivery to the lungs, which decreases the risk of systemic adverse effects. Product selection is based on preference for dosage form, delivery device, and cost.

Recommended doses of ICS are provided in Tables 15–2 and 15–3. ICS have a flat dose–response curve; doubling the dose has a limited additional effect on asthma control.[17] Cigarette smoking decreases the response to ICS, and smokers require higher doses of ICS than nonsmokers.[18] Although some beneficial effect is seen within 12 hours of administration of an ICS, 2 weeks of therapy is necessary to see significant clinical effects.

Table 15–2

Estimated Comparative Daily Dosages for Inhaled Corticosteroids and Inhaled Corticosteroid–Long-Acting β_2-Agonist Combinations for Asthma in Ages 12 Years and Older[1]

Medication	Low Dose	Medium Dose	High Dose
Beclomethasone HFA Redihaler 80 mcg/inhalation	80 mcg: 1 inhalation twice daily	80 mcg: 2 inhalations twice daily	80 mcg: > 2 inhalations twice daily
Budesonide DPI Flexhaler 90 or 180 mcg/inhalation	90 mcg: 2 inhalations twice daily 180 mcg: 1 inhalation twice daily	180 mcg: 2 inhalations twice daily	180 mcg: > 2 inhalations twice daily
Ciclesonide HFA MDI 80 or 160 mcg/inhalation	80 mcg: 1 inhalation twice daily	160 mcg: 1 inhalation twice daily	160 mcg: > 1 inhalation twice daily

Fluticasone furoate/Vilanterol DPI Ellipta 100/25 mcg, 200/25 mcg	100/25 mcg: 1 inhalation daily		200/25 mcg: 1 inhalation daily

DPI, dry powder inhaler; HFA, hydrofluoroalkane; ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist; MDI, metered-dose inhaler.

Longer treatment may be necessary to realize the full effects on airway inflammation.

Local adverse effects associated with ICS therapy include oral candidiasis, cough, and dysphonia. For most delivery devices, the majority of the drug is deposited in the mouth and throat and swallowed. The incidence of local adverse effects can be reduced by using an MDI with a spacer and by having the patient rinse the mouth with water and expectorate after use. Decreasing the dose reduces the incidence of hoarseness. Systemic adverse effects, such as adrenal suppression and decreased bone mineral density, may also occur with long-term high doses of ICS. Growth suppression is a concern of some parents whose children are prescribed an ICS. However, final adult height is not thought to be affected by ICS use, but growth velocity is slightly reduced (by less than half a centimeter per year), and height after 1 year of treatment is decreased by less than 1 cm in children treated with low- and medium-dose ICS.[19,20] Risk of pneumonia is increased with higher ICS doses in adults.[21] An important drug interaction causing Cushing syndrome and adrenal insufficiency occurs when potent inhibitors of CYP3A4 (eg, ritonavir, itraconazole, ketoconazole) are administered with high doses of ICS; therefore, coadministration should be avoided whenever possible.[22] Poor adherence to ICS treatment is common and contributes to uncontrolled asthma.[23] The cost, slow onset of action and concerns about side effects are major deterrents to using these highly effective medications.

Considerable variability in response to ICS exists, with up to 40% of patients not responding to ICS. This lack of response may be related to functional glucocorticoid-induced transcript 1 gene (*GLCCI1*) variant in some patients with asthma.[24]

Systemic Corticosteroids Add-on low-dose oral corticosteroids (prednisone, prednisolone, methylprednisolone) are considered a last-line option for patients with severe, uncontrolled asthma when all other add-on treatment options have been

Table15–3

Estimated Comparative Daily Dosages for Inhaled Corticosteroids and Inhaled Corticosteroid—Long-Acting β_2-Agonist Combinations for Asthma in Children < 12 Years Old[1]

Medication	Low Dose	Medium Dose	High Dose
Beclomethasone HFA BAI 40 or 80 mcg/inhalation	5 years of age: 40 mcg: 1 inhalation twice daily 6–11 years of age: 40 mcg: 1–2 inhalations twice daily 80 mcg: 1 inhalation twice daily	6–11 years of age: 80 mcg: 2 inhalations twice daily	6–11 years of age: 80 mcg: > 2 inhalations twice daily
Budesonide DPI 90 or 180 mcg/inhalation	6–11 years of age: 90 mcg: 1 inhalation twice daily	6–11 years of age: 180 mcg: 1 inhalation twice daily	6–11 years of age 180 mcg: > 2 inhalations twice daily
Budesonide inhalation suspension for nebulization 0.25 mg/2 mL, 0.5 mg/2 mL, 1 mg/2 mL	0–4 years of age: 0.25 mg once or twice daily 5–11 years of age: 0.25 mg twice daily or 0.5 mg once daily	0–4 years of age: 0.25–0.5 mg twice daily 5–11 years of age: 0.5 mg twice daily	0–4 years of age: > 0.5 mg twice daily 5–11 years of age: 1 mg twice daily
Fluticasone propionate HFA MDI 44, 110, or 220 mcg/inhalation	4–11 years of age: 44 mcg: 1 inhalation twice daily	4–11 years of age: 44 mcg: 2 inhalations twice daily	6–11 years of age: 110 mcg: ≥ 1 inhalation twice daily[1]
Fluticasone propionate DPI 50 or 100 mcg/inhalation	4–11 years of age: 50 mcg: 1 inhalation twice daily	4–11 years of age: 100 mcg: 1 inhalation twice daily	4–11 years of age: 100 mcg: 1 inhalation twice daily
Fluticasone furoate DPI 50 mcg/inhalation	5–11 years of age: 50 mcg: 1 inhalation daily		
Mometasone HFA MDI 50 mcg/inhalation	5–11 years of age: 50 mcg: 1 inhalation twice daily	5–11 years old: 50 mcg: 1 inhalation twice daily	5–11 years old 50 mcg: 2 inhalations twice daily
Mometasone DPI 110 mcg/inhalation	4–11 years of age: 110 mcg: 1 inhalation daily in the evening		
Combined ICS/LABA			
Fluticasone/Salmeterol DPI 100/50 mcg	4–11 years of age: 100/50 mcg: 1 inhalation twice daily		
Budesonide/Formoterol HFA MDI 80/4.5 mcg	6–11 years of age: 80/4.5 mcg: 2 inhalations twice daily		
Mometasone/Formoterol HFA MDI 50/5 mcg	5–11 years of age: 50/5 mcg: 2 inhalations twice daily		

BAI, breath-actuated inhaler; DPI, dry powder inhaler; HFA, hydrofluoroalkane; ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist; MDI, metered-dose inhaler.

expended. Prior to considering addition of oral corticosteroids, barriers to asthma control should be assessed (eg, poor inhaler technique, nonadherence to inhaled treatments, exposure to environmental triggers). If systemic therapy is necessary, once-daily or every-other-day therapy is used with repeated attempts to decrease the dose or discontinue the drug. Patients must be counseled on potential adverse effects including weight gain, mood disturbances, hypertension, impaired wound healing, adrenal suppression, and decreased bone mineral density.

Long-Acting Inhaled β_2-Agonists LABAs are frequently used as add-on maintenance therapy for asthma that is not controlled on an ICS alone. Class benefits of LABAs when used as maintenance therapy in combination with an ICS include improved pulmonary function, increased symptom-free days, and decreased need for SABA use. Adding a LABA to a low-dose ICS is at least as effective in improving symptoms and decreasing asthma exacerbations as doubling the dose of an ICS or adding an LTRA to ICS.[25] Adding a LABA to ICS therapy also reduces the amount of ICS necessary for asthma control.[5] LABAs should not be used as monotherapy for chronic asthma because there may be an increased risk of severe asthma exacerbations and asthma-related deaths when LABAs are used alone.[26] Labeling for all drugs containing LABAs includes a box warning against their use without an ICS. The risk of increased severe asthma exacerbations does not appear to be increased in adults receiving both a LABA and ICS.[27]

Salmeterol is available as a single-ingredient product and as a fixed-ratio combination product containing an ICS. Formoterol is available in combination with ICS for asthma and as an inhalation solution for nebulization for COPD. Vilanterol is available only in combination with ICS. Combination products may increase adherence because of the need for fewer inhalers and inhalations. The individual LABAs vary both in their onset and duration of action. Vilanterol has the longest duration of action, allowing for once-daily dosing, while salmeterol and formoterol must be dosed every 12 hours. Salmeterol has a delayed onset of action compared to the other LABAs; both vilanterol and formoterol have an onset of action of around 5 minutes, whereas salmeterol onset is around 15 minutes.

Long-Acting Muscarinic Antagonists (LAMAs) Muscarinic antagonists inhibit the effects of acetylcholine on muscarinic receptors in the airways and protect against cholinergic-mediated bronchoconstriction. Tiotropium bromide is an inhaled LAMA available as a slow-mist inhaler for asthma. It has an onset in approximately 30 minutes and a duration longer than 24 hours. Tiotropium is used as a long-term controller medication in patients at least 6 years of age with uncontrolled asthma already taking an ICS or an ICS and LABA combination.[28,29] Addition of a LABA is preferred over adding a LAMA to patients who are not adequately controlled on an ICS alone.[12] Addition of tiotropium to combined ICS-LABA therapy has been associated with improved asthma control and quality of life with no change in exacerbations.

Umeclidinium is another LAMA available as a three-drug combination with fluticasone and vilanterol for treatment of asthma in patients at least 18 years of age. This is currently the only once-daily single inhaler with triple therapy available for treatment of asthma. In clinical trials, combination umeclidinium–fluticasone–vilanterol showed statistically significant improvements in FEV_1 when compared to combination fluticasone–vilanterol.[30] Muscarinic-antagonists may cause adverse effects such as urinary retention, dry mouth, headache, and upper respiratory tract infections. Refer to Table 15–4 for LAMA dosing recommendations.

Leukotriene Receptor Antagonists The LTRAs are anti-inflammatory medications that either inhibit 5-lipoxygenase (zileuton) or competitively antagonize the effects of leukotriene D_4 (montelukast, zafirlukast). These agents improve FEV_1 and decrease asthma symptoms, SABA use, and asthma exacerbations. Although they offer the convenience of oral administration, they are significantly less effective than ICS.[4,31] Combining an LTRA with an ICS is not as effective as an ICS plus a LABA but is considered steroid sparing.[1,4] LTRAs are beneficial for asthma patients with allergic rhinitis, aspirin sensitivity, or exercise-induced bronchospasm (EIB).[1]

Montelukast has a boxed warning about serious mental health side effects. All three LTRAs have reports of neuropsychiatric events, such as sleep disorders, aggressive behavior, and suicide. Zileuton and zafirlukast are less commonly used because of the risk of hepatotoxicity. Zileuton use requires liver function tests prior to use, monthly for 3 months, every 3 months for the first year, and periodically thereafter. Zileuton and zafirlukast are metabolized through the CYP 2C9 hepatic pathway and have significant drug interactions. Refer to Table 15–4 for LTRA dosing recommendations.

Biologic Agents About 3.7% of patients with asthma have severe, difficult to treat asthma requiring high doses of ICS and at least one other controller medication along with frequent bursts of oral corticosteroids or daily use of oral corticosteroids.[32,33] These patients have poor symptom control despite good adherence to medications and appropriate inhaler technique. Biologic agents target Th2 inflammation, allowing for reduction or discontinuation in corticosteroid use, fewer asthma exacerbations, and improved lung function. Assessing inflammatory markers such as IgE, blood eosinophils, and FeNO help identify the appropriateness of an individual biologic agent.

Anti-IgE Monoclonal Antibody Omalizumab is a recombinant humanized monoclonal anti-IgE antibody that inhibits binding of IgE to receptors on mast cells and basophils, resulting in inhibition of inflammatory mediator release and attenuation of the early- and late-phase allergic response. Omalizumab is indicated for patients with moderate-to-severe persistent asthma whose symptoms are not controlled by ICS and who have a positive skin test or in vitro reactivity to aeroallergens and elevated IgE (30–700 IU/mL [kIU/L] for patients age 12 and older or 30–1300 IU/mL [kIU/L] for ages 6–11 years). Omalizumab significantly decreases ICS use, reduces the number and length of exacerbations, and increases asthma-related quality of life.[34] The initial dose is based on the patient's weight and baseline total serum IgE concentration. See Table 15–4 for dosing recommendations. Subsequent IgE levels are not monitored.

The most common adverse effects of omalizumab are injection-site reactions (bruising, redness, pain, stinging, itching, and burning). Anaphylactic reactions are rare but may occur at any time after medication administration. Monitoring the patient for an anaphylactic reaction for 2 hours after medication administration is recommended for the first 3 months; thereafter, monitoring time can be reduced to 30 minutes.[35] It is also important to issue a prescription for subcutaneous epinephrine and educate the patient on its use for anaphylactic reactions to omalizumab.

Interleukin-5 (IL-5) and IL-5R (Receptor) Antagonist Monoclonal Antibody For patients with severe asthma exacerbations in the past year and high blood eosinophil counts, starting a medication that decreases eosinophils improves asthma outcomes. Mepolizumab and reslizumab are monoclonal antibodies that block the cytokine IL-5 from recruiting eosinophils. Benralizumab is a monoclonal antibody that binds directly to the IL-5 receptor alpha on eosinophils and destroys the cells. All three medications decrease asthma exacerbations and symptoms.[36–38] Common side effects include nasopharyngitis, headache, hypersensitivity reactions, and worsening asthma or upper respiratory tract infections. Long-term side effects are unknown. See Table 15–4 for dosing.

Interleukin-4 (IL-4) Receptor Alpha Antagonist Monoclonal Antibody Dupilumab improves the symptoms of patients with high IgE and eosinophil counts by inhibiting IL-4 and IL-13 signaling in Th2 inflammation. Dupilumab decreases asthma exacerbations, oral corticosteroid dosing, and asthma symptoms.[39] The most common side effects are injection site pain and transient blood eosinophilia.

Macrolides Recent evidence indicates that azithromycin 500 mg orally three times weekly decreases asthma exacerbations and improves quality of life for adults with asthma not controlled with a medium-to-high dose ICS and LABA.[40] Results were similar in patients with both eosinophilic and noneosinophilic asthma. Potential benefits result from anti-inflammatory and not antimicrobial properties. Screening for hearing impairment, cardiac arrhythmias, and drug interactions is recommended prior to initiating treatment. There is no clear evidence on how long azithromycin should be continued, but a clear benefit was not seen until after 3 months of treatment. Treatment for at least 6 months is recommended.[1]

▶ *Reliever Medications*

Short-Acting Inhaled B_2-Agonists SABAs such as albuterol (known as salbutamol outside the United States) reverse acute airway obstruction caused by bronchoconstriction and block the early-phase response to antigen in an asthma exacerbation. They also increase mucociliary clearance and stabilize mast-cell membranes. Due to their rapid onset of action for reversing bronchoconstriction, inhaled SABAs have been considered the cornerstone of therapy for acute asthma exacerbations. More recent evidence shows that SABA use without an ICS increases the risk of asthma-related death, urgent asthma-related healthcare, and reduced lung function.[41] Based on these findings, SABAs may still be used to manage acute asthma symptoms, but guidelines recommend that an ICS be given concomitantly in patients age 6 years and older.[1] Scheduled SABA use decreases the duration of bronchodilation provided by the SABA and is not recommended.

Table 15–4

Usual Doses of Long-Term Control Medications in Asthma[a]

Medication	Dosage Form	Ages 0–11 Years	Adults and Children > 12 Years
Inhaled Corticosteroids (see Tables 15–2 and 15–3)			
Inhaled Corticosteroids/Long-Acting β_2-Agonists (see Tables 15–2 and 15–3)			
Long-Acting β_2-Agonists			
Salmeterol	DPI 50 mcg/blister	Ages 0–3 years: N/A Ages 4–11 years: One inhalation every 12 hours	One inhalation every 12 hours
Long-Acting Muscarinic Agents			
Tiotropium	SMI 1.25 mcg/actuation	Ages 0–5: N/A Ages 6–11: Two inhalations of 1.25 mcg once daily	Two inhalations once daily
Inhaled Corticosteroid/Long-Acting β_2-Agonists/Long-Acting Muscarinic			
Fluticasone/Umeclidinium/Vilanterol	DPI 100/62.5/25 mcg/actuation or 200/62.5/25 mcg/actuation	N/A	Age 12-17: N/A Age 18 and older: One inhalation daily
Leukotriene Modifiers			
Montelukast	4 mg or 5 mg chewable tablets 4 mg granule packets 10 mg tablet	Ages 1–5 years: 4 mg at bedtime Ages 6–11 years: 5 mg at bedtime	Ages 12–14 years: 5 mg at bedtime Ages 15 and older: 10 mg at bedtime
Zafirlukast	10 or 20 mg tablets	Ages 0–4 years: N/A Ages 5–11 years: 10 mg twice daily	20 mg twice daily
Zileuton	600 mg extended-release tablet 600 mg immediate-release tablet	N/A: only approved for those 12 years of age and older	Extended-release tablets: 1200 mg twice daily after morning and evening meals Immediate-release tablets: 600 mg four times daily
Anti-IgE Monoclonal Antibody			
Omalizumab	Injection: 75 mg/0.5 mL and 150 mg/mL solution in prefilled syringe and 150 mg powder in single-dose vial for reconstitution	Ages 0–5: N/A Ages 6–11: 75–375 mg SC every 2–4 weeks, depending on body weight and pretreatment serum IgE level; see dosing chart[b]	150–375 mg SC every 2–4 weeks, depending on body weight and pretreatment serum IgE level; see dosing chart[b]
Interleukin-5 and Interleukin-5 Receptor Antagonist Monoclonal Antibodies			
Mepolizumab	Injection: 100 mg/mL, single-dose, prefilled autoinjector or prefilled syringe and 100 mg powder for reconstitution	Age 0-5: N/A Ages 6-11: 40 mg SC once every 4 weeks	100 mg SC once every 4 weeks; suggested AEC ≥150–300 cells/μL (0.15×10^9–0.3×10^9/L)
Reslizumab	Injection: 100 mg/10 mL vial	N/A	Ages 12-17: N/A Ages 18 and older: 3 mg/kg IV infusion over 20–50 minutes every 4 weeks; suggested AEC ≥ 400 cells/μL (0.4×10^9/L)
Benralizumab	Injection, 30 mg/mL prefilled syringe and single-dose autoinjector pen	N/A	30 mg SC every 4 weeks for the first 3 doses, followed by once every 8 weeks; suggested AEC > 300 cells/μL (0.3×10^9/L)
Interleukin-4 Receptor Alpha Antagonist Monoclonal Antibody			
Dupilumab	Injection: 200 mg/1.14 mL and 300 mg/2 mL prefilled syringe; 300 mg/2 mL and 200 mg/1.14 mL solution in a prefilled pen	N/A	400 mg SC, followed by 200 mg SC every other week; suggested AEC >150 cells/μL (0.15×10^9/L) or FeNO ≥ 25 ppb OR 600 mg SC, followed by 300 mg SC every other week for patients on OCS or also having atopic dermatitis and asthma

[a] Dosages are provided for products that have been approved by the US FDA or have sufficient clinical trial safety and efficacy data in the appropriate age ranges to support their use.

[b] XOLAIR (omalizumab) Dosing for Allergic Asthma, CIU & Nasal Polyps (xolairhcp.com).

AEC, absolute eosinophil count; DPI, dry powder inhaler; FeNO fraction of exhaled nitric oxide ppb parts per billion; IgE, immunoglobulin E; IV, intravenous; N/A, safety and efficacy not established; OCS, oral corticosteroid; SC, subcutaneous; SMI, slow mist inhaler.

Inhaled SABAs have an onset in less than 5 minutes and a duration of action of 4 to 6 hours. Albuterol is the most commonly used inhaled SABA and is available as an MDI, breath-actuated DPI, and an inhalation solution for nebulization. Levalbuterol, the pure R-enantiomer of albuterol (referred to as R-salbutamol outside the United States), is available as an MDI and an inhalation solution for nebulization. Levalbuterol has similar efficacy to albuterol and is purported to have fewer side effects; however,

Table 15–5

Usual Dosages for Reliever Medications for Asthma in Home Setting[a,b]

Medications	Dosage Form	Children 0–11 Years	Adults and Children 12 Years of Age and Older
Inhaled SABA			
Albuterol HFA	MDI (inhalation suspension) 90 mcg/inhalation, 200 actuations/canister	0–11 years: 2–6 inhalations every 4–6 hours as needed[1]	2 inhalations every 4–6 hours as needed
Albuterol	DPI (inhalation powder) 90 mcg/inhalation, 200 actuations/canister	Not approved for <12 years of age	2 inhalations every 4–6 hours as needed
Albuterol	Inhalation solution 0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL, 5 mg/mL (0.5%)	0–4 years: 0.63–2.5 mg every 4–6 hours as needed 5–11 years: 1.25–5 mg every 4–8 hours as needed	2.5–5 mg every 6–8 hours as needed
Levalbuterol HFA	MDI (inhalation suspension) 45 mcg/Inhalation, 200 actuations/canister	0–3 years: N/A 4–11 years: 1–2 inhalations every 4–6 hours as needed	2 inhalations every 4–6 hours as needed
Levalbuterol	Inhalation solution 0.31 mg/3 mL, 0.63 mg/3 mL, 1.25 mg/0.5 mL, 1.25 mg/3 mL	6–11 years: 0.31–0.63 mg every 8 hours as needed	0.63 mg every 6–8 hours as needed; may titrate to 1.25 mg every 8 hours if inadequate response
Systemic Corticosteroids			
Methylprednisolone	2, 4, 8, 16, 32 mg oral tablets	1–2 mg/kg/day by mouth in 2 divided doses (max 20 mg/day for <2 years; 30 mg/day for <6 years; 40 mg/day for <12 years) for 3–5 days	40–50 mg/day by mouth as single or two divided doses for 5–7 days
Prednisolone	5 mg oral tablets; 5 mg/5 mL and 15 mg/5 mL oral liquid		
Prednisone	1, 2.5, 5, 10, 20, 50 mg oral tablets; 5 mg/mL and 5 mg/5 mL oral liquid		

[a] Dosages are provided for products that have been approved by the US FDA or have sufficient clinical trial safety and efficacy data in the appropriate age ranges to support their use.

[b] Doses are increased in the hospital/emergency department setting.

DPI, dry powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler; N/A; safety and efficacy not established; SABA, short-acting β_2-agonist.

clinical trials have not demonstrated this benefit.[42] See Table 15–5 for SABA dosing recommendations. During an asthma exacerbation, albuterol doses may be increased to 4 to 10 puffs every 20 minutes for up to 1 hour to gain rapid control of symptoms, and then continued at a higher dose and frequency as determined by treatment response. The dose and frequency of reliever medications should be individualized based on the severity and frequency of the patient's exacerbation history and should be included in the patient's asthma action plan. Repeated SABA use over 1 to 2 days signals a lack of response and the need to contact the healthcare provider. Adverse effects of SABAs include tachycardia, tremor, and hypokalemia, which are usually not troublesome with inhaled dosage forms unless high doses are required to treat an exacerbation.

ICS–formoterol KEY CONCEPT As-needed use of formoterol combined with a low-dose ICS is considered the preferred reliever treatment for adults and adolescents with mild asthma.[1] This combination may be recommended as the sole treatment for patients with intermittent asthma or in combination with a daily maintenance inhaler containing an ICS or ICS–formoterol for patients with more severe asthma. Clinical trials showed decreased severe exacerbations when as-needed budesonide–formoterol was compared to a SABA alone in patients with mild asthma.[43] Furthermore, patients with infrequent asthma symptoms have poor adherence to prescribed maintenance medications, exposing them to the risks of SABA-only treatment.[1] Use of as-needed ICS–formoterol provides the added benefit of ICS therapy to combat airway inflammation while decreasing the burden of daily ICS use.

Although other combinations of ICS–formoterol may be considered, current evidence only exists for the combination of budesonide and formoterol. Patients using budesonide–formoterol as a reliever medication should not exceed 72 mcg of formoterol per day. As-needed ICS–formoterol has not been studied in children 11 years of age and younger, and the recommended reliever treatment is different for this age group.

Short-Acting Muscarinic Antagonists (SAMAs) Ipratropium bromide is available as an MDI and inhalation solution for nebulization. Its onset is approximately 15 minutes, and the duration is 4 to 8 hours. Addition of ipratropium bromide to a SABA during a moderate-to-severe asthma exacerbation improves pulmonary function and decreases hospitalization rates in both adult and pediatric patients.[44] Combining a SABA with ipratropium to increase bronchodilation is only indicated in the emergency department setting. The bronchodilator effects of SAMAs are not as pronounced as SABAs in asthma.[1,4] See Table 15–5 for dosing recommendations of ipratropium.

Systemic Corticosteroids Prednisone, prednisolone, and methylprednisolone are the cornerstone of treatment for acute asthma not responding to a SABA (see Table 15–5 for recommended doses).[1,4] The onset of action for systemic corticosteroids is 4 to 12 hours. For this reason, systemic corticosteroids are started early in the course of severe acute exacerbations (eg, PEF < 60% of personal best, patient not responding to treatment over 48 hours, or patients with history of sudden severe exacerbations). The oral route is preferred in acute asthma; it is less invasive, less costly, and has a quicker onset of action compared to intravenous corticosteroid administration. For children, the liquid formulation is preferred to tablets. Prednisolone sodium phosphate oral solution (15 mg/5 mL) rather than prednisolone base is more palatable for children.[45] The duration of therapy usually ranges from 5 to 7 days. Tapering the corticosteroid dose in patients receiving less than 2 weeks of therapy is usually not necessary because any adrenal suppression is transient and rapidly reversible.[1]

Patient Encounter Part 2

Current Home Medication Regimen:

- Albuterol MDI 2 inhalations every 4 to 6 hours as needed for shortness of breath. Last filled 28 days ago.
- Albuterol 2.5-mg solution for inhalation every 6 hours as needed for wheezing. Last filled 2 weeks ago.
- Loratadine 10 mg orally daily for allergies. Purchases over the counter. She does not buy often because of cost.
- Fluticasone nasal spray 50 mcg/actuation: 1 spray in each nostril twice daily. Last filled 3 months ago.
- Daily multivitamin

Medication History

- Montelukast 10 mg at bedtime. Discontinued ~2 years ago because of nonadherence. Per patient "I just always seemed to fall asleep before taking it."
- Fluticasone DPI 100 mcg twice daily. Discontinued ~3 years ago because of nonadherence. Patient said it didn't seem to help and it gave her oral thrush.
- Prednisone 40 mg 1 tablet daily × 7 days.

Vaccinations: Receives yearly influenza vaccine; unable to recall what other vaccines she has received.

Discuss whether the patient is currently receiving the preferred drug therapy for asthma management.

What motivational interviewing techniques may be used to discuss medication adherence with the patient?

Which vaccines should the patient receive based on her asthma history?

Treatment of Chronic Asthma

KEY CONCEPT Current clinical practice guidelines recommend control-based asthma management, where pharmacologic treatment is adjusted in a continuous cycle that involves assessment, treatment, and review.[1] In this approach, asthma control and future risk are used to determine the initial treatment, and then the response to treatment is evaluated to determine if further adjustment is needed to achieve asthma control. The least amount of medications necessary to meet the therapeutic goals is used.

The first step in asthma management is determining the frequency of asthma symptoms and the risk for future exacerbations. Pharmacologic treatment is then initiated based on the recommendations for that particular risk category (Tables 15–6 and 15–7). From there, a stepwise approach is used to adjust treatment based on patient response. Therapeutic plans must be individualized, and patient/caregiver preferences should be taken into consideration.

Table 15–6

GINA Recommendations for Initial Treatment in Adults and Adolescents

Symptom Presentation	Preferred Option for Adults/Adolescents	Preferred Option for children 6–11 Years of Age
Asthma symptoms < 2×/month; no risk factors for exacerbations	As-needed low-dose ICS–formoterol OR Low-dose ICS whenever SABA is taken	As-needed SABA with low-dose ICS whenever SABA is taken
Asthma symptoms or need for ≥2×/month	Low-dose ICS with a SABA as-needed OR As-needed low-dose ICS–formoterol	Low-dose ICS with a SABA
Asthma symptoms most days or waking up due to asthma at least once/week	Low-dose ICS-formoterol as controller and reliever therapy OR Low-dose ICS-LABA with as-needed SABA OR Medium-dose ICS with SABA	Low-dose ICS-LABA with as-needed SABA OR Medium-dose ICS with as-needed SABA OR Low-dose ICS-formoterol daily and as reliever
Daily symptoms, waking with asthma symptoms once a week or more or FEV1<65%	High-dose ICS with as-needed SABA +/– oral steroid burst OR Medium-dose ICS-formoterol daily and as-needed +/– oral steroid burst	Medium-dose ICS-LABA with as-needed SABA +/– oral steroid burst OR low dose ICS-formoterol daily and as a reliever

GINA, Global Initiative for Asthma; ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist, LTRA, leukotriene receptor antagonist; OCS, oral corticosteroid; SABA, short-acting β_2-agonist.

Data from Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention, 2021. www.ginasthma.org.

Table 15–7

Risk Factors for Asthma Exacerbation

- Uncontrolled asthma symptoms
- Frequent use of SABA
- Inadequate ICS therapy
- Low FEV$_1$ (especially if < 60% predicted)
- Major psychological or socioeconomic problems
- Exposures: smoking, allergen exposure if sensitized
- Comorbidities: Obesity, rhinosinusitis, confirmed food allergy
- Sputum or blood eosinophilia; elevated FeNO (in adults with allergic asthma)
- Pregnancy
- History of intubation or treatment in ICU for asthma
- 1 or more severe exacerbations in the past 12 months

FeNO, fraction of exhaled nitric oxide; FEV$_1$, forced expiratory volume in the first second; ICS, inhaled corticosteroid; ICU, intensive care unit; SABA, short-acting β_2-agonist.

▶ *Intermittent Asthma*

This classification includes patients with EIB, seasonal asthma, or asthma symptoms associated with infrequent trigger exposure. Patients with intermittent asthma continue to have chronic inflammation, and preferred treatment options include ICS–formoterol as needed or as-needed SABA with low-dose ICS.[1] Although a SABA alone is still an option for intermittent asthma, this regimen has been associated with an increased risk of severe exacerbations when compared to treatment regimens that also contain an ICS.[1]

Exercise is one of the most common precipitants of asthma symptoms. Shortness of breath, wheezing, or chest tightness usually occur during or shortly after vigorous exercise, peak 5 to 10 minutes after stopping the activity, and resolve within 20 to 30 minutes. Warming up prior to exercise and covering the mouth and nose with a scarf or mask during cold weather may prevent EIB (Table 15–1). Pretreatment with a SABA or low-dose ICS–formoterol 5 to 20 minutes prior to exercise is the treatment of choice for EIB and will protect against bronchospasm for 2 to 3 hours. Regular treatment with an ICS is recommended if treatment is needed daily before exercise.[46]

▶ *Persistent Chronic Asthma*

ICS are the long-term control medications of choice at all levels of asthma severity (mild, moderate, and severe) and in all age groups.[1,4–6] Single Maintenance and Reliever Therapy (SMART) therapy, which refers to the use of ICS–formoterol as both controller therapy and reliever therapy, is now considered the treatment of choice for adults and adolescents 12 years and older with moderate persistent asthma.[12] SMART therapy has shown superiority to a higher daily dose of an ICS with an as-needed SABA, a daily same-dose ICS plus LABA and an as-needed SABA, and a higher daily dose ICS plus LABA and an as-needed SABA.[12] Addition of a LAMA, biologic agents, and/or oral corticosteroids may be considered for patients who are unable to achieve control on SMART therapy alone. Patients should be assessed 1 to 3 months after changes to their medication regimen to determine whether asthma control has been achieved and a "step up" in therapy should be considered if symptoms persist (Table 15–8 and 15–9). Adherence to the treatment regimen as well as proper inhaler technique should always be assessed prior to making changes in therapy.

Patients with controlled asthma are monitored at 3- to 12-month intervals to ensure that control is maintained. A gradual step-down in long-term controller therapy is attempted once control has been maintained for 3 months.[1] If treatment is stepped down too far or too quickly, exacerbation risk may increase even if symptoms remain controlled.[1] Factors associated with a poor response to step-down therapy include serious exacerbations in the past 12 months and a low baseline FEV$_1$.[1] Controversy exists about how best to taper long-term controller medication. A safe approach seems to be stepping down ICS dose by 25% to 50% at 3-month intervals.[1] Complete cessation of ICS is not recommended because it is associated with a significant risk of exacerbations, and stopping LABA therapy has been shown to result in increased hospitalizations and reduced lung function.[47] Therefore, it is vital to monitor patients closely during step-down therapy, provide them with an asthma

Table 15–8

Assessment of Asthma Control in Adults, Adolescents, and Children

Adults, Adolescents, and Children 6–11 Years		Children ≤ 5 Years	
Asthma Symptoms	**Level of Symptom Control**	**Asthma Symptoms**	**Level of Symptom Control**
In the past 4 weeks, has the patient had: • Daytime asthma symptoms more than twice per week • Nighttime awakening due to asthma • Reliever needed for symptoms more than twice per week • Activity limitation due to asthma	If yes to none of these = well controlled If yes to 1–2 of these = partly controlled If yes to 3–4 of these = uncontrolled	In the past 4 weeks, has the child had: • Daytime asthma symptoms for more than a few minutes, more than once a week • Nighttime awakening or nighttime coughing due to asthma • SABA needed more than once per week • Activity limitation due to asthma	If yes to none of these = well controlled If yes to 1–2 of these = partly controlled If yes to 3–4 of these = uncontrolled

1. If asthma is not well controlled, assess inhaler technique, adherence to therapies, and environmental controls before considering adjustment of therapy.
2. Consider stepping up therapy if uncontrolled symptoms or recent exacerbations or high risk for exacerbations (see Table 15–6 and 15–7). Refer to Table 15–9 for stepwise approach to control asthma symptoms.
3. Consider stepping down therapy if symptoms controlled for 3 months + low risk for exacerbations.

Data from Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention, 2021. www.ginasthma.org.

Table 15–9

GINA Stepwise Approach to Control Symptoms and Minimize Future Risk

Adolescents and Adults 12 Years and Older

Step	Preferred Controller	Preferred Reliever
1	As-needed low-dose ICS–formoterol	As-needed low-dose ICS–formoterol
2	As-needed low-dose ICS–formoterol	As-needed low-dose ICS–formoterol
3	Daily low-dose ICS-formoterol	As-needed low-dose ICS–formoterol
4	Daily medium-dose ICS-formoterol	As-needed low-dose ICS–formoterol
5	Refer for expert advice. High-dose ICS-formoterol + add-on treatment LAMA, anti-IgE, anti-IL5/5R, OR anti-IL4Rα	As-needed low-dose ICS–formoterol

Children Aged 6-11 Years of Age

Step	Preferred Controller Option	Other Controller Options	Preferred Reliever
1	Low-dose ICS taken when SABA taken	Daily low-dose ICS	SABA
2	Daily low-dose ICS	LTRA OR low-dose ICS taken whenever SABA taken	SABA
3	Daily low-dose ICS-LABA OR medium-dose ICS, OR very low dose ICS-formoterol	Low-dose ICS + LTRA	SABA OR as-needed low-dose ICS-formoterol if patient is on ICS-formoterol as maintenance
4	Medium-dose ICS-LABA OR low dose ICS-formoterol. Refer for expert advice	Medium-dose ICS-LABA + tiotropium OR medium-dose ICS-LABA + LTRA	SABA OR as needed low-dose ICS-formoterol if patient is on ICS-formoterol as maintenance
5	High-dose ICS-LABA + add on treatment LAMA, anti-IgE; Refer for expert advise	Add anti-IL5 (mepolizumab) OR add low-dose OCS	SABA

Children Ages 5 Years and Younger

Step	Preferred Controller Option	Other Controller Options	Preferred Reliever
1	No controller		SABA
2	Low-dose ICS	LTRA Intermittent ICS at symptom onset	SABA
3	Medium-dose ICS; Refer for expert advice	Low-dose ICS + LTRA	SABA
4	Medium-dose ICS; Refer for expert advice	Add LTRA OR increase ICS frequency OR add intermittent ICS	SABA

*If patient is on a LABA other than formoterol, then a SABA should be used as reliever

GINA, Global Initiative for Asthma; ICS, inhaled corticosteroid; LABA, long-acting β_2 agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroid; SABA, short-acting β_2 agonist.

Data from Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention, 2021. www.ginasthma.org.

action plan, and ensure that they have a supply of their controller medication at home to resume if necessary.

Treatment of Acute Asthma

KEY CONCEPT In acute asthma, early and appropriate intensification of therapy is important to resolve the exacerbation and prevent relapse and future severe airflow obstruction. Both SABA therapy and as-needed ICS–formoterol are optional reliever medications for self-management of asthma exacerbations. However, use of SABA reliever is less effective in preventing progression to severe exacerbation requiring oral corticosteroids than low-dose ICS–formoterol.[1] If adherence to an ICS is problematic, increasing the ICS dose during acute exacerbations may be acceptable directions to provide in the action plan. Based on the initial response to these self-management strategies, the severity of the exacerbation is assessed, and treatment is appropriately intensified. Patients should add an oral corticosteroid if worsening asthma symptoms persist for 48 hours.[1] Patients deteriorating quickly or not responding to reliever medications should go to the emergency department for assessment and treatment of the exacerbation.

Patients achieving a sustained response in the emergency department are generally discharged home with a 5- to 7-day course of oral corticosteroids, an appropriate long-term controller medication, and a reliever medication. Patients who do not respond adequately to intensive therapy in the emergency department within 3 to 4 hours are admitted to the hospital. Refer to Table 15–10 for treatment recommendations in the emergency setting.

Regardless of the severity of an asthma exacerbation, patients should see their primary healthcare provider within 1 week to identify the potential cause of the exacerbation and adjust pharmacologic and nonpharmacologic therapy as necessary.

Asthma Self-Management

Self-management plans give patients the freedom to adjust therapy based on personal assessment of disease control using predetermined written instructions from the physician. Written asthma action plans (a part of standard care) guide at-home treatment of worsening asthma to potentially prevent hospitalizations and death.

The action plan includes instructions on daily management and how to recognize and manage worsening asthma.[1,4]

Table 15–10

Assessment and Treatment of Asthma Exacerbations in the Urgent or Emergency Care Setting

	Signs and Symptoms		
Severity	**> 5 Years of Age**	**Children ≤ 5 Years of Age**	**Clinical Course**
Mild to Moderate	Talks in sentences Prefers sitting to lying Not agitated Respiratory rate increased Accessory muscles not used Pulse rate 100–120 bpm O_2 saturation (on air) 90%–95% (0.90–0.95) PEF > 50% predicted or personal best	Talks in sentences Breathless Wheezing may be present May be agitated Pulse rate < 100 bpm if mild Pulse rate < 180 bpm (0–3 years) or ≤ 150 bpm (4–5 years) if moderate O_2 saturation ≥ 92% (0.92)	• SABA by nebulizer or MDI + spacer • Ipratropium bromide may decrease need for hospitalization and improve FEV_1 compared to SABA alone • Systemic corticosteroid × 5–7 days for adult; 3–5 days for children • Oxygen (if needed); target saturation 93%–95% (0.93–0.95) for adults; 94%–98% (0.94–0.98) for children; > 95% (0.95) during pregnancy • Epinephrine indicated only if exacerbation is associated with anaphylaxis and angioedema
Severe	Talks in words, not sentences Sits hunched forward Respiratory rate > 30/min Accessory muscles in use Pulse rate > 120 bpm O_2 saturation (on air) < 90% (0.90) PEF < 50% predicted or personal best	Talks in words, not sentences Pulse rate > 180 bpm (0–3 years) or > 150 bpm (4–5 years) O_2 saturation < 92% (0.92) Marked subcostal and/or subglottic retractions	• Requires ED visit and likely hospitalization; immediate transfer to hospital is indicated if child ≤ 5 years of age • Give inhaled SABA + ipratropium bromide in ED setting; no benefit from adding ipratropium to SABA once hospitalized • Oxygen to maintain saturation 93%–95% (0.93–0.95) for adults; 94%–98% (0.94–0.98) for children; > 95% (0.95) during pregnancy • Oral or IV systemic corticosteroids; oral preferred if possible • Consider IV magnesium[a] • Epinephrine indicated only if exacerbation is associated with anaphylaxis and angioedema
Subset: Life Threatening	Too dyspneic to speak Drowsiness Confusion Silent chest Central cyanosis Pulse rate > 200 bpm PEF < 25% predicted or personal best	Unable to speak or drink Central cyanosis Silent chest Confusion	• Transfer to ICU • While waiting, start SABA + ipratropium bromide, IV corticosteroids, and O_2 to maintain saturation 93%–95% (0.93–0.95) for adults; 94%–98% (0.94–0.98) for children; > 95% (0.95) during pregnancy • Prepare patient for intubation • Consider IV magnesium[a] • Epinephrine indicated only if exacerbation is associated with anaphylaxis and angioedema

[a] Intravenous magnesium sulfate is not recommended for routine use in asthma exacerbations; however, it reduces hospital admissions in some patients, including adults with FEV_1 < 25%–30% predicted at presentation; adults and children who fail to respond to initial treatment and have persistent hypoxemia; and children whose FEV_1 fails to reach 60% predicted after 1 hour of care. The role of magnesium sulfate is not established for children ages 5 years and younger but may be considered as an adjuvant to standard treatment in children 2 years or age and older with severe asthma.

bpm, beats per minute; ED, emergency department; FEV_1, forced expiratory volume in first second; ICU, intensive care unit; MDI, metered-dose inhaler; O_2, oxygen; PEF, peak expiratory flow; SABA, short-acting β_2-agonist.

Data obtained from Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention, 2021. Available from: www.ginasthma.org.

Asthma control is assessed by evaluating symptoms of worsening asthma and/or monitoring PEF. Early signs of deterioration include increasing nocturnal symptoms, increasing use of reliever medication, or symptoms that do not respond to increased use of reliever medication. Providing patients with a prescription for oral corticosteroids to use on an as-needed basis at the onset of an asthma exacerbation is part of asthma self-management.

Measurement of PEF is considered for patients with moderate-to-severe persistent asthma, poor perception of worsening asthma or airflow obstruction, and those with an unexplained response to environmental or occupational exposures.[4] PEF measurements are not necessary for a patient to receive an asthma action plan; the plan can be based on symptoms only. PEF is measured daily in the morning upon waking or when asthma symptoms worsen. For PEF-based action plans, the patient's personal best PEF is established over a 2- to 3-week period when the patient is receiving optimal treatment.[4] Subsequent PEF measurements are evaluated in relation to their variability from the patient's best PEF measurement. PEF measurements in the range of 80% to 100% of personal best (green zone) indicate that current therapy is acceptable. A PEF in the range of 50% to 79% of personal best (yellow zone) indicates an impending exacerbation, and therapy is intensified with reliever therapy, possibly oral corticosteroids, and a call to the physician. A PEF less than 50% (red zone) signals a medical alert; patients use their reliever medications immediately, take oral corticosteroids, and go to the emergency department. PEF measurements alone should not be used to determine the severity of airflow limitation. Measurements can be falsely elevated or decreased with poor technique, such as coughing into the meter or insufficient patient effort. Smaller airways may become inflamed

Patient Encounter Part 3

CC: "One minute I felt fine and then I just couldn't breathe."

HPI: Patient presented to ED with complaints of worsening shortness of breath not relieved by use of albuterol 4 inhalations every 20 minutes. Symptoms began this morning while she was visiting with her mother and worsened despite use of albuterol MDI. It became difficult for her to speak in full sentences, so her husband brought her to the emergency department. She was treated with albuterol–ipratropium inhalation solution and started on oral prednisone 40 mg daily. Supplemental oxygen was given because O$_2$ saturation was 92% (0.92) upon arrival. O$_2$ saturation now improved to 98% (0.98) on room air. Patient is feeling better and is able to speak in full sentences. Patient states that her asthma symptoms have been worse lately because she has been spending a lot of time outside gardening. She's been using her albuterol inhaler 3 to 4 days a week after being outdoors for extended periods.

ROS:

General: no fever/chills, night sweats; + obesity

ENT: + allergic rhinitis, + nasal congestion, + postnasal drip, occasional mouth breathing

Respiratory: + shortness of breath, no cough

The reminder of the ROS is noncontributory.

PE:

VS: Temp 36.3°C, BP 138/84 mm Hg, Pulse 90 bpm, RR 20 breaths/min, Sao$_2$ 98% (0.98), Ht 162 cm, Wt 85 kg, BMI 32.4 kg/m^2

Gen: NAD

Eyes: PERRL, EOMI

HEENT: OP clear, septal spur with deviation to the left noted, TMs clear

Lungs: + slight wheezing at both bases

CV: RRR no m/r/g

Abd: Soft, NT/ND

Skin: No rash/hives, + hyperpigmented cheeks

Neuro/Psych: Grossly normal, normal affect

Asthma Control Test: 15 out of 25 (goal above 20); 3 months prior to today's visit ACT: 23

PEFR: 350 L/min best. 210 L/min in ED today

FeNO: 50 ppb at last visit

Review of RAST testing: Pollen, ragweed, trees, grass, roaches, mold, dogs, and cats

Spirometry from 1 month ago:

	Measured	% Predicted
FVC (L)	3.87	112.73
FEV$_1$ (L)	3.10	75.09
FEV$_1$/FVC (%)	80	–
TLC (L)	5.93	92.47
DLCO (mL/min/mm Hg)	29.31	143.09

Summary: Normal FEV$_1$/FVC. FVC is normal and FEV$_1$ is decreased. There is a response to inhaled bronchodilator (not shown in the table). The TLC and diffusing capacity are normal.

Labs:

Na 141 mEq/L (mmol/L)
K 3.6 mEq/L (mmol/L)
Cl 104 mEq/L (mmol/L)
CO$_2$ 30 mEq/L (mmol/L)
Anion gap 7
Ca 9.3 mg/dL (2.33 mmol/L)
Scr 0.92 mg/dL (81 μmol/L)
eGFR 106 mL/min/1.73 m^2

WBC 9.6 × 103 cells/μL (9.6 × 10^9/L)
Absolute eosinophil count 400 cells/μL (0.4 × 10^9/L)
Hgb 15.4 g/dL (154 g/L; 9.56 mmol/L)
Hct 43.9% (0.439)
Plt 216 × 103 cells/μL (216 ×10^9/L)
IgE 90 IU/mL (kIU/L)
Aspergillus antibody: none detected

What therapeutic regimens are available for this patient?

Provide this patient with an asthma action plan.

Recommend monitoring and follow-up for this patient.

during severe exacerbations, and the PEF is unable to detect this, possibly causing a patient to be discharged from the hospital with an unresolved exacerbation. Use the PEF meter as a tool along with assessing the patient's symptoms for best care. It is important to advise patients who use peak flow meters as a monitoring tool to treat asthma symptoms in accordance with their asthma action plan even if the PEF does not indicate airflow impairment.

OUTCOME EVALUATION

Chronic Asthma

- Assess onset, duration, and timing of subjective symptoms such as wheezing, shortness of breath, chest tightness, cough, nocturnal awakenings, and activity level. Use validated questionnaires (such as the Asthma Control Test, Asthma Therapy Assessment Questionnaire, or Asthma Control Questionnaire) to objectively document control.
- Monitor use of reliever medications to help determine asthma control and if a step-up in therapy is warranted.
- Determine the frequency of patient exacerbations. Frequent exacerbations, unscheduled clinic visits, emergency department visits, and hospitalizations due to asthma may indicate the need to reassess the patient's asthma regimen and environment.
- Measure lung function using office spirometry yearly in patients older than 5 years.
- Identify environmental factors triggering asthma exacerbations and provide trigger avoidance recommendations.
- Perform medication reconciliation to identify discrepancies in medications prescribed and used by the patient and to determine drug and disease state interactions.
- Assess adherence to medications and inhaler technique at every visit and always ensure adherence and proper technique before stepping up therapy.

Patient Care Process: Chronic Asthma

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements. Identify allergies to medications and other substances.
- Review previous full pulmonary function tests, RAST, CBC, IgE levels, and chemistry panel.
- Assess patient's peak flow measurement (if applicable).
- Collect current asthma control using validated questionnaire (eg, ACT or c-ACT) results.
- Document current height, weight, blood pressure, heart rate, and pulse oximetry.
- Auscultate the lungs for wheezing. Look in the mouth for signs of oral candidiasis if on ICS.
- Identify asthma exacerbations since the last visit, including emergency room visits or hospitalizations, or use of oral corticosteroid bursts.
- Ask about tobacco use and exposure to secondhand smoke (tobacco or marijuana).
- Ask the patient to demonstrate inhaler use. Ask when the inhaler is used, how many times in the past week the inhaler was used, and when the inhaler was last refilled.
- Identify the number of missed days of school or work because of asthma.
- Ask about patient (or caregiver) goals and satisfaction with asthma control.
- Collect diet and exercise information and use of SABA or reliever before exercise.
- Identify comorbid conditions that may affect asthma control including gastroesophageal reflux disease (GERD), allergic rhinitis, sleep apnea, anxiety, and depression.

Assess the Information:

- Evaluate medication side effects (rapid heart rate, jitteriness, bad taste, cough, dysphonia, lack of efficacy).
- Verify medication adherence. Examine the patient's inhaler for the number of doses remaining. Call the dispensing pharmacy to determine fill history of inhalers.
- Determine whether the patient is taking any medications (including prescription, OTC, or supplements) that may cause cough or worsen asthma control.
- Determine if patient's asthma medications are appropriate based on spirometry results, exacerbation history, and current asthma control.
- Identify changes in home, work, or school environment that may contribute to worsening asthma symptoms.
- Assess for worsening in comorbid conditions that may contribute to worsening asthma symptoms.
- Identify factors that may be affecting medication adherence including side effects, cost issues, formulary issues, and unclear understanding of purpose of inhalers.
- Assess inhaler technique. Identify any barriers that inhibit the patient from using their inhaler correctly.
- Determine if the patient needs the influenza, COVID-19 and pneumococcal vaccines.
- Assess the patient's readiness to stop using tobacco or marijuana.

Develop a Care Plan:

- Document the patient's specific goals for asthma control.
- If the patient is not controlled, before adding medications or increasing dosing, make sure the patient is using the current inhalers correctly and is willing to use the inhalers.
- If asthma is not controlled and patient is adherent to their asthma medications and using them correctly, consider a step up in therapy.
- Identify patient preference, ability to pay, and insurance coverage for MDI, DPI, SMI, BAI, or nebulization.
- If the patient is controlled and has been on the current regimen for 3 months or longer, consider discontinuing or lowering the dose of controller medications.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential new adverse effects, and how to manage and report adverse effects that may occur.
- Review patient's technique with inhalers. Use physical demonstration with placebo inhalers, standardized checklists, pictures, and videos of inhalers (http://use-inhalers.com/).
- Provide an updated medication list with indication and use of each inhaler device.
- Provide an updated asthma action plan with medication changes.
- Review environmental asthma triggers and avoidance plans.
- Administer and update vaccinations.
- Discuss diet and exercise (using SABA or ICS–formoterol prior to exercise if needed).
- Refill all asthma-related medications, including medications to treat allergic rhinitis and GERD.

Follow-up: Monitor and Evaluate:

- Schedule follow-up physician visits depending on asthma control (3–6 months).
- Check spirometry yearly.
- Review adherence and inhaler technique at every visit.
- Update asthma action plan yearly or with each medication change.
- Monitor ACT quarterly.
- Monitor medication refill history.
- Evaluate asthma-related hospitalizations, emergency department visits, and oral corticosteroid use.

- Assess the patient's understanding of the indication for long-term controller medication and identify adverse events, cost issues, and need for refills.
- Review and update the asthma action plan and provide the patient with a written copy of the plan.
- Update the patient's immunization status and provide an annual influenza vaccination.

Acute Asthma

In addition to the outcomes measured for chronic asthma, acute asthma monitoring also includes the following:

- Assess asthma symptoms and measure the PEF. The goal is improved asthma symptoms and a PEF measurement greater than 70% of the patient's personal best peak flow after the first three doses of an inhaled SABA or reliever. Spirometry is not usually conducted in the emergency department.
- Check respiratory rate and measure oxygenation using pulse oximetry and provide oxygen via nasal cannula if needed. The goal oxygen saturation is 93% to 95% (0.90–0.95) in adults and 94% to 98% (0.94–0.98) in children, pregnant women, and patients with coexisting cardiovascular disease.
- Obtain a pCO_2 measurement via arterial blood gases in patients with severe asthma exacerbations. An increased pCO_2 indicates the potential for respiratory failure.
- Monitor serum potassium for hypokalemia upon admission and periodically throughout the admission in patients receiving high-dose or continuous nebulization of SABA.

Abbreviations Introduced in This Chapter

AERD	Aspirin-exacerbated respiratory disease
BAI	Breath actuated inhaler
DPI	Dry powder inhaler
EIB	Exercised induced bronchospasms
FeNO	Fraction of exhaled nitric oxide
FEV_1	Forced expiratory volume in 1 second
FVC	Forced vital capacity
GLCCI1	Glucocorticoid-induced transcript 1 gene
HFA	Hydrofluoroalkane
ICS	Inhaled corticosteroid
IgE	Immunoglobulin E
IL-5	Interleukin 5
LABA	Long-acting β_2-agonist
LTRA	Leukotriene receptor antagonist
LAMA	Long-acting muscarinic antagonist
MDI	Metered-dose inhaler
NHLBI	National Heart, Lung, and Blood Institute
pCO_2	Partial pressure of carbon dioxide
PEF	Peak expiratory flow
SABA	Short-acting β_2-agonist
SAMA	Short-acting muscarinic antagonist
SMI	Slow mist inhaler
Th_2	Type 2 T-helper $CD4^+$ cell

Chronic Obstructive Pulmonary Disease

Jon P. Wietholter and Tara R. Whetsel

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of chronic obstructive pulmonary disease (COPD).
2. Assess a patient for signs and symptoms of COPD.
3. List the treatment goals for a patient with COPD.
4. Design an appropriate COPD maintenance treatment regimen based on patient-specific data.
5. Design an appropriate COPD exacerbation treatment regimen based on patient-specific data.
6. Develop a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for COPD.
7. Formulate an appropriate education plan for a patient with COPD.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a progressive disease characterized by airflow limitation that is not fully reversible. Previous definitions of COPD included chronic bronchitis and emphysema. Chronic bronchitis is defined clinically as a chronic productive cough for at least 3 months in each of 2 consecutive years in a patient in whom other causes have been excluded.[1] Emphysema is defined pathologically as destruction of alveoli.[1] The major risk factor for both conditions is cigarette smoking, and many patients share characteristics of each one. Therefore, current guidelines focus instead on chronic airflow limitation.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) is an expert panel of health professionals who developed consensus guidelines for the diagnosis and care of patients with COPD that are updated annually.[1]

EPIDEMIOLOGY AND ETIOLOGY

COPD is a major cause of morbidity and mortality and a significant cause of disability worldwide. In 2017, the estimated prevalence of COPD in the United States was 6.4%.[2] Over 169,000 adults died from COPD, making it the fourth leading cause of death.[2,3] Personal health care spending in the United States on COPD was estimated to be $53.8 billion in 2013.[4] In addition, patients with COPD have a higher prevalence of coronary artery disease and hypertension.[5] Other common comorbidities that can impact disease course and prognosis include lung cancer, heart failure, gastroesophageal reflux disease (GERD), obstructive sleep apnea, osteoporosis, and depression/anxiety.[1,5]

COPD is caused by repeated inhalation of noxious particles or gases, most commonly cigarette smoke. Marijuana and other forms of tobacco, including secondhand smoke, are also risk factors.[1] Not all smokers develop clinically significant COPD, which suggests that genetic susceptibility plays a role. The best documented genetic factor is a rare hereditary deficiency of α_1-antitrypsin (AAT). Severe deficiency of this enzyme results in premature and accelerated development of emphysema. Factors that potentially reduce maximal attained lung function (eg, maternal smoking, preterm birth, early childhood lung infections, air pollution, childhood asthma, and active smoking during adolescence) increase the risk of COPD.[1,6] Other COPD risk factors include occupational exposure to dusts and chemicals (vapors, irritants, and fumes), biomass smoke inhalation, asthma, and bronchial hyperresponsiveness. Outdoor air pollution has been implicated as a cause, but its exact role is unclear.

PATHOPHYSIOLOGY

Repeated exposure to noxious particles and gases causes chronic inflammation, resulting in pathologic changes in the central and peripheral airways, lung **parenchyma**, and pulmonary vasculature that lead to obstruction.[1,7,8] An imbalance between **proteases** and **antiproteases** in the lungs and oxidative stress are also important in the pathogenesis of COPD (**Figure 16–1**).

Inflammation is present in the lungs of all smokers, yet not all smokers develop COPD. In patients with COPD, the inflammatory response is amplified, likely due to a genetic predisposition, although the exact mechanisms are unknown. KEY CONCEPT The inflammation of COPD differs from that seen in asthma, so the use of and response to anti-inflammatory medications is different. The inflammation of asthma is mainly mediated through eosinophils and mast cells. In COPD, the primary inflammatory cells are neutrophils, macrophages, and $CD8^+$ T lymphocytes.[7] A subset of patients with COPD also have increased eosinophils, which appears to predict a more favorable response to bronchodilators and corticosteroids and may indicate coexisting asthma.[7] Activated inflammatory cells release mediators (eg, interleukin-1, interleukin-8 [CXCL8], tumor necrosis factor-α) and secrete proteases (eg, elastase, proteinase-3, matrix metalloproteinase-9) which sustain and amplify inflammation and damage lung structures.[1,7]

Proteases and antiproteases are part of the normal protective and repair mechanisms in the lungs. An imbalance of

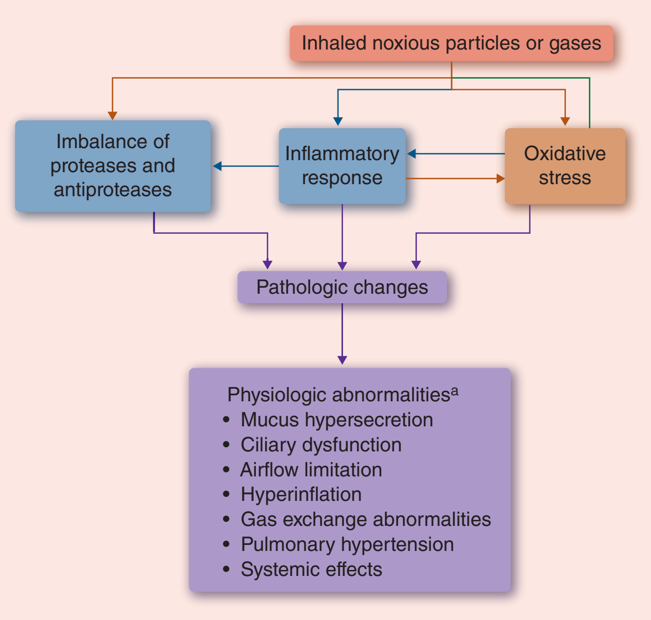

FIGURE 16–1. Pathophysiology of COPD. [a]The physiologic abnormalities usually develop in this order.

protease-antiprotease activity in COPD results from either increased production or activity of destructive proteases or inactivation or reduced production of protective antiproteases. AAT (an antiprotease) inhibits trypsin, elastase, and several other proteolytic enzymes. Deficiency of AAT results in unopposed protease activity, which promotes destruction of alveolar walls and lung parenchyma, leading to emphysema.

Oxidative stress occurs from smoke exposure and an increase in activated neutrophils and macrophages. Oxidative stress promotes inflammation and contributes to the protease-antiprotease imbalance by reducing antiprotease activity. In addition, oxidants constrict airway smooth muscle, contributing to reversible airway narrowing.

In the central airways (the trachea, bronchi, and larger bronchioles), inflammatory cells and mediators stimulate mucus gland hyperplasia and mucus hypersecretion. Mucus hypersecretion and ciliary dysfunction lead to chronic cough and sputum production. The major site of airflow obstruction is the peripheral airways (small bronchi and bronchioles). Narrowing of small airways results from fibrosis, increased mucus, and accumulation of inflammatory debris.[1,7,8] The reduced airway diameter causes increased resistance to airflow. Parenchymal destruction leads to loss of elasticity and structural support resulting in closure of small airways during expiration, further obstructing airflow.

As airflow obstruction worsens, the rate of lung emptying slows and the interval between inspirations does not allow expiration to the relaxation volume of the lungs. This leads to pulmonary hyperinflation, which initially only occurs during exercise but later is also seen at rest. Hyperinflation contributes to the discomfort associated with airflow obstruction by flattening the diaphragm and placing it at a mechanical disadvantage.

In advanced COPD, airflow obstruction, damaged bronchioles and alveoli, and pulmonary vascular abnormalities lead to impaired gas exchange, resulting in hypoxemia and eventually hypercapnia. Hypoxemia is initially present only during exercise but occurs at rest as the disease progresses. Inequality in the ventilation/perfusion ratio (V_A/Q) is the major mechanism underlying hypoxemia. As hypoxemia worsens, the body may increase erythrocyte production in an attempt to increase oxygen delivery to tissues.

Pulmonary hypertension develops late in the course of COPD, usually after development of severe hypoxemia. It is the most common cardiovascular complication of COPD and can result in cor pulmonale, or right-sided heart failure. Progressive loss of skeletal muscle mass in longstanding COPD contributes to exercise limitation and declining health status.

CLINICAL PRESENTATION AND DIAGNOSIS

See accompanying box for the clinical presentation of COPD.

Diagnosis

A suspected diagnosis of COPD should be based on patient symptoms and history of exposure to risk factors. Spirometry is required to confirm the diagnosis, using the ratio of forced expiratory volume in the first second (FEV_1) to forced vital capacity (FVC). A postbronchodilator FEV_1/FVC ratio less than 70% (0.70) confirms airflow limitation that is not fully reversible.[1] Spirometry results can further be used to classify severity of airflow limitation in these patients. The GOLD classification categories of severity based on postbronchodilator FEV_1 are as follows: GOLD 1, mild = 80% predicted or greater; GOLD 2, moderate = 50% to

Clinical Presentation of COPD

General

- Patients are initially asymptomatic. COPD is usually not diagnosed until declining lung function leads to significant symptoms and prompts patients to seek medical care.

Symptoms

- Symptom onset is variable and does not correlate well with severity of airflow limitation measured by FEV_1.[1]
- Initial symptoms include chronic cough (for > 3 months) that may be intermittent at first, chronic sputum production, and dyspnea on exertion. Patients may complain of a sensation of chest heaviness or increased effort to breathe.
- As COPD progresses, dyspnea at rest and/or orthopnea develop, and ability to perform activities of daily living declines.

Signs

- Inspection may reveal use of accessory muscles of respiration (paradoxical movements of the chest and abdomen in a seesaw-type motion), pursed-lips breathing, and hyperinflation of the chest with increased anterior–posterior diameter ("barrel chest").
- On lung auscultation, patients may have distant breath sounds, wheezing, a prolonged expiratory phase, and rhonchi.
- In advanced COPD, signs of hypoxemia may include cyanosis and tachycardia.
- Signs of cor pulmonale include increased pulmonic component of the second heart sound, jugular venous distention (JVD), lower extremity edema, and hepatomegaly.

79% predicted; GOLD 3, severe = 30% to 49% predicted; GOLD 4, very severe = less than 30% predicted.[1] Full pulmonary function tests (PFTs) with lung volumes and diffusion capacity and arterial blood gases (ABGs) are not necessary to establish the diagnosis or severity of COPD.

Pulse oximetry should be obtained in patients with signs or symptoms suggestive of cor pulmonale or respiratory failure.[1] If oxygen saturation is less than 92% (0.92), ABGs should be assessed.[1] Patients may exhibit increased arterial carbon dioxide tension ($Paco_2$) and decreased arterial oxygen tension (Pao_2).

A complete blood count (CBC) may reveal an elevated hematocrit that may exceed 55% (0.55; polycythemia). An AAT level is recommended in all COPD patients, especially in areas with a high prevalence of AAT deficiency.[1] Chest radiography may show lung hyperinflation and signs of emphysema.

It is important to distinguish COPD from asthma because treatment and prognosis differ. Differentiating factors include age of onset, symptom variability, smoking history, triggers, occupational history, and coexisting conditions (eg, presence of allergic rhinitis and/or eczema favors asthma). In some patients, a clear distinction between asthma and COPD is not possible. Management of these patients should be like that of asthma.

TREATMENT

Desired Outcomes

The goals of COPD management include (a) smoking cessation if applicable, (b) reducing symptoms, and (c) preventing and treating exacerbations.[1]

General Approach to Treatment

KEY CONCEPT An integrated approach of health maintenance (eg, smoking cessation), vaccinations, pharmacotherapy, and supplemental therapy (eg, oxygen and pulmonary rehabilitation) should be used via an individualized approach. Symptom severity, risk of COPD exacerbations, adverse effects, comorbidities, and the patient's response and/or desires should be used to guide therapy decisions.[1]

Either the modified Medical Research Council (mMRC) Questionnaire or COPD Assessment Test (CAT) is recommended for symptom assessment. The CAT is preferred because it provides a more comprehensive assessment.[1] An mMRC grade of 0 or 1 or a CAT score less than 10 indicates fewer symptoms. Patients with more symptoms will have an mMRC grade of 2 or more or a CAT score of 10 or more. These patients require inhaled long-acting bronchodilators on a scheduled basis.[1]

Risk of future COPD exacerbation is assessed using number of exacerbations per year. Patients with a history of two or more exacerbations per year or one or more exacerbation(s) requiring hospitalization are at high risk for future exacerbations. Patients at high risk of COPD exacerbations also require inhaled long-acting bronchodilators on a scheduled basis to reduce the frequency of exacerbations.[1] Figure 16–2 provides an overview of the management of COPD.

Patient Encounter, Part 1

A 62-year-old woman with a medical history of asthma, type 2 diabetes mellitus, heart failure with reduced ejection fraction (HFrEF), and previous tobacco abuse (35 pack-year history) presents to the clinic complaining of shortness of breath with moderate physical activity, a "heavy" chest, chronic cough, and chronic sputum production for more than 3 years; however, her symptoms have worsened considerably over the last 3 months.

What symptoms and/or risk factors does she have that are suggestive of COPD?

What additional information do you need before creating a treatment plan for this patient?

Nonpharmacologic Therapy

▶ Smoking Cessation

KEY CONCEPT Smoking cessation slows the rate of decline in pulmonary function in patients with COPD.[9,10] Cessation can also reduce cough and sputum production and decrease exacerbations and all-cause mortality.[9,11] Therefore, it is a critical part of any treatment plan and should be encouraged at every visit. The "5 As" can be used as a framework to help guide interventions (Table 16–1). Even brief (< 3 minutes) counseling urging smokers to quit improves smoking cessation rates.[1,11]

Tobacco users who are ready to quit should be treated with a combination of behavioral counseling and pharmacotherapy. Varenicline or dual nicotine replacement therapy (NRT) (eg, nicotine patch plus as needed nicotine gum, lozenge, inhaler, or nasal spray) are the most effective options.[11] Bupropion and other combinations (eg, varenicline plus bupropion or NRT, bupropion plus NRT) are also effective strategies. Refer to the section "Tobacco Cessation" in Chapter 37.

▶ Pulmonary Rehabilitation

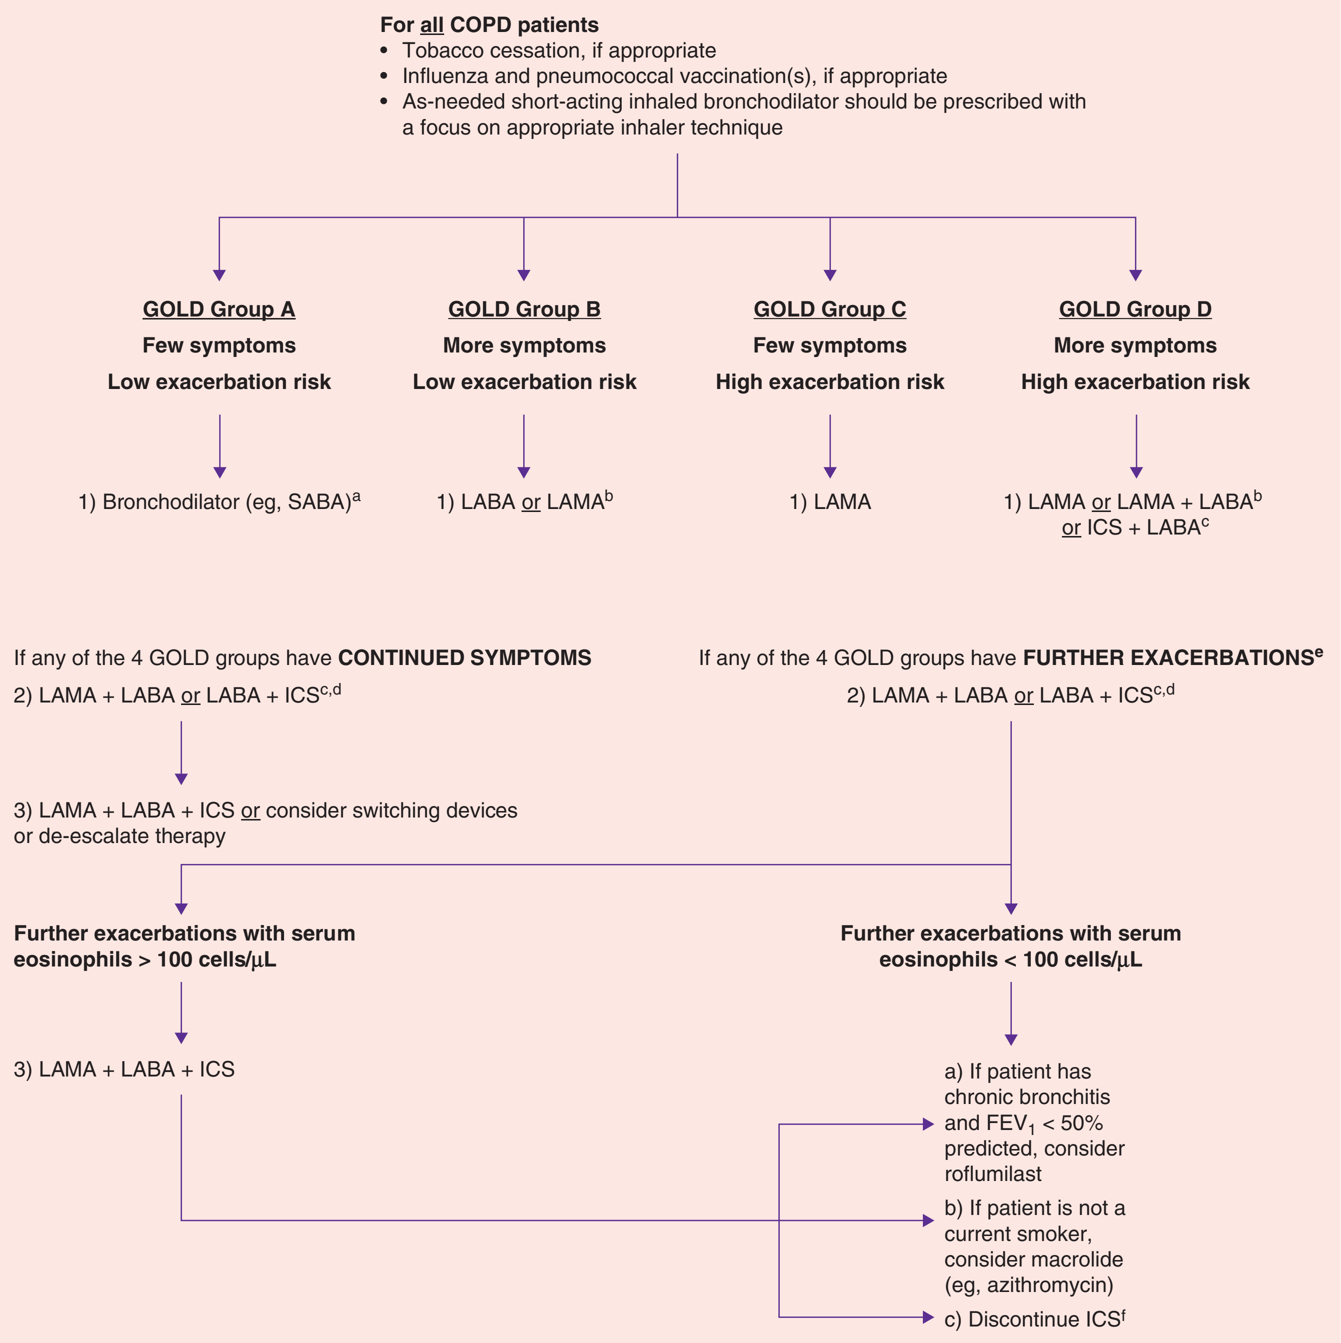
Pulmonary rehabilitation results in significant and clinically meaningful improvements in dyspnea, exercise tolerance, health status, health care utilization, and symptoms of anxiety or depression.[1,12] Initiating pulmonary rehabilitation within 2 weeks of hospitalization for an acute exacerbation can reduce readmissions and mortality.[1] Benefits have been observed in all grades of COPD severity but appear greatest in moderate-to-severe COPD.[1,12] An individualized pulmonary rehabilitation program should include at least twice weekly maximally tolerated load or interval and strength training, education, and self-management interventions aimed at behavior change.[1,12]

Rehabilitation programs may be conducted in multiple settings. The most effective length of a program is 6 to 8 weeks; extending the program to more than 12 weeks does not confer additional benefits.[1] It is important for patients to continue with a home exercise program to maintain the benefits gained from the pulmonary rehabilitation program.[1]

▶ Long-Term Oxygen Therapy

Long-term oxygen administration (> 15 hrs/day) in patients with chronic hypoxic respiratory failure has been shown to reduce mortality.[1] Oxygen therapy should be initiated in stable patients with COPD who have Pao_2 at or below 55 mm Hg (7.3 kPa) or oxygen saturation (Sao_2) at or below 88% (0.88), or with evidence of pulmonary hypertension, peripheral edema suggesting heart failure, or polycythemia. Patients should be reassessed with repeat ABG or oxygen saturation after 60 to 90 days.[1]

The goal is to increase baseline oxygen saturation to at least 90% (0.90) and/or Pao_2 to at least 60 mm Hg (8.0 kPa), allowing adequate oxygenation of vital organs. Hypoxemia worsens during



For all COPD patients
• Tobacco cessation, if appropriate
• Influenza and pneumococcal vaccination(s), if appropriate
• As-needed short-acting inhaled bronchodilator should be prescribed with a focus on appropriate inhaler technique
GOLD Group A
Few symptoms
Low exacerbation risk
GOLD Group B
More symptoms
Low exacerbation risk
GOLD Group C
Few symptoms
High exacerbation risk
GOLD Group D

High exacerbation risk
1) Bronchodilator (eg, SABA)[a]
1) LABA or LAMA[b]
1) LAMA
1) LAMA or LAMA + LABA[b] or ICS + LABA[c]
If any of the 4 GOLD groups have CONTINUED SYMPTOMS
2) LAMA + LABA or LABA + ICS[c,d]
3) LAMA + LABA + ICS or consider switching devices or de-escalate therapy
If any of the 4 GOLD groups have FURTHER EXACERBATIONS[e]
2) LAMA + LABA or LABA + ICS[c,d]
Further exacerbations with serum eosinophils > 100 cells/μL
Further exacerbations with serum eosinophils < 100 cells/μL
3) LAMA + LABA + ICS
a) If patient has chronic bronchitis and FEV_1 < 50% predicted, consider roflumilast
b) If patient is not a current smoker, consider macrolide (eg, azithromycin)
c) Discontinue ICS[f]

FIGURE 16–2. Pharmacotherapy Treatment Algorithm for COPD[1]. ICS, inhaled corticosteroid; LABA, long-acting β-agonist; LAMA, long-acting muscarinic antagonist; SABA, short-acting β-agonist. [a]If patient was not placed on a long-acting bronchodilator initially, should be started on either a LABA or LAMA if symptoms continue. [b]GOLD guidelines suggest considering combination LABA/LAMA therapy in highly symptomatic patients. [c]ICS/LABA may be more effective with serum eosinophils > 300 cells/microliter or in patients with concomitant asthma. However, ICS therapy increases the risk of pneumonia. [d]If patient is on ICS/LABA and has continued symptoms or exacerbations, could switch to LABA/LAMA, particularly in those with low serum eosinophil count. [e]If patients are suffering from both continued symptoms and exacerbations, use further exacerbations treatment pathway recommendations. [f]If an ICS is being used at any point and there is a lack of response or development of pneumonia, consider discontinuation of ICS, particularly in those with low serum eosinophil count.

air travel; patients requiring oxygen should generally increase their flow rate by 3 L/min during flight.[1] For patients with chronic hypercapnia and a recent hospitalization for respiratory failure, utilizing noninvasive ventilation (NIV) may improve respiratory acidosis, time to readmission, exacerbation rates, quality of life, and overall mortality.[1,13]

▶ *Surgery*

Bullectomy, lung volume reduction, and lung transplantation are surgical options for very severe COPD refractory to appropriate pharmacologic therapy. These procedures may result in improved lung function, health status, and exercise capacity and

Table 16–1

The 5 As for Brief Intervention for Tobacco Users

Ask: Identify and document tobacco-use status for every patient at every visit
Advise: Strongly urge every tobacco user to quit
Assess: Is the tobacco user willing to make a quit attempt at this time?
Assist: Use counseling and pharmacotherapy to help patients willing to make a quit attempt
Arrange: Schedule follow-up contact, preferably within the first week after the quit date

reduced exacerbations. Patient selection for each of these is critical because not all patients benefit.[1]

▶ *Other Nonpharmacologic Options*

Other treatment considerations include palliative measures in those with end-stage COPD (eg, oxygen in nonhypoxemic patients, fans blowing onto the face, hospice care). Nutritional support, particularly in patients with a low body mass index (BMI), can improve overall health status and respiratory muscle strength. Cognitive behavioral therapy and mind–body interventions can help manage anxiety and depression and may improve lung function and symptoms.[1]

Pharmacologic Therapy of Stable COPD

KEY CONCEPT Medications available for COPD are effective for reducing or relieving symptoms, improving exercise tolerance, reducing the number and severity of exacerbations, and improving health status but have not irrefutably slowed the rate of lung function decline or improved mortality. An individualized evaluation of symptoms, comorbidities, patient preferences, and a patient's future risk for exacerbations should be the guiding principles to determine appropriate pharmacologic management of COPD. Importantly, lung function may continue to worsen even with appropriate therapy.[1]

▶ *Bronchodilators*

KEY CONCEPT Bronchodilators are the mainstay of treatment for symptomatic COPD. They can increase FEV_1, reduce symptoms, reduce frequency and severity of exacerbations and hospitalization rates, and improve exercise tolerance, pulmonary rehabilitation efficacy, and health status.[1,14] They can be used as needed for symptoms or on a scheduled basis to prevent or reduce symptoms. The inhaled route is preferred, but attention must be paid to proper inhaler technique, both on initiation and at each follow-up visit because long-term appropriate adherence rates may be seen in only 23% of patients.[1] Long-acting bronchodilators are more expensive than short-acting bronchodilators but are preferred due to improved clinical outcomes. Toxicity to bronchodilators is dose related, and there is a relatively flat dose–response curve to these agents.[1]

β_2-Agonists These agents cause airway smooth muscle relaxation by stimulating adenyl cyclase to increase formation of cyclic adenosine monophosphate (cAMP). β_2-Agonists are available in inhalation, oral, and parenteral dosage forms; the inhalation route is preferred because of fewer adverse effects.

These drugs are available in short-acting and long-acting formulations (Table 16–2). The short-acting β_2-agonists (SABAs) used in COPD include albuterol (known as salbutamol outside the United States) and levalbuterol (known as R-salbutamol outside the United States). They are used as "rescue" therapy for acute symptom relief or in those with only occasional symptoms.

Long-acting β_2-agonists (LABAs) include salmeterol, formoterol, arformoterol, indacaterol, olodaterol, and vilanterol. Arformoterol and formoterol are both available for nebulization, providing an alternative for patients with poor inhaler technique. Indacaterol, olodaterol, and vilanterol (only available in combination) are long acting, allowing for once-daily dosing. While some studies suggest potential spirometric benefits of one LABA over another (usually indacaterol), definitive data on actual patient outcome differences among agents is lacking.[15] Insurance coverage, patient response, patient preference for type of inhaler device, and prescriber preference are considerations when selecting a LABA. Patients treated with LABAs should also have a SABA such as albuterol for as-needed use ("rescue" medication) but should be advised to avoid excessive use.

Adverse effects of both LABAs and SABAs are dose related and include palpitations, tachycardia, cough, hypokalemia, sleep disturbance, and tremor.

Antimuscarinics Ipratropium, tiotropium, aclidinium, glycopyrrolate (also known as glycopyrronium bromide), revefenacin, and umeclidinium are all available for inhalation treatment of COPD. They produce bronchodilation by competitively blocking muscarinic receptors in bronchial smooth muscle and may also decrease mucus secretion. Tiotropium, revefenacin, and umeclidinium have once-daily dosing while aclidinium and glycopyrrolate, which have shorter half-lives, require twice-daily dosing; each is considered a long-acting muscarinic antagonist (LAMA). While certain studies suggest potential spirometric benefits of one LAMA over another, definitive data on actual patient outcome differences among agents are still lacking.[16] Choice of LAMA should be based on insurance coverage, patient response and preferences, and prescriber preferences.

KEY CONCEPT LAMAs may be more effective than LABAs for reducing exacerbations and decreasing hospitalizations and have fewer adverse effects in patients with moderate-to-very-severe COPD.[1,17] Patients using LAMA maintenance therapy should be prescribed a SABA rather than ipratropium as their rescue therapy to minimize the potential for excessive anticholinergic effects.

Inhaled antimuscarinics are well tolerated with the most common adverse effects being dry mouth, headache, and nasopharyngitis. Occasional metallic taste has also been reported, most commonly with ipratropium. Other anticholinergic adverse effects include constipation, tachycardia, blurred vision, urinary retention, and precipitation of narrow-angle glaucoma symptoms. Increased cardiovascular events in COPD patients who regularly use ipratropium has also been reported.[1,17]

Methylxanthine Theophylline is an oral methylxanthine derivative and nonselective phosphodiesterase inhibitor that increases intracellular cAMP within airway smooth muscle resulting in bronchodilation and may also improve inspiratory function. Its use is limited due to a narrow therapeutic index, multiple drug interactions, questionable efficacy, and adverse effects.[1,18] Theophylline should be reserved for patients who cannot use inhaled medications or who remain symptomatic despite appropriate use of inhaled bronchodilators.[1]

Therapeutic drug monitoring is needed to optimize therapy because of wide interpatient variability. Multiple factors can alter theophylline clearance including concomitant medications (through CYP450 interactions), age, tobacco smoke, and marijuana. Chemicals in tobacco smoke induce theophylline metabolism and increase its clearance. The most common adverse effects of theophylline include headache, heartburn, insomnia, tachycardia, palpitations, and tremor. Dose-related adverse effects include nausea and vomiting, seizures, and arrhythmias.

Table 16–2

Maintenance Medications for COPD

	Medication	Onset	Duration	Usual Dose
Short-Acting β_2-Agonists	**Albuterol**[a]			
	Nebulization	≤ 5 minutes	3–6 hours	2.5 mg every 4–6 hours as needed
	Inhalation	5–8 minutes	2–6 hours	MDI or DPI (90 mcg/puff) two puffs every 4–6 hours as needed
	Levalbuterol[a]			
	Nebulization	10–17 minutes	5–8 hours	0.63–1.25 mg three times/day, 6–8 hours apart as needed
	Inhalation	5–10 minutes	3–6 hours	MDI (45 mcg/puff) two puffs every 4–6 hours as needed
Long-Acting β_2-Agonists	**Formoterol**			
	Inhalation	≤ 3 minutes	12 hours	DPI (12 mcg/inhalation) 12 mcg every 12 hours[b]
	Nebulization	≤ 3 minutes	12 hours	20 mcg every 12 hours
	Salmeterol			
	Inhalation	2 hours	12 hours	DPI (50 mcg/inhalation) one inhalation every 12 hours
	Indacaterol			
	Inhalation	5 minutes	24 hours	DPI (75 mcg/inhalation) one inhalation every 24 hours
	Olodaterol			
	Inhalation	5 minutes	24 hours	MDI (2.5 mcg/inhalation) two inhalations every 24 hours
	Vilanterol			
	Inhalation	15–30 minutes	24 hours	Only in combination inhalers
	Arformoterol			
	Nebulization	7–20 minutes	12 hours	15 mcg every 12 hours
Short-Acting Muscarinic Antagonists	**Ipratropium**			
	Nebulization	≤ 15 minutes	4–8 hours	0.5 mg every 6–8 hours as needed
	Inhalation	≤ 15 minutes	2–4 hours	MDI (17 mcg/puff) two puffs four times/day as needed
Long-Acting Muscarinic Antagonists	**Tiotropium**			
	Inhalation	30–60 minutes	24 hours	DPI (18 mcg/inhalation) one inhalation every 24 hours MDI (2.5 mcg/inhalation) two inhalations every 24 hours
	Aclidinium			
	Inhalation	10 minutes	12 hours	DPI (400 mcg/inhalation) one inhalation every 12 hours
	Umeclidinium			
	Inhalation	≤ 15 minutes	24 hours	DPI (62.5 mcg/inhalation) one inhalation every 24 hours
	Glycopyrrolate			
	Inhalation	5 minutes	24 hours	DPI (15.6 mcg/inhalation) one inhalation every 12 hours
	Nebulization	25 minutes	12 hours	25 mcg every 12 hours
	Revefenacin			
	Nebulization	≤ 45 minutes	24 hours	175 mcg every 24 hours[c]
Phosphodiesterase-4 Inhibitor	**Roflumilast** Oral	4 weeks	–	250 mcg daily for 4 weeks, followed by 500 mcg daily[c]
Inhaled Corticosteroids	**Beclomethasone**	1–14 days		MDI (40, 80 mcg/puff) 50–200 mcg every 12 hours as part of combination therapy
	Budesonide			
	Inhalation	1 day		DPI (90, 180 mcg/inhalation) 100–200 mcg every 12 hours as part of combination therapy
	Nebulization	2–8 days		0.25–0.5 mcg/day as part of combination therapy
	Fluticasone	Variable		MDI (44, 110, 220 mcg/puff) 50–250 mcg every 12 hours as part of combination therapy DPI (50, 100, 250 mcg/inhalation) 50–250 mcg every 12 hours as part of combination therapy

[a] Outside the United States, albuterol is known as salbutamol and levalbuterol is known as levosalbutamol (or R-salbutamol).

[b] Formoterol inhalation (Foradil aerolizer) is no longer available in the United States.

[c] Not recommended in patients with hepatic impairment.

DPI, dry powder inhaler; MDI, metered-dose inhaler.

▶ *Corticosteroids*

Inhaled corticosteroids (ICS) in combination therapy improve symptoms, lung function, health status, and exacerbation rates in patients with moderate-to-very-severe COPD.[1,19] However, there appears to be a limited response of COPD-associated inflammation, and the long-term safety of ICS in COPD patients is unclear.[1]

KEY CONCEPT ICS are recommended in patients with moderate-to-very-severe COPD with increased exacerbation risk who are not adequately controlled by first-line long-acting bronchodilators (eg, LAMA); they appear to be most beneficial in preventing exacerbations in patients with elevated serum eosinophils (> 220–300 cells/μL $0.22–0.3 \times 10^9$/L).[1,19] Monotherapy with an ICS is less

Table 16–3

FDA-Approved Combination Inhalers for Management of COPD

Inhaled Corticosteroid/Long-acting β_2-Agonist (ICS/LABA)

Brand Name	Corticosteroid	β_2-Agonist	Dosage Strengths	Frequency
Advair Diskus	Fluticasone propionate	Salmeterol	250 mcg/50 mcg	Twice daily
Symbicort	Budesonide	Formoterol	160 mcg/4.5 mcg	Twice daily
Breo Ellipta	Fluticasone furoate	Vilanterol	100 mcg/25 mcg	Daily

Long-acting Muscarinic Antagonist/Long-acting β_2-Agonist (LAMA/LABA)

Brand Name	Antimuscarinic	β_2-Agonist	Dosage Strengths	Frequency
Anoro Ellipta	Umeclidinium	Vilanterol	62.5 mcg/25 mcg	Daily
Stiolto Respimat	Tiotropium	Olodaterol	2.5 mcg/2.5 mcg	Daily
Bevespi Aerosphere	Glycopyrrolate	Formoterol	9 mcg/4.8 mcg	Twice daily
Utibron Neohaler	Glycopyrrolate	Indacaterol	15.6 mcg/27.5 mcg	Twice daily
Duaklir Pressair	Aclidinium	Formoterol	400 mcg/12 mcg	Twice daily

Short-acting Muscarinic Antagonist/Short-acting β_2-Agonist (SAMA/SABA)

Brand Name	Antimuscarinic	β_2-Agonist	Dosage Strengths	Frequency
Combivent Respimat	Ipratropium	Albuterol	20 mcg/100 mcg	Four times daily

Long-acting Muscarinic Antagonist/Long-acting β_2-Agonist/Inhaled Corticosteroid (LAMA/LABA/ICS)

Brand Name	Antimuscarinic	β_2-Agonist	Corticosteroid	Dosage Strengths	Frequency
Trelegy Ellipta	Umeclidinium	Vilanterol	Fluticasone furoate	62.5 mcg/25 mcg/100 mcg	Daily
Breztri Aerosphere	Glycopyrrolate	Formoterol	Budesonide	9 mcg/4.8 mcg/160 mcg	Twice daily

effective than combined therapy with a LABA and is therefore not recommended.[1] Combination inhaler devices are convenient and ensure that patients receive both medications (Table 16–3).

The most common adverse effects from ICS include oropharyngeal candidiasis and hoarse voice. These can be minimized by rinsing the mouth after use and by using a spacer device with metered-dose inhalers (MDIs). Increased bruising, decreased bone density, increased risk of diabetes, cataracts, and mycobacterial infections have been reported; an increased pneumonia risk exists with ICS usage, particularly in those using fluticasone, those with a blood eosinophil count less than 2% (0.02), those with more severe COPD, elderly patients, smokers, or underweight patients.[1,14,19,20] Long-term use of systemic corticosteroids should be avoided due to an unfavorable risk-to-benefit ratio.[1]

▸ *Phosphodiesterase-4 (PDE-4) Inhibitor*

Roflumilast is an oral PDE-4 inhibitor approved for improving lung function and preventing moderate and severe COPD exacerbations in patients with severe-to-very-severe COPD associated with chronic bronchitis and a history of exacerbations.[1,21] Roflumilast is believed to reduce inflammation by inhibiting breakdown of cAMP but does not cause direct bronchodilation. Roflumilast has more frequent adverse events than inhaled medications and has little effect on symptoms and quality of life.[21] Adverse effects typically occur early during treatment and include diarrhea, weight loss, nausea, headache, insomnia, decreased appetite, and abdominal pain; neuropsychiatric effects (eg, anxiety, depression, suicidal thoughts) have also been reported.[21] Due to these concerns, it should be avoided in underweight patients or those with depression.[1] Roflumilast can be considered in patients with chronic bronchitis, an FEV_1 less than 50%, and exacerbations while being treated with combination inhaled therapy, particularly LABA/ICS combinations or if they had a hospitalization within the previous year.[1,10]

▸ *Combination Therapy*

For patients who remain symptomatic on monotherapy, a combination of bronchodilators can be used to reduce symptoms and exacerbations.[1,10] Combination therapy should include medications with different mechanisms, which can lower the risk of side effects versus increasing the dose of a single agent.[1] When combination therapy is indicated, multi-ingredient inhalers should be selected over single-ingredient inhalers to reduce medication administration and cost burden to the patient (Table 16–3). Potential benefits and risks of any combination therapy should be considered on a case-by-case basis. While certain studies suggest potential spirometric benefits of one LABA/LAMA combination over another, definitive data on actual patient outcome differences among agents is still lacking.[22] LABA/LAMA combinations have a lower pneumonia risk when compared to LABA/ICS combinations.[1,23,24] LABA/LAMA combinations appear to reduce exacerbations more than LABA/ICS combinations, particularly in patients with normal blood eosinophil counts.[1,20,23]

Triple therapy with ICS, LABA, and LAMA is commonly used in patients who remain symptomatic on dual therapy and reduces symptoms and moderate or severe exacerbations while improving lung function when compared to ICS/LABA or LABA/LAMA combinations.[1,25] Additionally, recent data suggests that triple therapy may reduce mortality rates when compared to LABA/LAMA combination therapy in severe-to-very-severe COPD patients with a history of frequent or severe exacerbations.[26] However, triple therapy appears to increase the incidence of pneumonia when compared to LABA/LAMA combinations.[25]

While spirometry could potentially worsen in the short term, exacerbation rates may not increase when ICS are withdrawn from patients with moderate-to-severe COPD and low blood eosinophil counts.[1,19,27] Based on these results, a step-down in therapy can be considered in the subgroup of nonfrequent exacerbating stable COPD patients with blood eosinophil counts less than 300 cells/μL (0.3×10^9/L).[27]

▶ *Vaccinations*

KEY CONCEPT COPD exacerbations, hospitalizations, and death in COPD patients can be reduced with annual influenza vaccination.[1,28] The optimal time for vaccination is early fall, September through October.

Pneumococcal polysaccharide vaccine (PPSV23) should be administered to all adults with COPD, regardless of age. Patients 65 years old and older should be revaccinated with PPSV23 if it has been more than 5 years since initial vaccination and they were younger than 65 years at the time. Pneumococcal conjugate vaccine (PCV13) can be used in select patients 65 years old and older who have not previously received PCV13 if it is deemed appropriate by shared clinical-decision making. Considerations for giving PCV13 include the individual patient's risk for exposure to PCV13 serotypes and their risk of invasive pneumococcal disease. The risk of exposure is highest in patients living in nursing homes or other long-term care facilities, residing in an area with low pediatric PCV13 uptake, or traveling to an area with no pediatric PCV13 program. Patients with the following risk factors for invasive pneumococcal disease may benefit from PCV13 vaccination: older age; immunocompromising conditions; chronic heart, lung, or liver disease; diabetes; alcoholism; more than one chronic medical condition; and cigarette smoking.[29] If a patient is to receive both pneumococcal vaccines, PCV13 should be administered first, with PPSV23 administered at least 12 months after PCV13.[29]

▶ *α_1-Antitrypsin Augmentation Therapy*

Augmentation therapy consists of weekly intravenous transfusions of pooled human AAT with the goal of maintaining adequate plasma levels (> 11 μmol/L) of the enzyme.[30] Augmentation therapy appears to minimize the progression of lung disease and slow decline in FEV_1, and appears to be most beneficial in never- or ex-smokers with an FEV_1 of 35% to 49% predicted; however, it should be considered in all AAT deficient patients with progressive lung disease.[1,30] The most common adverse effects of augmentation include rash, fatigue, and gastrointestinal upset but are typically mild and self-limiting.[30]

▶ *Other Pharmacologic Therapies*

N-Acetylcysteine has mucolytic activity, and it may reduce exacerbations and improve health status in patients not receiving ICS.[1]

Prophylaxis with macrolides (eg, azithromycin) significantly reduced exacerbations and hospital readmissions in patients susceptible to exacerbations; their benefit was greatest in current nonsmokers.[1,31] Macrolides are associated with cardiovascular adverse effects, hearing loss, and bacterial resistance; electrocardiography should be completed prior to starting therapy to detect a prolonged QTc interval, which may predispose to cardiac arrhythmias with therapy.[32]

Anti-interleukin-5 monoclonal antibodies (eg, mepolizumab) may reduce moderate or severe exacerbations in patients with elevated serum eosinophils and a history of exacerbations while on LABA/LAMA/ICS therapy. While they appear to be well tolerated, their efficacy has not been consistently documented and their current place in therapy warrants further investigation.[1,33]

In patients with low serum vitamin D levels, supplementation may reduce exacerbations.[34]

β-Blockers may reduce mortality and exacerbation rates in COPD patients.[35] Historically, β-blockers were avoided in patients with COPD due to concerns of worsening respiratory status. While much of their benefit may be derived from cardioprotective properties, they may also work via upregulation of β_2-receptors that may have been down-regulated due to long-term adrenergic stimulation. They appear to be safe (particularly β_1-selective agents) and can be continued, particularly when used to treat cardiovascular comorbidities.

Multiple traditional Chinese medicines (eg, Bu Zhong Yi Qi, Bu-Fei Yi-Shen, Yu Ping Feng San) have reduced exacerbations and improved lung function and symptoms when added to standard therapy. However, most trials have been small, flawed studies, and large randomized controlled trials are needed to confirm their efficacy.[36,37]

COPD Exacerbations

An exacerbation is defined as "an acute worsening of respiratory symptoms that results in additional therapy."[1] Exacerbations negatively impact health status, hasten lung function decline, increase rates of hospitalization, and have a reported mortality rate of 10% to 64% when requiring hospitalization and a 5-year mortality rate of roughly 50%.[1,38] While it is often difficult to discern what causes an exacerbation, many precipitating factors have been identified, including air pollution and viral (usually rhinovirus) and bacterial (usually *Haemophilus influenzae*) respiratory tract infections; exacerbations associated with viral infections are often more severe.[1,32,38]

Exacerbations are classified as mild (only short-acting bronchodilators needed), moderate (additional antibiotics and/or corticosteroids needed), or severe (hospitalization or emergency room visit required, often with acute respiratory failure present) and are based on the patient's clinical status.[1] During an exacerbation, patients often have increased inflammation, increased mucus production, increased gas trapping, and reduced expiratory function, which leads to increased dyspnea with symptoms typically lasting 7 to 10 days.[1,38] Factors associated with an increased risk of exacerbation include a history of exacerbation(s), worsening airflow limitation, GERD, the winter months, and old age.[1,38,39]

The treatment goals for exacerbations are to limit the impact of the current exacerbation and to prevent future exacerbations. Patients presenting with signs of a severe COPD exacerbation often use accessory muscles to breathe and are tachypneic, hypoxemic, and hypercarbic. Additionally, patients may be cyanotic and have peripheral edema. Life-threatening signs and symptoms include mental status changes, worsening respiratory status despite ventilatory support, hemodynamic instability, and acidosis. Presence of these signs and symptoms should prompt evaluation for hospital and/or intensive care unit admission.[1,38]

▶ *Nonpharmacologic Management*

Pulse oximetry or blood gases may be useful for determining whether supplemental oxygen therapy is needed during a COPD exacerbation. If necessary, oxygen should be titrated to a saturation of 88% to 92% (0.88–0.92).[1,38] Blood gases should be checked frequently to confirm appropriate oxygenation without compensatory carbon dioxide retention or acidosis.[1]

If mechanical ventilation is required, it can be provided by noninvasive (nasal or face mask) or invasive (orotracheal tube or tracheostomy) methods. NIV decreases acute respiratory acidosis, length of hospital stay, intubation rates, and mortality and should be attempted prior to invasive methods.[1,38,40]

▶ *Pharmacologic Management*

Bronchodilators Administration of a SABA with or without ipratropium is considered standard bronchodilator therapy during a COPD exacerbation.[1,38] Increased doses and/or frequency

Patient Encounter, Part 2: The Medical History, Physical Examination, and Diagnostic Tests

PMH: Asthma × 28 years, HFrEF × 5 years, type 2 diabetes mellitus × 10 years

Allergies: Anaphylaxis to amoxicillin and azithromycin

SH: Smoked one pack per day for 35 years but quit 5 years ago; social intake of alcohol (2–3 drinks per week); no illicit drug use

FH: Noncontributory

Meds: Carvedilol 6.25 mg twice daily, lisinopril 10 mg daily, budesonide DPI 180 mcg every 12 hours, albuterol MDI one puff every 4 to 6 hours as needed, metformin 500 mg twice daily

ROS: (–) fever, chills, or night sweats; (–) nasal congestion, drainage; (–) chest pain, paroxysmal nocturnal dyspnea; (+) orthopnea; (+) shortness of breath, chest heaviness, cough with clear phlegm; (+) mild wheezing; (–) hemoptysis; (–) N/V/D, change in bowel habits; (–) pedal edema

PE:

VS: BP 150/90 mm Hg, P 96 beats/min, RR 24/min, T 36.8°C (98.2°F), Wt 80 kg (176 lb), Ht 65 in. (165 cm), BMI 29.3 kg/m^2

HEENT: EOMI; moist mucous membranes; no JVD; no palpably enlarged cervical lymph nodes

Lungs: Expiratory phase is diminished; mild wheezes bilaterally; no crackles; (+) rhonchi

CV: RRR, normal S_1, S_2; no murmur, gallop, or rub

Abd: Soft, nontender, normoactive bowel sounds, no hepatomegaly

Ext: No cyanosis, edema, or finger clubbing

Pulmonary Function Tests

	Prebronchodilator		Postbronchodilator	
	Actual	% Predicted	Actual	% Predicted
FVC (L)	3.08		3.08	
FEV_1 (L)	1.52	66%	1.76	77%
FEV_1/FVC			57% (0.57)	

CXR: Upper lobe bullous emphysema with hyperexpansion bilaterally; no evidence of pneumonia or pulmonary edema

COPD Assessment Test score: 20

Brain Natriuretic Peptide (BNP): 27 pg/mL (ng/L; 7.8 pmol/L)

History of Exacerbations: No previous exacerbations

Given this additional information, what is your assessment of the patient's condition?

What nonpharmacologic and pharmacologic alternatives are available for managing this patient's COPD?

With the data provided, create a care plan for managing the patient's COPD.

may provide benefit during an exacerbation and an MDI with or without a spacer or a noncontinuous air-driven nebulizer can be used.[1,38,41] Maintenance bronchodilator therapy should be continued during an exacerbation or initiated once stable. However, LAMAs should be discontinued if ipratropium is used as part of the exacerbation bronchodilator regimen to minimize the potential for excessive anticholinergic effects.

Corticosteroids KEY CONCEPT Systemic corticosteroids shorten recovery time, improve lung function, reduce the risk of early relapse, reduce the risk of treatment failure, and reduce length of hospitalization during COPD exacerbations, particularly in patients with higher levels of blood eosinophils (> 2% [0.02]).[1,42] A 5-day course of oral prednisone or prednisolone 40 mg daily is recommended, and patients should be monitored closely for hyperglycemia.[1,38,43] IV corticosteroids should be used only if the oral route is not tolerated because there is no clinical benefit over oral therapy.[1] Nebulized budesonide may be used as an alternative in patients unable to take systemic corticosteroids due to lack of availability or significant systemic adverse effects.[1]

Antibiotics Exacerbations with purulent sputum production have shown increased bacteria, but routine antibiotic use is controversial due to the possibility of nonbacterial causes.[1] Approximately 50% of exacerbations are caused by bacterial infections; antibiotics given for 5 to 7 days reduce risk of treatment failure, hospitalization duration, and mortality when indicated, particularly in ICU patients.[1,32,38,42] Procalcitonin and C-reactive protein (CRP) levels, when low, may have value in determining when to avoid antibiotics in exacerbations specifically in non-ICU patients.[1,38,42,44] Current guidelines recommend antibiotics for patients with increased sputum purulence and either increased sputum volume or increased dyspnea, patients with all three of these symptoms, or patients who require mechanical ventilation.[1] Appropriate antibiotic selections for COPD exacerbations are included in Table 16–4. The oral route is preferred whenever possible, and severity of exacerbation and local resistance patterns should be considered when selecting an antimicrobial regimen.[1]

Other Therapies Hospitalized patients with COPD exacerbations should receive thromboprophylaxis due to increased risk of venous thromboembolism, and their fluid balance should be

Table 16–4

Recommended Antibiotics for Acute Exacerbations of COPD[1,34]

Suspected Pathogens	Commonly Used Antibiotics[a]
Haemophilus influenzae	Amoxicillin ± β-lactamase inhibitor
Streptococcus pneumoniae	Azithromycin or clarithromycin
Moraxella catarrhalis	Doxycycline
Pseudomonas aeruginosa	Ciprofloxacin[b] or levofloxacin Piperacillin–tazobactam Cefepime or ceftazidime Meropenem or doripenem Gentamicin or tobramycin[c]
Methicillin-resistant *Staphylococcus aureus* (MRSA)	Vancomycin[d] Linezolid[d]

[a] Refer to local antibiogram to determine which antibiotic selection is most appropriate.

[b] Limited efficacy against *Streptococcus pneumoniae*.

[c] Aminoglycosides are not effective against *Streptococcus pneumoniae*.

[d] Not effective against *Haemophilus influenzae* or *Moraxella catarrhalis*.

Patient Encounter, Part 3

Two months later, the patient arrives at the local emergency department complaining of significant shortness of breath even while resting, tachypnea, increasing sputum production, and change in sputum color over the last 5 days. Upon examination, she is using accessory muscles and pursed lips to breathe, has an oxygen saturation of 85% (0.85), has a respiratory rate of 28 breaths/min, and is hypercarbic without acidosis. She is diagnosed with a COPD exacerbation and is admitted to the hospital.

What additional signs and symptoms should be evaluated to determine the severity of her exacerbation?

What nonpharmacologic and pharmacologic alternatives are available for this patient?

With the data provided, create a care plan for managing this COPD exacerbation.

closely monitored.[1] Medication reconciliation, proper inhaler technique, vaccination status evaluation, and patient counseling on the importance of smoking cessation are necessary both during the exacerbation and upon hospital discharge. Patients are at a high risk for recurrence during the first 8 weeks after an exacerbation and may also be at increased risk of cardiovascular events within 30 days of an exacerbation if they have cardiovascular disease or are at increased cardiovascular risk.[42,45]

OUTCOME EVALUATION

- Check inhaler technique and adherence at every visit. Make sure that technique is appropriate for the type of inhaler device(s) the patient has.
- Monitor patients for improvement in symptoms. Ask if there is a difference since starting treatment and if so, is it meaningful to them? Are they less breathless? Can they do more activities and/or sleep better? If treatment response was inadequate and the patient was using the medication correctly, consider discontinuing the medication and selecting another agent.
- Changes in FEV_1 should not be the main outcome assessed because FEV_1 changes correlate weakly with symptoms, exacerbations, and health-related quality of life. The GOLD guidelines recommend annual spirometry to identify patients who are declining quickly.[1]
- The CAT is an eight-item questionnaire that can be used to assess for trends and changes in symptoms and disease impact on daily life.[1] Higher CAT scores may also be predictive of future exacerbations, depression, and mortality.[46] The test can be accessed at www.catestonline.org.
- The mMRC dyspnea scale can be used to monitor physical limitation due to breathlessness. The scale is simple to administer, correlates well with health status, and predicts future mortality risk. However, the CAT is preferred because it is more comprehensive.[1]
- A timed walking test (eg, 6-minute walking distance or shuttle-walking test) can be used to monitor functional capacity.
- Monitor theophylline levels with goal serum concentrations of 5 to 15 mcg/mL (mg/L; 28–83 μmol/L). However, bronchodilator effects are small when the serum concentration is below 10 mcg/mL (mg/L; 55 μmol/L).[47] Obtain trough levels 1 to 2 weeks after initiation of treatment and after any dosage adjustment. Routine levels are not necessary unless toxicity is suspected or symptoms have worsened.
- Monitor the patient for adverse effects of the medications selected.
- Monitor the patient for exacerbation frequency and severity.

Patient Care Process

Collect Information:

- Review medical history, physical assessment findings, blood eosinophil count (if available), and PFTs.
- Assess the type, frequency, and severity of the patient's symptoms. Use the CAT to measure symptom impact.
- Ask about disease impact on the patient's life, including limitation of activity, missed work, and feelings of depression or anxiety.
- Obtain a thorough history of prescription, nonprescription, and dietary supplement use.
- Speak with the patient and review records to identify smoking history, exacerbation history (number in the previous 12 months and whether each required hospitalization), immunization status, preferences, health goals, and socioeconomic factors that affect access to medications and/or health care.

Assess the Information:

- Assess efficacy, safety, inhaler technique, and patient adherence.
- Assess appropriateness of each COPD medication based on patient symptoms, blood eosinophil count, and exacerbation risk (Figure 16–2).
- Determine symptom burden using the CAT.
- Identify any significant adverse drug effects or interactions.
- Assess for barriers to medication access. COPD medications can be costly even for patients with insurance.
- Assess immunization records for influenza and pneumococcal vaccinations.
- Determine if current smokers are ready to quit.
- Identify comorbidities that may impact disease course.

(Continued)

Patient Care Process (Continued)

Develop a Care Plan:

- Design a therapeutic plan including lifestyle modifications (eg, smoking cessation) and optimal drug therapy (Figure 16–2). Consider the need for pulmonary rehabilitation, oxygen therapy, and/or surgery.
- Use combination inhalers when appropriate to minimize drug administration burden.
- Review insurance formularies for medication coverage. Use manufacturer patient assistance programs as needed to ensure medication access.
- Write an action plan for the patient. An example COPD action plan is available from the American Lung Association at lung.org/copd.

Implement the Care Plan:

- Provide annual influenza vaccination and pneumococcal vaccination if needed.
- Provide patient education and self-management training:
  - Smoking cessation including behavioral strategies for quitting and proper use of pharmacotherapy.
  - Maintaining or increasing physical activity, ensuring adequate sleep, maintaining a healthy diet.
  - Proper inhaler technique and when to take medications, importance of adherence, adverse effects and how to minimize them.
  - Signs and symptoms of an exacerbation and what to do if one occurs; provide written action plan.
  - Advanced directives and end-of-life issues for patients with severe disease.
- Address any patient concerns about COPD and its management.
- Refer to pulmonary rehabilitation program, if indicated.

Follow-up: Monitor and Evaluate:

- Follow up within 1 month after an acute exacerbation because this can reduce hospital readmissions; additional follow-up at 3 months is also recommended.[1]
- For stable patients, follow up every 3 to 6 months to assess effectiveness and safety of therapy.
- Review smoking status, oxygen saturation, symptoms, exacerbation frequency and severity, recent hospitalizations, and medication regimen (efficacy, adherence, inhaler technique, adverse reactions, drug interactions, issues affecting medication access).
- Obtain spirometry annually to assess disease progression.

List of Abbreviations

AAT	α_1-Antitrypsin
ABG	Arterial blood gas
cAMP	Cyclic adenosine monophosphate
CAT	COPD Assessment Test
COPD	Chronic obstructive pulmonary disease
FEV$_1$	Forced expiratory volume in the first second
FVC	Forced vital capacity
GOLD	Global Initiative for Chronic Obstructive Lung Disease
ICS	Inhaled corticosteroid
LABA	Long-acting β_2-agonist
LAMA	Long-acting muscarinic antagonist
MDI	Metered-dose inhaler
mMRC	Modified Medical Research Council
NIV	Noninvasive ventilation
NRT	Nicotine replacement therapy
Paco$_2$	Partial pressure of arterial carbon dioxide
Pao$_2$	Partial pressure of arterial oxygen
PCV13	Pneumococcal conjugate vaccine
PDE-4	Phosphodiesterase-4
PFTs	Pulmonary function tests
PPSV23	Pneumococcal polysaccharide vaccine
SABA	Short-acting β_2-agonist
SAMA	Short-acting muscarinic antagonist
Sao$_2$	Arterial oxygen saturation
$V_A/\dot{Q}$	Ventilation/perfusion ratio

Cystic Fibrosis

Kimberly J. Novak

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of cystic fibrosis (CF) and its multiorgan system involvement.
2. Describe the common clinical presentation and diagnosis of CF.
3. Consider long-term treatment goals with respect to clinical course and prognosis of CF.
4. Identify nonpharmacologic therapies for CF management.
5. Recommend appropriate pharmacologic therapies for chronic CF management.
6. Design appropriate antibiotic regimens for acute pulmonary exacerbations of CF.
7. Apply pharmacokinetic principles when calculating drug doses in CF patients.
8. Formulate monitoring plans for acute and chronic CF pharmacotherapy.

INTRODUCTION

Cystic fibrosis (CF) is an inherited multiorgan system disorder affecting children and, increasingly, adults. It is the most common life-shortening genetic disease among White patients and the major cause of severe chronic lung disease and pancreatic insufficiency in children. Disease generally manifests as mucosal obstruction of exocrine glands caused by defective ion transport within epithelial cells. Due to the array of affected organ systems and complicated medical therapies, appropriate CF treatment necessitates interprofessional team collaboration.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, CF most commonly occurs in White patients, affecting approximately 1 in 3200 individuals. CF is less common in Hispanics (1 in 14,000), African Americans (1 in 15,000), and Asian Americans (1 in 35,000).[1] CF is inherited as an autosomal recessive trait, and approximately 1 in 25 White patients are **heterozygous** carriers. Offspring of a carrier couple (each parent being heterozygous) have a 1 in 4 chance of having the disease (**homozygous**), a 1 in 2 chance of being a carrier (heterozygous), and a 1 in 4 chance of receiving no trait. The *CFTR* gene mutation is found on the long arm of chromosome 7 and encodes for the CF transmembrane regulator (CFTR) protein, which functions as a chloride channel to transport water and electrolytes. Over 2000 mutations have been described in the *CFTR* gene; however, the *Phe508del* mutation (also known as *F508del* or *ΔF508*) is most common and present in about 70% to 90% of CF patients.[1–3]

PATHOPHYSIOLOGY

CF is a disease of exocrine gland epithelial cells where CFTR expression is prevalent. Normally, these cells transport chloride through CFTR chloride channels with sodium and water accompanying this flux across the cell membrane (Figure 17–1). CFTR is regulated by protein kinases in response to varying levels of the intracellular second messenger cyclic-3′,5′-adenosine monophosphate (cAMP). CFTR also downregulates the epithelial sodium channel and regulates calcium-activated chloride and potassium channels, and it may function in exocytosis and formation of plasma membrane molecular complexes and proteins important in inflammatory responses and mucociliary clearance.[3,4] **KEY CONCEPT** In CF, the CFTR chloride channel is dysfunctional and usually results in decreased chloride secretion and increased sodium absorption, leading to altered viscosity of fluid excreted by the exocrine glands and mucosal obstruction. *CFTR* gene mutations are assigned to classes (I–VI) based on degree of residual CFTR protein function (Figure 17–2 for cellular location of the CFTR protein defects). Classes I (absent CFTR synthesis), II (blocked CFTR trafficking), and III (blocked CFTR regulation or gating) mutations result in no CFTR function. Classes IV (altered CFTR conductance), V (reduced CFTR synthesis), and VI (shortened CFTR life span) mutations have some remaining functional protein.[2,3,5]

Pulmonary System

Chronic lung disease leads to death in 90% of patients. **KEY CONCEPT** Pulmonary disease is characterized by thick mucus secretions, impaired mucus clearance, chronic airway infection and colonization, obstruction, and an exaggerated neutrophil-dominated inflammatory response.[1,3] This process leads to air trapping, **atelectasis**, mucus plugging, **bronchiectasis**, cystic lesions, pulmonary hypertension, and eventual respiratory failure. Pulmonary function (measured as FEV_1) declines approximately 1% to 2% per year; an individual's rate of decline depends on severity of CFTR dysfunction and comorbidities, which may cause a more rapid decline (more than 5% per year).[6] Sinusitis and nasal polyps are also common, and microbial colonization is similar to that of the lungs.

Bacterial pathogens are often acquired in age-dependent sequence. Early infection is most often caused by *Staphylococcus aureus*

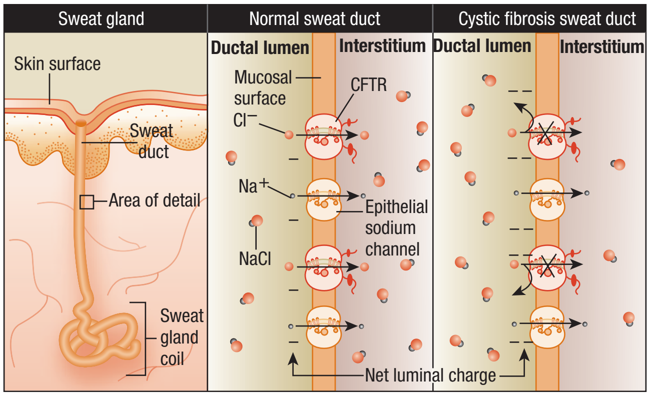

FIGURE 17–1. Pathophysiology of elevated sodium chloride levels in the sweat of patients with CF. Sweat ducts (Section A) in patients with CF have reduced ability to reabsorb chloride before the appearance of sweat on the skin surface. A major pathway for chloride absorption is through CFTR situated within mucosal membranes of cells lining the duct (Section B). In CF, decreased chloride reabsorption in the setting of continued sodium uptake leads to an elevated transepithelial potential difference across the wall of the sweat duct. Due to the failure to reabsorb chloride, the lumen becomes more negatively charged (Section C). Subsequently, sodium chloride flux is markedly decreased, leading to increased sweat chloride content. (Reprinted with permission from Wright CC, Vera YY. Cystic fibrosis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. McGraw-Hill Education; 2017: www.accesspharmacy.com.)

(usually methicillin sensitive) and nontypeable *Haemophilus influenzae*. *Pseudomonas aeruginosa* infection is the most significant pathogen among all age groups. *P. aeruginosa* expresses extracellular toxins that perpetuate lung inflammation. Mucoid strains of *P. aeruginosa* produce an alginate biofilm layer that interferes with antibiotic penetration. Methicillin-resistant *S. aureus* (MRSA) is also a significant CF pathogen, and incidence is increasing in some geographic areas. Respiratory organisms identified later in the disease course include *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, *Burkholderia cepacia* complex, fungi including *Candida* and *Aspergillus* species, and nontuberculous mycobacteria among others.[1,3] Cultured organisms may represent initial infection, chronic colonization, or microbial overgrowth in an acute exacerbation.

Gastrointestinal System

Gastrointestinal (GI) involvement often presents as **meconium** ileus, small-bowel obstruction shortly after birth due to abnormally thick meconium. Older CF patients may develop distal intestinal obstruction syndrome (DIOS) due to fecal impaction in the terminal ileum and cecum.

Maldigestion due to pancreatic enzyme insufficiency is present in 85% to 90% of CF patients.[1,7] Thick pancreatic secretions and cellular debris obstruct pancreatic ducts and lead to fibrosis. Volume and concentration of pancreatic enzymes and bicarbonate are reduced, leading to maldigestion of fat and protein and subsequent malabsorption of fat-soluble vitamins (A, D, E, and K). Symptoms include abdominal distention, **steatorrhea**, flatulence, and malnourishment despite voracious appetite. Maldigestion is progressive and may develop later in a previously pancreatic-sufficient patient. Other complications may include GI reflux, dysmotility, salivary dysfunction, **intussusception**, **volvulus**, **atresia**, **rectal prolapse**, complications related to corrective surgery for meconium ileus, and increased risk of GI cancers later in life.[7]

Hepatobiliary disease occurs due to bile duct obstruction from abnormal bile composition and flow. Hepatomegaly, splenomegaly, and cholecystitis may be present. Hepatic **steatosis** may be present due to effects of malnutrition. Progression from cholestasis (impaired bile flow) to cirrhosis, esophageal varices, and portal hypertension takes several years. Many patients are compensated and asymptomatic but may be susceptible to acute decompensation in the event of extrinsic hepatic insult from viruses, medications, or other factors.[7]

Endocrine System

CF-related diabetes (CFRD) occurs in approximately 20% of adolescents and 40% to 50% of adults, disproportionally affecting

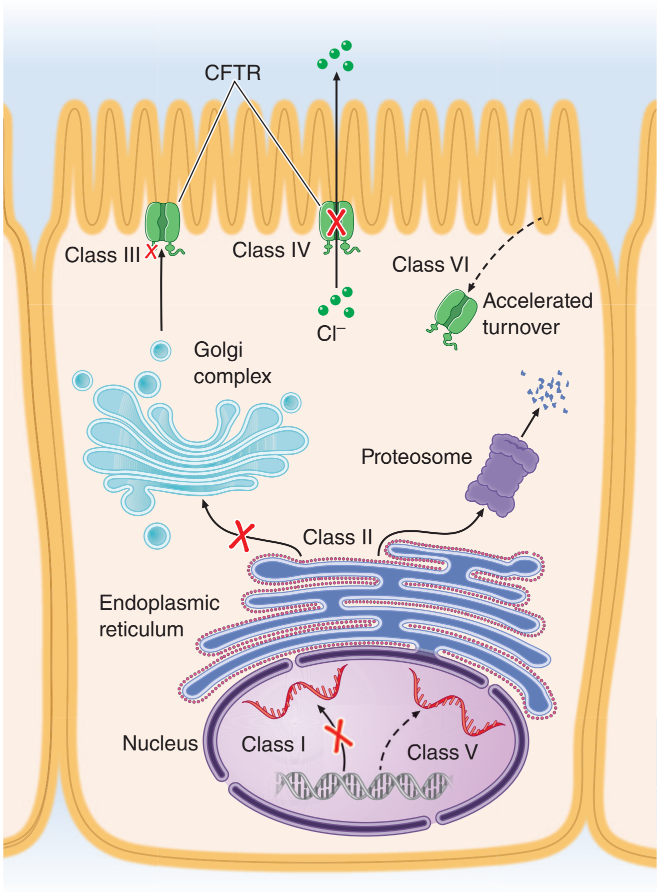

FIGURE 17–2. Categories of CFTR mutations. Classes of defects in the *CFTR gene* include the absence of synthesis (class I); defective protein maturation and premature degradation (class II); disordered gating/regulation, such as diminished adenosine triphosphate (ATP) binding and hydrolysis (class III); defective conductance through the ion channel pore (class IV); a reduced number of CFTR transcripts due to a promoter or splicing abnormality (class V); and accelerated turnover from the cell surface (class VI). (Reprinted with permission from Jameson J, Fauci AS, Kasper DL, Hauser SL, Longo DL, Loscalzo J. Cystic Fibrosis. In: Harrison's Principles of Internal Medicine, 20e; 2018: www.accesspharmacy.com.)

women. Although it shares characteristics of both type 1 and type 2 diabetes mellitus, CFRD is categorized separately. Reduced functional pancreatic islet cells and increased islet **amyloid** deposition result in insulin insufficiency, the primary cause of CFRD. Insulin secretion is delayed in response to glucose challenge, and absolute insulin secretion over time is reduced. Some insulin resistance may also be present in CFRD and may fluctuate in relation to infection and inflammation.[8,9]

Postprandial hyperglycemia is common, but because some basal insulin secretion is maintained, fasting hyperglycemia is less severe and ketosis is rare. Diet, acute and chronic infection, and corticosteroid use lead to fluctuation in glucose tolerance over time.[8,9] CFRD is associated with greater nutritional failure, increased pulmonary disease, and earlier mortality. Pulmonary function decline and nutritional consequences associated with progressive CFRD have historically overshadowed risks of long-term macrovascular and microvascular complications; however, these complications are now emerging with longer life expectancy.[8,9]

Reproductive System

CF patients often experience delayed puberty. In girls, menarche occurs 18 months later than average; menstrual irregularity is common, and fertility is reduced due to increased cervical mucus viscosity. Due to increasing life expectancy and highly effective therapies, pregnancy is becoming more common; however, outcomes depend on prepartum nutritional and pulmonary status. Almost all males with CF are **azoospermic** due to congenital absence of the vas deferens with resultant obstruction; however, conception still occurs occasionally. Conception can also occur through application of assisted reproductive technologies.[9,10]

Musculoskeletal System

Several factors contribute to development of bone disease in CF: (a) malabsorption of vitamins D and K and calcium, (b) poor nutrition and decreased body mass, (c) physical inactivity, (d) corticosteroid therapy, (e) inflammation, and (f) delayed puberty and hypogonadism. Chronic pulmonary infection, through release of inflammatory cytokines, can increase bone resorption and decrease formation. Osteopenia, osteoporosis, pathological fractures, and **kyphosis** can occur.[9] Episodic or chronic arthritis may occur due to immune complex formation in response to chronic inflammation.[11] Digital **clubbing** is common and a marker for chronic hypoxia.

Clinical Presentation of Cystic Fibrosis

General

- Usually diagnosed in neonates (meconium ileus or newborn screening) or during early childhood. May present later in life due to less severe symptoms or misdiagnosis.

Symptoms

- Pulmonary: Chronic cough, sputum production, decreased exercise tolerance, and recurrent pneumonia and sinusitis. Exacerbations may be marked by increased cough, sputum changes (darker, thicker), hemoptysis, dyspnea, and fever.
- GI: Numerous large, foul-smelling loose stools (steatorrhea), flatulence, and abdominal pain. Intestinal obstruction may present as abdominal pain and distention and/or decreased bowel movements.
- Nutritional: Poor weight gain despite voracious appetite and hunger. Dry skin, skin rash, and visual disturbances may be noted in vitamin deficiency.
- CFRD: Weight loss, increased thirst, and more frequent urination.

Signs

- Obstructive airways disease: Tachypnea, dyspnea, cyanosis, wheezes, crackles, sternal retractions, digital clubbing, and barrel chest.
- Failure to thrive: Below age-based normal of both height and weight in children; adults may be near/below ideal body weight or have a low body mass index (BMI).
- Salty taste to the skin.
- Hepatobiliary disease: Hepatomegaly, splenomegaly, and prolonged bleeding may occur.
- Recurrent pancreatitis (usually in pancreatic-sufficient patients): Episodic epigastric abdominal pain, persistent vomiting, and fever.

Laboratory Tests

- Leukocytosis with increase in polymorphonuclear (PMN) leukocytes and bands may occur in acute pulmonary exacerbations.
- Maldigestion: Decreased serum levels of fat-soluble vitamins (A, D, E, and K). Decreased vitamin K levels may result in elevated prothrombin time (PT) and international normalized ratio (INR). Elevated fecal fat content, reduced pancreatic stool elastase (< 200 mcg/g of feces).
- Glucose intolerance: Blood glucose between 140 and 199 mg/dL (7.8–11 mmol/L) 2 hours after an oral glucose-tolerance test.
- CFRD: Blood glucose 200 mg/dL (11.1 mmol/L) or higher 2 hours after an oral glucose-tolerance test or fasting hyperglycemia (fasting blood glucose 126 mg/dL [7 mmol/L] or more regardless of the postglucose challenge level).
- Hepatobiliary disease: Serum aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, γ-glutamyltransferase, and bilirubin may be elevated.

Other Tests

- Microbial cultures (sputum, throat, bronchoalveolar lavage, or sinus): Isolation of *Pseudomonas aeruginosa, Staphylococcus aureus, Stenotrophomonas maltophilia,* and other CF-related organisms.
- Pulmonary function tests (PFTs): Decreased forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC), typically lower during acute pulmonary exacerbations.
- Chest X-ray or CT scan: Infiltrates, atelectasis, bronchiectasis, and mucus plugging.
- Abdominal X-ray or CT scan: Intestinal obstruction may be manifested as meconium ileus, DIOS, or intussusception. Rectal prolapse may be noted on physical examination.

Hematological System

Anemia may be present due to impaired erythropoietin regulation, nutritional factors (vitamin E and iron malabsorption), or chronic inflammation. Increased cytokine production can lead to shortened red blood cell survival, reduced erythropoietin response, and impaired mobilization of iron stores. Additionally, with chronic hypoxia, normal hemoglobin and hematocrit values may represent relative anemia.[12] Increased red blood cell production is a physiological response to hypoxia; however, this response may be blunted in CF and may result in symptoms of anemia despite normal lab values.

Abnormal bleeding or clotting may also be observed as a result of vitamin K malabsorption, antibiotic-associated depletion of GI flora and vitamin K synthesis, reduced coagulation factor synthesis due to liver disease, and/or a procoagulant state due to inflammation.

Integumentary System

Sweat contains abnormally high concentrations of sodium and chloride due to impaired reabsorption within the sweat duct from loss of CFTR channels, a target for CF diagnosis.[1] This may impart a characteristic salty taste to the skin. Patients are usually otherwise asymptomatic. In rare instances such as hot weather or excessive sweating during physical activity, patients may become dehydrated and experience symptoms of hyponatremia (nausea, headache, lethargy, and confusion).

CLINICAL PRESENTATION AND DIAGNOSIS

See the accompanying box for the clinical presentation of CF.

Diagnosis

Testing for CF is part of required newborn screening panels in all US states in an effort to identify patients prior to symptom development, initiate early treatment, and improve long-term outcomes.[13] A positive newborn screen for CF is not diagnostic (due to false-positive results among CF carriers), nor does a negative screen universally exclude the diagnosis. All "positive screens," as well as individuals presenting with signs and symptoms of CF, are referred to a CF care center for sweat chloride test and genetic evaluation. Diagnosis of CF is based on two separate elevated sweat chloride concentrations of 60 mEq/L (mmol/L) or greater obtained through pilocarpine **iontophoresis** ("sweat test"). Genetic testing (*CFTR* mutation analysis) is performed to confirm the diagnosis and determine eligibility for precision medicine therapy, screen in utero, or detect carrier status. More than 70% of diagnoses are made by 12 months of age.[13]

Patient Encounter Part 1

A 4-week-old male term neonate is being evaluated at CF clinic due to an abnormal newborn screen (elevated immunoreactive trypsinogen; gene mutations *G551D* and *Phe508del* on initial testing). Sweat chloride testing is performed on bilateral thighs with results reported as follows:

Sample 1: Sweat chloride 120 mEq/L (mmol/L)

Sample 2: Sweat chloride 116 mEq/L (mmol/L)

Upon parental interview, the neonate is a voracious eater and has 7 to 10 loose stools per day that have a white oily appearance. He is mostly breastfed, with some supplemental 20 kcal/oz (0.67 kcal/mL; 2.8 kJ/mL) infant formula, and he weighs 2.95 kg (birth weight of 3.1 kg). Parents also report that he needed oral laxatives and enemas to help pass his meconium while in the newborn nursery.

What information is consistent with a diagnosis of CF?

What are the next steps in the CF diagnostic process?

The parents are overwhelmed with the diagnosis of CF and are very worried about life expectancy. How would you explain the infant's prognosis?

Clinical Course and Prognosis

Clinical course varies because of multiple genetic mutations and the heterogeneous profile of the *Phe508del* mutation. Some patients develop severe lung disease early in childhood and reach end-stage disease by adolescence, whereas others maintain near-normal lung function into adulthood. Newly diagnosed adults tend to have *CFTR* mutations associated with residual CFTR function and may present with milder respiratory symptoms, pancreatitis, or infertility.[3,5]

Life expectancy has greatly increased from a predicted survival of 16 years of age in 1970 to more than 40 years for patients born in the 1990s.[3,5] According to the Cystic Fibrosis Foundation Registry, 54.6% of patients are over 18 years of age.[14]

TREATMENT

Desired Outcomes

Therapeutic outcomes in CF care relate to chronic and acute treatment goals. With chronic management, the primary goals are to delay disease progression and optimize quality of life. **KEY CONCEPT** Maximizing nutritional status through pancreatic enzyme replacement and vitamin and nutritional supplements is necessary for normal growth and development and for maintaining long-term lung function. Reduction of airway inflammation and infection and aggressive preventive therapies minimize acute pulmonary exacerbations and delay pulmonary decline. In pulmonary exacerbations, therapy is directed toward reducing acute airway inflammation and obstruction through aggressive airway clearance and antibiotic therapy with a goal of returning lung function to preexacerbation levels or greater.

Nonpharmacologic Therapy

▶ *Airway Clearance Therapy*

KEY CONCEPT Airway clearance therapy is a necessary routine for all CF patients to clear secretions and control infection, even at diagnosis prior to becoming symptomatic. Waiting until development of a first pulmonary exacerbation or daily symptoms delays benefits and may accelerate pulmonary decline. The traditional form of chest physiotherapy (CPT) is percussion and postural drainage. Areas of the patient's chest, sides, and back are rapidly "clapped" by hand in different patient positions, followed by cough or forced expiration to mobilize secretions. Patients may also be taught autogenic drainage, which consists of deep breathing exercises followed by forced cough.

Several airway clearance devices are also available. Flutter valve devices use oscillating positive expiratory pressure (OPEP) to cause vibratory airflow obstruction and an internal percussive effect to mobilize secretions. Intrapulmonary percussive ventilation (IPV) provides continuous oscillating pressures during inhalation and exhalation. High-frequency chest compression (HFCC) with an inflatable vest that provides external oscillation is most commonly used and often preferred because patients can perform therapy independently from an early age. Exercise may be an adjunctive modality for airway clearance.[15]

Effective cough and expectoration of mucus are essential for good clearance technique. Airway clearance therapy is typically performed once or twice daily for maintenance care and increased to three or four times per day during acute exacerbations.

▶ *Nutrition*

Most CF patients have increased caloric needs due to increased energy expenditure through increased work of breathing, increased basal metabolism, and maldigestion. Prevention of malnutrition requires early patient-specific nutritional intervention. Caloric requirements to promote age-appropriate weight gain or maintenance are typically 110% to 200% of the recommended daily allowance (RDA) for age, gender, and size and increase as disease progresses. Diets in CF patients should comprise 35% to 40% of calories from fat, 15% to 20% of calories from protein, and no more than 50% calories from carbohydrates. Historically recommended low-fat high-carbohydrate diets are no longer recommended.[16]

Nutrition in malnourished patients consists of baseline required calories plus additional calories for weight gain via a high-calorie high-fat diet. Even with aggressive diet and oral supplements, placement of a gastrostomy or jejunostomy tube for nighttime supplemental feeds may be necessary.[16,17] Patients with refractory malabsorption, CFRD, and/or tube feedings have unique caloric needs. Collaboration with dieticians specially trained in CF nutrition is essential.

Pharmacologic Therapy

▶ *Airway Clearance Therapy*

Airway clearance therapy is often accompanied by bronchodilator treatment with albuterol (known as salbutamol outside the United States) to stimulate mucociliary clearance and prevent bronchospasm associated with other inhaled therapies (Table 17–1).

A mucolytic agent is administered subsequently to reduce sputum viscosity and enhance clearance. Dornase alfa (Pulmozyme) is a recombinant human (rh) DNase that selectively cleaves extracellular DNA released during neutrophil degradation in viscous CF sputum. Nebulization of dornase alfa improves daily pulmonary symptoms and function, reduces pulmonary exacerbations, and improves quality of life.[15,18] Daily dosing is most common, but some patients benefit from twice daily administration. Hypertonic saline for inhalation (HyperSal) 7% or 3.5% is often used as an alternative or add-on mucolytic agent for osmotic effects in airway surface liquid or sputum. It must be preceded by a bronchodilator due to greater incidence of bronchospasm and may not be tolerated by some patients.[18] *N*-acetylcysteine is another mucolytic agent, but its unpleasant odor and taste limit patient acceptance.

CF guidelines do not recommend β_2-agonists or inhaled corticosteroids in patients without asthma or allergic bronchopulmonary aspergillosis (ABPA).[18] Inhaled corticosteroids may attenuate reactive airways and reduce airway inflammation in some patients; however, clear benefit in CF has not been established.[15,18] Patients with asthma or recurrent wheezing or dyspnea who improve with albuterol (salbutamol) should be considered for maintenance asthma therapy, as should patients with bronchodilator-responsive PFTs. Drug delivery to the site of inflammation is limited by mucus plugging, which may limit efficacy. Patients on asthma therapies should administer these medications after airway clearance to optimize drug delivery.

Montelukast, antihistamines, and/or intranasal steroids are used for CF patients with allergic or rhinosinusitis symptoms.

Long-term systemic corticosteroids reduce airway inflammation and improve lung function. However, beneficial effects diminish upon discontinuation, and concern for long-term adverse effects limits use as maintenance therapy.[18,19] Systemic corticosteroids may be used short term in acute exacerbations

Table 17–1

Common Medications Used in Cystic Fibrosis

Medication	Pediatric Dose	Adult Dose
Albuterol (salbutamol)	2.5 mg nebulized with chest physiotherapy two to four times daily; alternatively, two puffs via metered-dose inhaler may be substituted	2.5 mg nebulized with chest physiotherapy two to four times daily; alternatively, two puffs via metered-dose inhaler may be substituted
Dornase alfa	2.5 mg nebulized once or twice daily	2.5 mg nebulized once or twice daily
Hypertonic saline 7%, 3.5%, or 3%	4 mL nebulized one to four times per day	4 mL nebulized one to four times per day
Ibuprofen[a]	20–30 mg/kg/dose given twice daily	20–30 mg/kg/dose given twice daily
Azithromycin	Body weight 25–39 kg: 250 mg on Mondays, Wednesdays, and Fridays	Body weight 40 kg or more: 500 mg on Mondays, Wednesdays, and Fridays
Ivacaftor[b]	25–150 mg every 12 hours (minimum age 4 months)	150 mg every 12 hours
Lumacaftor/ivacaftor[c]	100–400 mg/125–250 mg every 12 hours (minimum age 2 years)	400 mg/250 mg every 12 hours
Tezacaftor/ivacaftor[b]	50–100 mg/75–150 mg in the morning and 0 mg/75–150 mg in the evening (minimum age 6 years)	100 mg/150 mg in the morning and 0 mg/150 mg in the evening
Elexacaftor/tezacaftor/ivacaftor[b]	100–200 mg/50–100 mg/75–150 mg in the morning and 0 mg/0 mg/75–150 mg in the evening (minimum age 6 years)	200 mg/100 mg/150 mg in the morning and 0 mg/0 mg/150 mg in the evening

[a] Adjusted to achieve peak serum concentrations of 50 to 100 mcg/mL (243–485 μmol/L). Maintain chronic dosing with same dosage form and manufacturer. Note that therapy is not always continued into adulthood.

[b] Dose may require adjustment in patients with moderate or severe hepatic impairment and/or when coadministered with moderate or strong CYP3A inhibitors.

[c] Dose may require adjustment in patients with moderate or severe hepatic impairment and/or when coadministered with strong CYP3A inhibitors. Other medication dosages may need increased due to multienzyme CYP induction by lumacaftor.

or for treatment of allergic response to *Aspergillus* colonization (ABPA); however, dose and duration of therapy should be minimized.

High-dose ibuprofen targeting peak concentrations of 50 to 100 mcg/mL (243–485 μmol/L) has been shown to slow disease progression, particularly in children 6 to 17 years of age with mild lung disease ($FEV_1 > 60\%$ predicted). At high doses, ibuprofen inhibits the lipoxygenase pathway, reducing neutrophil migration and function as well as release of lysosomal enzymes. At lower concentrations achieved with analgesic dosing, neutrophil migration increases, potentially increasing inflammation. A dose of 20 to 30 mg/kg given twice daily is usually needed to attain target levels, but interpatient variability necessitates serum concentration monitoring.[18,20] Due to monitoring requirements and concerns regarding long-term safety and tolerability, only a few CF centers prescribe high-dose ibuprofen.

Azithromycin is a macrolide antibiotic commonly used in CF as an anti-inflammatory agent to improve overall lung function and reduce exacerbations in patients colonized with *Pseudomonas* and to reduce exacerbations in those without *Pseudomonas*.[18,21] Proposed mechanisms include interference with *Pseudomonas* alginate biofilm production, bactericidal activity during stationary *Pseudomonas* growth, neutrophil inhibition, cytokine inhibition, and reduction in sputum viscosity.[21] Due to its long tissue half-life, azithromycin is typically dosed 3 days/week (Monday, Wednesday, and Friday). Alternatively, patients may take 500 or 250 mg either daily or only Monday through Friday, based on the same weight parameters.[21] Patients should have a screening acid-fast bacillus sputum culture prior to initiation and then every 6 to 12 months, because isolation of nontuberculous mycobacteria is a contraindication to chronic azithromycin therapy.[18]

▶ *Antibiotic Therapy*

KEY CONCEPT Antibiotic therapy is used in three distinct situations: (a) eradication and delay of colonization in early lung disease (treatment of positive cultures regardless of symptoms), (b) suppression of bacterial growth once colonization is present, and (c) reduction of bacterial load in acute exacerbations in an attempt to return lung function to preexacerbation levels or greater.[22] **KEY CONCEPT** Antibiotic selection is based on periodic culture and sensitivity data, typically covering all organisms identified during the preceding year. If no culture data are available, empirical antibiotics should cover the most likely organisms for the patient's age group. Due to altered pharmacokinetics and microorganism resistance, dose optimization is key (Table 17–2).

Table 17–2

Selected Antibiotic Dosing in Cystic Fibrosis[a]

Antibiotic	Pediatric Dose (mg/kg/day)	Adult Maximum Daily Dose	Interval (hours)
Intravenous			
Tobramycin, gentamicin[b]	10–15	None	8–24
Amikacin[b]	30–45	None	8–24
Ceftazidime	150–400	8–12 g	6–8
Cefepime	150–200	6–8 g	8
Ceftolozane–tazobactam[c]	120	6 g	8
Ceftazidime–avibactam[c]	150–200	6–8	6–8
Piperacillin–tazobactam[c]	400–600	18–24 g	6
Ticarcillin–clavulanate[c]	400–600	12–18 g	4–6
Meropenem	120	6 g	8
Meropenem–vaborbactam[c]	120	6 g	8
Imipenem–cilastatin[c]	100	2–4 g	6
Aztreonam	200–300	8–12 g	6
Ciprofloxacin	30	1.2 g	8–12
Levofloxacin	10–20	750 mg	12–24
Nafcillin	200	12 g	4–6
Vancomycin[b]	60–80	None	6–12
Linezolid	30	1.8 g	8–12
Colistin	5–8	480 mg	8–12
Chloramphenicol[b]	60–80	4 g	6
Oral			
Amoxicillin ± clavulanic acid[c]	90	4 g	12
Dicloxacillin	100	2 g	6
Cephalexin	50–100	4 g	6–8
Trimethoprim–sulfamethoxazole[d]	12–20	1280 mg	6–12
Clindamycin	30	1.8 g	6–8
Ciprofloxacin	40	2 g	12
Levofloxacin	10–20	750 mg	12–24
Doxycycline[e]	4	200 mg	12–24
Minocycline[e]	4	400 mg	12
Linezolid	30	1.8 g	8–12
Inhaled			
Tobramycin	160–600 mg/day	600 mg	12
Aztreonam lysine	225 mg/day	225 mg	8
Colistin	75–150 mg/day	300 mg	12

[a] All doses assume normal renal and hepatic function. Consult a specialized drug reference for dosage adjustment if function is impaired. Dose and/or interval may require adjustment.

[b] Empirical starting doses only. Adjust dose per therapeutic drug monitoring.

[c] Dose based on β-lactam component.

[d] Dose based on trimethoprim component.

[e] Children older than 8 years.

Oral Antibiotic Therapy Severity of pulmonary symptoms also guides antibiotic selection. For recent-onset or mild symptoms, patients may be treated with outpatient oral and inhaled antibiotics for 10 to 14 days. Oral fluoroquinolones are a mainstay for *P. aeruginosa* treatment in CF, even in children.[22] Despite concerns regarding cartilage and tendon toxicity in young animals, clinical practice has not shown an increased risk in human children.[23] Inhaled tobramycin, aztreonam, or colistin is usually continued or added for double coverage if the patient is not on suppressive inhaled antibiotics. Methicillin-sensitive *S. aureus* (MSSA) may be treated with oral amoxicillin–clavulanic acid, dicloxacillin, first- or second-generation cephalosporins, trimethoprim–sulfamethoxazole, clindamycin, doxycycline, or minocycline, depending on sensitivity. MRSA may be treated with oral trimethoprim–sulfamethoxazole, clindamycin, doxycycline, minocycline, or linezolid. *H. influenzae* often produces β-lactamases but can usually be treated with amoxicillin–clavulanic acid, a cephalosporin, or trimethoprim–sulfamethoxazole. Oral trimethoprim–sulfamethoxazole, minocycline, or doxycycline may be used to treat *S. maltophilia*. Delafloxacin, a novel fluroquinolone with activity against both *P. aeruginosa* and MRSA, should be avoided at this time until pharmacokinetic data are known in CF patients to avoid potential underdosing and risk for development of resistance.

Intravenous Antibiotic Therapy For severe infections or patients failing outpatient therapy, IV antibiotic therapy is often prescribed for 10 to 14 days as inpatient therapy. Some patients may be discharged to finish their IV course or even receive their entire IV course at home. **KEY CONCEPT** Typical regimens for severe infections include an antipseudomonal β-lactam plus an aminoglycoside for added synergy and delay of resistance development.[24,25] Cephalosporins tend to be better tolerated and offer the benefit of less frequent administration. Extended-spectrum penicillins have been associated with a higher incidence of allergy. Aztreonam offers little cross-reactivity in penicillin- or cephalosporin-allergic patients; however, it has no gram-positive coverage. Meropenem should be reserved for organisms resistant to all other antibiotics to minimize development of resistance in the carbapenem drug class. Newer agents targeting highly resistant organism (ie, ceftolozane/tazobactam, ceftazidime/avibactam, and meropenem/vaborbactam) should also be restricted.

Tobramycin IV is generally the first-line aminoglycoside. Isolates are usually resistant to gentamicin, and amikacin is reserved for tobramycin-resistant strains. Pharmacokinetic targets are listed in Table 17–3. Higher peak serum concentrations are desired to maximize efficacy, whereas lower trough levels reduce risk of toxicity. Once-daily dosing targets higher peaks and lower troughs, optimizing the concentration-dependent killing of aminoglycosides (eg, tobramycin 10–15 mg/kg/day or amikacin 30–45 mg/kg/day) and is preferred over three times daily dosing.[25] However, time below the minimum inhibitory concentration (MIC) is prolonged with once-daily administration in some children, possibly leading to loss of synergy for a substantial portion of the dosing interval or development of resistance. Traditional dosing may be used in these patients. Incorporation of patient-specific pharmacokinetic history is essential for optimal aminoglycoside dosing. Long-term studies are needed to examine the efficacy and resistance patterns associated with once-daily aminoglycosides in CF patients.[24,25]

As with *Pseudomonas* infections, most other serious gram-negative infections are also treated with combination therapy. *S. maltophilia* is highly resistant and most often treated with trimethoprim–sulfamethoxazole, minocycline, doxycycline, or ticarcillin–clavulanate (not currently available in the United States). There are few options for *A. xylosoxidans* and *B. cepacia*, and multidrug therapy is often used.

An oral fluoroquinolone may be substituted for an IV aminoglycoside based on sensitivity data or presence of renal dysfunction and/or ototoxicity. Due to excellent bioavailability, fluoroquinolones, trimethoprim–sulfamethoxazole, doxycycline, minocycline, and linezolid should be used orally for most patients able to take enteral medications. Due to toxicity risk, colistin IV and chloramphenicol IV are reserved for life-threatening or highly resistant infections.

Inpatient treatment of MRSA can consist of IV vancomycin or oral agents as previously described, depending on the severity of infection and concomitant organisms.[26]

Inhaled Antibiotic Therapy Chronic or rotating inhaled antibiotic maintenance therapy may be used to suppress *P. aeruginosa* colonization in CF patients of all ages; however, long-term systemic antibiotics are not recommended due to emergence of resistance.[18,19,27,28] Inhaled antibiotic therapy is also recommended for eradication of initial *P. aeruginosa* infection.[29] Inhaled tobramycin (TOBI, Bethkis) is typically administered to patients 6 years of age and older in alternating 28-day cycles of 300 mg nebulized twice daily, followed by a 28-day washout period to minimize development of resistance. Long-term cyclical administration improves pulmonary function, decreases microbial burden, and reduces hospitalization for IV therapy.[18] A dry powder formulation of tobramycin (TOBI Podhaler, 112 mg inhaled twice daily) can also be used in 28-day on/off cycles with reduced administration time. Due to minimal systemic absorption, pharmacokinetic monitoring is not necessary with normal renal function. Lower doses of nebulized tobramycin solution for injection have been used in younger children, and *Pseudomonas* eradication studies used 300 mg twice daily in children as young as 6 months.[29]

Aztreonam lysine for inhalation (Cayston) is also used for *P. aeruginosa* suppression in 28-day on/off cycles for CF patients 6 years of age and older.[18] It has been used in children as young as 3 months of age for *P. aeruginosa* eradication.[29] A dose of 75 mg three times daily is given via the Altera nebulizer system, a high-efficiency drug delivery device with shorter administration time.

Nebulized colistin using the IV formulation may be an option in patients with tobramycin-resistant strains or intolerance to

Table 17–3

Target Intravenous Antibiotic Serum Concentrations in Cystic Fibrosis

	Traditional Units of Measurement		SI Units of Measurement	
Antibiotic	**Goal Peak[a] (mcg/mL)**	**Goal Trough[b] (mcg/mL)**	**Goal Peak[a] (μmol/L)**	**Goal Trough[b] (μmol/L)**
Tobramycin, gentamicin	10–12[c]	< 1.5[c]	21–26[c]	< 3.2[c]
	20–40[d]	< 1[d]	42–84[d]	< 2.1[d]
Amikacin	30–40[c]	< 5[c]	51–68[c]	< 8.6[c]
	60–120[d]	< 3[d]	103–206[d]	< 5.1[d]
Vancomycin	–[e]	15–20	–[e]	10–14

Note: Values reported in mcg/mL are numerically equivalent to mg/L.

[a] Peaks calculated 30 minutes after end of infusion for aminoglycosides.

[b] Troughs calculated immediately prior to the time the dose is due.

[c] Goals refer to traditional dosing (every 8 or 12 hours). Higher peaks may be targeted with corresponding lower trough concentrations for aminoglycosides based on center practice.

[d] Goals refer to once-daily (high-dose extended interval) dosing (preferred).

[e] Not routinely measured unless obtained for basis of AUC calculations targeting an AUC:MIC of > 400 for MRSA.

inhaled tobramycin or aztreonam lysine.[30] Pretreatment with albuterol is necessary due to increased risk of bronchoconstriction.

Selection of inhaled antibiotics is based on culture data and patient preference. Alternating inhaled antibiotic regimens are sometimes used in patients with more advanced lung disease.[19] Inhaled antibiotics are typically stopped during acute exacerbations requiring IV therapy because drug delivery is reduced with increased sputum production, and concomitant use of IV aminoglycosides may increase risk of toxicity.[24]

Pharmacokinetic Considerations KEY CONCEPT CF patients have larger volumes of distribution for many antibiotics due to an increased ratio of lean body mass to total body mass and lower fat stores. CF patients also have enhanced total body clearance, although the exact mechanism has not been determined; both renal and extrarenal processes have been proposed.[25]

Because of these pharmacokinetic changes, higher doses of aminoglycosides are needed to achieve target serum levels and adequate tissue penetration.[25] Higher doses of β-lactam antibiotics are also needed to achieve and sustain levels above the MIC.[25] Trimethoprim–sulfamethoxazole displays enhanced renal clearance and hepatic metabolism in the CF population. Higher doses of fluoroquinolones, vancomycin, and linezolid may also be needed to attain inhibitory serum and tissue concentrations against CF pathogens.[25,26]

Although most CF patients have shorter drug half-lives and larger volumes of distribution than non-CF patients, some patients exhibit decreased renal clearance because of concomitant nephrotoxic medications, diabetic nephropathy, or other reasons. Chronic kidney disease is an emerging complication of older adults with CF.[5]

► *Gastrointestinal Therapy*

Pancreatic Enzyme Replacement Therapy (PERT) This is the mainstay of GI therapy. Most enzyme products available in the United States are formulated as capsules containing enteric-coated microspheres or microtablets that escape enzyme inactivation by gastric acid and promote dissolution in the more alkaline duodenum (Table 17–4). Capsules may be opened and the microbeads swallowed with food (for infants and young children), as long as they are not chewed or mixed with alkaline or hot foods (which denature enzymes). Although products may contain similar enzyme ratios, they are not bioequivalent and cannot be interchanged.

PERT is initiated at 1000 units/kg/meal of lipase component (because fats are most difficult to digest) with half-doses given for snacks. Enzymes should be taken at the beginning or divided throughout the meal and must be given with any fat-containing snack. Infants are typically started at 1500 to 2500 units of lipase/120 mL of formula or breast milk and may require division of capsule contents via visual estimation to obtain appropriate doses. Pancreatic enzymes cannot be placed in formula bottles due to inability to pass consistently through the nipple slit. Instead, enzyme microbeads are placed on a small dot of infant applesauce (or moistened infant rice cereal) and administered via infant spoon with subsequent nursing or bottle-feeding to facilitate swallowing. The oral mucosa must be examined afterward to ensure that all enzymes are swallowed because remnant microbeads can cause oral erosions (ulcers).

KEY CONCEPT Titration of PERT dosage is based on control of steatorrhea, stool output, and abdominal symptoms. Infants should have no more than three to four stools per day, whereas older patients should have no more than two to three (children) or one to two (adolescents/adults) well-formed stools per day. Doses are titrated at 2- to 3-week intervals in increments of 150 to 250 units of lipase/kg/meal (or the next easily administered capsule or half-capsule) up to 2500 units/kg/meal. Maximum infant doses are typically 4000 units of lipase/120 mL of formula. Higher doses should be used cautiously due to risk of fibrosing colonopathy observed with doses above 6000 units of lipase/kg/meal for more than 6 months.[16,17] Patients receiving enteral formulas via feeding tubes (either at nighttime or continuously) may receive intermittent doses of oral enzymes. They may also receive enzymes that are administered directly through the feeding tube using a vehicle such as an applesauce bolus, or they may receive crushed enzymes that are given as either intermittent doses via the feeding tube or added to the enteral formula bags in the actual feedings. An *ex vivo* cartridge device containing immobilized lipase (RELiZORB) may also be used with some enteral formulas to predigest fat within the tube feeding apparatus prior to the formula reaching the patient.[17]

Table 17–4

Common Pancreatic Enzyme Replacement Products

Trade Name[a]	Lipase (Units)	Amylase (Units)	Protease (Units)
CREON 3000	3000	15,000	9500
CREON 6000	6000	30,000	19,000
CREON 12,000	12,000	60,000	38,000
CREON 24,000	24,000	120,000	76,000
CREON 36,000	36,000	180,000	114,000
Pancreaze MT 2	2600	10,850	6200
Pancreaze MT 4	4200	24,600	14,200
Pancreaze MT 10	10,500	61,500	35,500
Pancreaze MT 16	16,800	98,400	56,800
Pancreaze MT 20	21,000	83,900	54,700
Pertzye 4000	4000	15,125	14,375
Pertzye 8000	8000	30,250	28,750
Pertzye 16,000	16,000	60,500	57,500
Pertzye 24,000	24,000	90,750	86,250
Viokace[b]	10,440	39,150	39,150
Viokace[b]	20,880	78,300	78,300
Zenpep 3000	3000	14,000	10,000
Zenpep 5000	5000	24,000	17,000
Zenpep 10,000	10,000	42,000	32,000
Zenpep 15,000	15,000	63,000	47,000
Zenpep 20,000	20,000	84,000	63,000
Zenpep 25,000	25,000	105,000	79,000
Zenpep 40,000	40,000	168,000	126,000

[a] The number after a trade name refers to the approximate number of thousands of units of lipase contained per dosage form.

[b] Nonenteric-coated enzyme. Must be given with a gastric acid suppressant. Often administered via feeding tube.

Patients responding poorly to maximal doses of one product may benefit from changing to another product and/or addition of a histamine H_2-receptor antagonist or proton pump inhibitor. Acid suppression may boost the effective enzyme dose if duodenal pH is not alkaline enough to neutralize residual gastric acid and dissolve enteric coating. Acid suppression also treats concomitant gastroesophageal reflux disease, which is common in CF.[16,17]

Fat-Soluble Vitamin Supplementation This is usually required in pancreatic insufficiency. Specially formulated products for CF patients (AquADEKs, DEKAs, MVW Complete Formulation, Choiceful) are usually sufficient to attain normal serum vitamin levels at a dose of 1 mL daily for infants, 1 tablet daily for younger children, and 1 tablet/capsule twice daily for teenagers and adults taken with food and pancreatic enzymes. Additional supplementation (calcium, iron, zinc) may be needed in uncontrolled malabsorption or for replacement of severe vitamin deficiency based on serum vitamin levels, and sodium supplementation is needed in infants.[16,17] Sodium supplementation is usually provided as table salt (1/8 teaspoonful per day if under 6 months of age and 1/4 teaspoonful per day if 6–12 months of age) divided among feedings in infants. Older children will transition to liberally salting their food once eating table food. Appetite stimulants such as cyproheptadine, dronabinol, mirtazapine, or megestrol may be an option for promoting nutrition and weight gain but must be balanced with potential side effects, which can range from drowsiness (cyproheptadine, dronabinol, mirtazapine) to adrenal suppression (megestrol).

Liver Disease Ursodiol 20 mg/kg/day in two divided doses is often used to slow progression of liver disease; however, efficacy data are lacking. It improves bile flow and may displace toxic bile acids that accumulate in a cholestatic liver, stimulate bicarbonate secretion into the bile, and reduce elevated liver enzymes.[7]

Intestinal Obstruction and Constipation Treatment of DIOS consists of enteral administration of polyethylene glycol (PEG) electrolyte solutions. Severe presentations may require surgical resection. Enemas may also be used to facilitate stool clearance. IV fluids are often required to correct dehydration due to vomiting or decreased oral intake. Reevaluation of enzyme adherence and dosing is essential to prevent recurrence, and some patients may require daily PEG administration (MiraLAX) or stimulant laxatives. Oral mineral oil should be avoided due to risk for aspiration.[7]

▶ CF-Related Diabetes

Patients with mild CFRD may be managed with carbohydrate modification if nutritional status is optimal. However, most patients present with poor nutrition and weight loss and require more aggressive treatment. **KEY CONCEPT** Because CFRD results from insulin insufficiency, exogenous insulin replacement is usually required. Many patients can be successfully managed by meal coverage with short- or rapid-acting insulin (regular, lispro, or aspart) dosed per carbohydrate counting. Patients with fasting hyperglycemia or patients receiving nighttime tube feedings typically also require longer acting basal insulin. Regular home glucose monitoring is essential to appropriate therapy. Insulin pump therapy and continuous glucose monitoring offer patients flexibility and reduced frequency of injections and finger sticks. Oral antidiabetic agents have not been studied adequately in CFRD, and routine use is not recommended.[8,9]

▶ Bone Disease and Arthritis

CF patients with low bone mineral density and low serum vitamin D levels may improve bone health through supplemental vitamin D analogs beyond those found in standard CF vitamins. The CF Foundation recommends 25-hydroxyvitamin D levels of at least 30 ng/mL (75 nmol/L) for all patients. For cholecalciferol (or ergocalciferol), a minimum of 400 to 500 IU and 800 to 1000 IU should be taken daily by infants and patients 1 to 10 years of age, respectively. Patients older than 10 years should take 800 to 2000 IU daily. Vitamin D concentrations should be measured annually in the winter for evaluation of dosing.[31] Total weekly or biweekly doses of 12,000 IU for children younger than 5 years of age and 50,000 IU for patients 5 years of age and older may be required to achieve target vitamin D concentrations. Supplemental calcium should be provided if 1300 to 1500 mg of elemental calcium intake cannot be achieved through diet.[9]

Patient Encounter Part 2

The parents received education about CF and met with the multidisciplinary CF team. The team would like to initiate first-line CF therapies because the baby displays symptoms of pancreatic insufficiency (see Part 1). The neonate weighs 2.95 kg and is 51 cm long.

Given this information, what is your assessment of the infant's nutritional status?

What are the treatment goals for this patient?

What nonpharmacologic therapy should be initiated?

What pharmacologic therapy should be initiated?

Antiresorptive agents (oral or IV bisphosphonates) may be used to treat adult CF patients with osteoporosis. Remaining upright daily for 30 minutes after dosing may be difficult for patients needing to perform airway clearance therapy, so products offering less frequent dosing should be considered.[9] Pamidronate 30 mg IV every 3 months or zoledronic acid 5 mg IV once yearly may be considered in adult CF patients. Androgen replacement may benefit bone health in some adult male CF patients with documented hypogonadism.[9]

▶ Precision Therapy

Since the discovery of the CF gene and the CFTR protein defect, research has focused on gene mutation-specific pharmacologic therapy to correct or modulate dysfunctional CFTR protein. Ivacaftor (Kalydeco, VX-770) is a CFTR potentiator that activates defective CFTR at the cell surface and improves CFTR function in patients with gating mutations. Ivacaftor is indicated for CF patients 6 months and older who have at least one mutation in the *CFTR* gene that is responsive to ivacaftor potentiation based on clinical and/or in vitro assay data. Ivacaftor treatment (added to standard CF care) is associated with improved lung function (approximately 10% increase in FEV_1), decreased pulmonary exacerbations, weight gain, and increased quality of life.[18,32] Ivacaftor given alone is not effective for patients homozygous for *Phe508del*. Ivacaftor should not be recommended, prescribed, or dispensed without first verifying that the patient has an appropriate *CFTR* gene mutation that has been identified to be responsive to ivacaftor.

The ivacaftor dose is 150 mg orally every 12 hours for patients aged 6 years and older. Patients 4 months to 5 years of age should receive 25 mg (if 5–6.9 kg), 50 mg (if 7–13.9 kg), or 75 mg (if > 14 kg) orally every 12 hours. Ivacaftor should be given with a fat-containing meal or snack and with PERT if pancreatic insufficient. Dosage must be reduced in moderate-to-severe hepatic impairment (Child-Pugh Class B or C) and when coadministered with moderate or strong CYP3A inhibitors (eg, azole antifungals, clarithromycin, erythromycin). Use with strong CYP3A inducers (eg, rifampin, rifabutin, phenytoin, phenobarbital, carbamazepine) is contraindicated. Ivacaftor therapy is generally well tolerated, although elevated liver enzymes have been reported. Hepatic enzymes should be monitored at least quarterly in the first year of therapy, and slit lamp eye exams should be performed at baseline and annually in pediatric patients to evaluate for potential cataract formation.

Another precision therapy contains a combination of lumacaftor (a CFTR corrector) and ivacaftor (Orkambi, VX-809/VX-770) to treat CF in patients 2 years and older who are homozygous for *Phe508del*. It is associated with a modest increase in FEV$_1$ (3.5%) and has been shown to reduce pulmonary exacerbations by 35%.[32] Lumacaftor stabilizes the CFTR protein so more reaches the cell surface, whereas ivacaftor potentiates ion transport. Lumacaftor/ivacaftor should not be prescribed without first verifying that the patient has two copies of the *Phe508del* gene mutation. Dosing is lumacaftor 400 mg/ivacaftor 250 mg orally every 12 hours for patients aged 12 years and older, lumacaftor 200 mg/ivacaftor 250 mg orally every 12 hours for patients 6 to 11 years of age, and lumacaftor 150 mg/ivacaftor 188 mg orally every 12 hours (≥14 kg) or lumacaftor 100 mg/ivacaftor 125 mg (< 14 kg) orally every 12 hours for patients 2 to 5 years of age. Lumacaftor/ivacaftor should be given with a fat-containing meal or snack and with PERT if pancreatic insufficient. Dosage must be reduced in moderate-to-severe hepatic impairment (Child-Pugh Class B or C). Dose titration may be needed when imitated in patients already on strong CYP3A inhibitors, and use with strong CYP3A inducers is contraindicated. Lumacaftor is also a strong inducer of several CYP enzymes, and interactions with many medications may require dose adjustment or alternative therapy. Hepatic enzymes should be monitored at least quarterly in the first year of therapy, and slit lamp eye exams should be performed at baseline and annually in pediatric patients to evaluate for potential cataract formation. Chest tightness, sometimes severe, has been observed in patients with lower lung function (FEV$_1$ < 40%).[32]

A third precision therapy consisting of tezacaftor and ivacaftor (Symdeko, VX-661/VX-770) is approved for CF patients 6 years and older who are homozygous for *Phe508del* or who have at least one gene responsive to therapy. Clinical outcomes are similar to those seen with lumacaftor/ivacaftor.[32] Oral dosing for patients 12 years and older and patients 6 to 11 years of age (≥ 30 kg) is tezacaftor 100 mg/ivacaftor 150 mg in the morning and ivacaftor 150 mg in the evening. Patients 6 to 11 years of age (< 30 kg) receive oral tezacaftor 50 mg/ivacaftor 75 mg in the morning and ivacaftor 75 mg in the evening. Tezacaftor/ivacaftor should be given with a fat-containing meal or snack and with PERT if pancreatic insufficient. Dosage must be reduced in moderate-to-severe hepatic impairment (Child-Pugh Class B or C) and when coadministered with moderate or strong CYP3A inhibitors. Use with strong CYP3A inducers is contraindicated. Hepatic enzymes should be monitored at least quarterly in the first year of therapy, and slit lamp eye exams should be performed at baseline and annually in pediatric patients to evaluate for potential cataract formation.

The groundbreaking triple modulator therapy consisting of elexacaftor/tezacaftor/ivacaftor (Trikafta), two correctors and a potentiator, is approved for patients with at least one copy of *Phe508del* or at least one gene responsive to therapy. Once approved in all age groups, CFTR modifier therapy will be available for up to 90% of CF patients. This highly effective modulator therapy is associated with an increased FEV$_1$ of 14.3%.[32] Dosing for patients 12 years of age and older and patients 6 to 11 years of age (≥ 30 kg) is elexacaftor 200 mg/tezacaftor 100 mg/ivacaftor 150 mg in the morning and ivacaftor 150 mg in the evening given orally with a fat-containing meal or snack and with PERT if pancreatic insufficient. Patients 6 to 11 years of age (< 30 kg) receive oral elexacaftor 100 mg/ tezacaftor 50 mg/ ivacaftor 75 mg in the morning and ivacaftor 75 mg in the evening. Dosage must be reduced in moderate-to-severe hepatic impairment (Child-Pugh Class B or C) and when coadministered with moderate or strong CYP3A inhibitors. Use with strong CYP3A inducers is contraindicated. As with other modulators, hepatic enzymes should be monitored at least quarterly in the first year of therapy, and slit lamp eye exams should be performed at baseline and annually in pediatric patients to evaluate for potential cataract formation. Clinical studies in younger patients are underway in 2021.

Patient Encounter Part 3

The infant is now 6 months old (weight: 7 kg) and is brought to a routine CF clinic appointment. His parents report that he has had a runny nose with green discharge, cough productive of yellow sputum for the past week, and an intermittent fever of up to 101.3°F (38.5°C) at home. Also, the baby has had some posttussive emesis, reduced oral intake, and has been sleeping more. Vital signs are as follows: BP 82/44 mm Hg, HR 130 beats/min, RR 44/min, 100.8°F (38.2°C), oxygen saturation 94% (0.94). Review of throat cultures since diagnosis reveals the following organisms:

- *Staphylococcus aureus*: sensitive to trimethoprim–sulfamethoxazole, minocycline, linezolid, and vancomycin; resistant to clindamycin, erythromycin, and nafcillin
- *Pseudomonas aeruginosa*: sensitive to ceftazidime, cefepime, piperacillin/tazobactam, aztreonam, meropenem, ciprofloxacin, and tobramycin; resistant to levofloxacin, amikacin, and gentamicin
- *Achromobacter xylosoxidans*: sensitive to trimethoprim–sulfamethoxazole, minocycline, ceftazidime, and piperacillin/tazobactam; resistant to meropenem and ciprofloxacin

The infant has no known drug allergies.

Based on the information available, design an antibiotic regimen for outpatient therapy of this first pulmonary exacerbation.

What antibiotic(s) and dose(s) would you recommend for inpatient therapy?

Develop a monitoring plan to assess antibiotic response.

What other therapy would you recommend?

Multiple agents, including gene and gene-editing therapies, are under investigation for the 10% of patients who do not have a qualifying genetic profile for current CFTR modulator therapies.

OUTCOME EVALUATION

Pulmonary Function

- Monitor for changes in pulmonary symptoms (cough, sputum production, respiratory rate, and oxygen saturation). Symptoms should improve with antibiotics and aggressive airway clearance therapy. PFTs should be markedly increased after 1 week and trend back to preexacerbation levels after 2 weeks of therapy. If improvement lags, 3 weeks of therapy may be needed.
- For IV antimicrobial therapy, obtain serum drug levels for aminoglycosides and/or vancomycin and perform pharmacokinetic analysis. Adjust the dose, if needed, according to the targets in Table 17–3. Obtain follow-up trough levels and serum creatinine at least weekly or more frequently if renal function is unstable.

Gastrointestinal Function

- Monitor short- and long-term nutritional status through evaluation of height, weight, and BMI. Ideally, parameters should be near the normals (50th percentile) for non-CF patients.
- Evaluate the patient's stool patterns. Steatorrhea indicates suboptimal enzyme replacement or noncompliance. Infants

Patient Care Process

Collect Information:

- Conduct a history of prescription, nonprescription, and alternative medications. Review drug allergies and intolerances, especially antibiotics.
- Review the medical history and physical assessment findings with a focus on frequency and quality of cough, sputum production, dyspnea, respiratory rate, oxygen saturations, temperature, and PFT trends. Review the patient's airway clearance methods and order of inhaled therapies. Review the patient's CFTR gene profile.
- Speak with the patient and/or caregivers and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Evaluate for signs and symptoms of pulmonary exacerbation. If present, determine if antibiotics are indicated.
- Review culture and sensitivity tests over the last 1 to 2 years. Review pharmacokinetic history. What antibiotics were used previously? Was response better to a particular regimen?
- Review other available laboratory tests (renal and hepatic function, complete blood count, vitamin levels, IgE level, blood glucose, A1C, bone density). Identify presence of CF comorbidities (eg, diabetes, liver disease, bone disease).
- Determine nutritional status, weight, height, and BMI trends. Assess GI symptoms: quantity and quality of bowel movements, gastroesophageal reflux, bloating, flatulence, or abdominal pain. Are oral supplements or tube feedings being used?
- Evaluate medications for effectiveness, drug interactions, and adverse reactions. Are all appropriate maintenance medications prescribed and dosed appropriately for weight and age?
- Assess adherence, including timing of inhaled medications with respect to airway clearance therapies and timing of enzymes, CFTR modulator therapy, and insulin with regard to meals.

Develop a Care Plan:

- Devise an appropriate IV or oral/inhaled antibiotic regimen for a pulmonary exacerbation. Optimize doses based on pharmacokinetic and pharmacodynamic parameters.
- Optimize maintenance therapies, doses, and schedules that promote efficacy and ease care burden.

Implement the Care Plan:

- Educate the patient and family about any changes in drug therapy, medication administration requirements, and potential side effects. Emphasize importance of therapy adherence.
- Review the patient's practices and technique for self-administration or caregiver-administration of therapies.
- Determine if the patient has insurance coverage, if there are any specialty pharmacy medication access restrictions, and if recommended agents are included on the institution's formulary. Determine if the patient qualifies for any patient assistance programs.

Follow-up: Monitor and Evaluate:

- For antibiotic regimens, evaluate pulmonary symptoms daily if inpatient or every 1 to 2 weeks if outpatient.
- For IV antibiotic regimens, obtain drug levels and perform pharmacokinetic dose adjustments as necessary. Monitor renal function labs at least weekly. Evaluate fluid intake and urine output daily.
- Review physical examination, lab tests, and results of other diagnostic tests to assess changes in clinical status. Assess effectiveness and safety of maintenance therapies at least quarterly.
- Assess medication adherence and access at least quarterly.

should have two to three well-formed stools daily, whereas older children and adults may have one or two stools daily.

- Monitor efficacy of vitamin supplementation through yearly serum vitamin levels. Obtain levels more frequently if treating a deficiency.

CF-Related Diabetes

- Monitor morning fasting and 2-hour postprandial blood glucose in patients with CFRD or those taking systemic corticosteroids. Follow A1C levels on an outpatient basis to assess long-term glucose control. Levels may be falsely low in CF due to a shorter red blood cell half-life.

Abbreviations Introduced in This Chapter

ABPA	Allergic bronchopulmonary aspergillosis
CF	Cystic fibrosis
CFRD	Cystic fibrosis-related diabetes
CFTR	Cystic fibrosis transmembrane regulator
CPT	Chest physiotherapy
DIOS	Distal intestinal obstruction syndrome
FEV$_1$	Forced expiratory volume in 1 second
FVC	Forced vital capacity
HFCC	High-frequency chest compression
IPV	Intrapulmonary percussive ventilation
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant *Staphylococcus aureus*
MSSA	Methicillin-sensitive *Staphylococcus aureus*
OPEP	Oscillating positive expiratory pressure
PEG	Polyethylene glycol
PERT	Pancreatic enzyme replacement therapy
PFT	Pulmonary function test
PMN	Polymorphonuclear
PT	Prothrombin time
RDA	Recommended daily allowance

18 Gastroesophageal Reflux Disease

Jeremy J. Prunty and Leesa M. Prunty

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of gastroesophageal reflux disease (GERD).
2. Understand the difference between typical, atypical, and alarm symptoms.
3. Determine when diagnostic tests should be recommended based on the clinical presentation.
4. Identify the desired therapeutic outcomes for patients with GERD.
5. Recommend appropriate nonpharmacologic and pharmacologic interventions for patients with GERD.
6. Educate patients on appropriate lifestyle modifications and drug therapy issues including adherence, adverse effects, and drug interactions.
7. Formulate a monitoring plan to assess the effectiveness and safety of pharmacotherapy for GERD.

INTRODUCTION

Gastroesophageal reflux is the retrograde, effortless movement of stomach contents into the esophagus. When troublesome symptoms or mucosal damage occurs as a result of this process, this is defined as gastroesophageal reflux disease (GERD).[1,2] Treatment is usually initiated based on symptom presentation rather than laboratory tests or invasive monitoring and consists of various lifestyle interventions and pharmacotherapy. Lack of response to empiric therapies may require further evaluation to identify potential underlying complicating conditions.[1,3]

EPIDEMIOLOGY AND ETIOLOGY

GERD is one of the most common gastrointestinal diagnoses associated with outpatient clinic visits in the United States. Up to 40% of Americans report intermittent GERD symptoms, with around 20% of the US population reporting at least weekly symptoms.[1] GERD symptoms can result in decreased work productivity and morbidity, accounting for approximately 110,000 hospital admissions annually.[4] In 2015, the US annual health-care expenditures for gastrointestinal diseases was $135.9 billion, with $18.1 billion from esophageal disorders.[5] The incidence of GERD complications such as erosive esophagitis and Barrett esophagus increases with age, especially in Caucasian men over 50 years of age with symptoms for more than 10 years.[3,4,6]

The precise etiology of GERD is difficult to determine in most patients. Increased intra-abdominal pressure or decreased lower esophageal sphincter (LES) tone may allow gastric refluxate to enter the esophagus causing GERD symptoms in some patients. These processes can be transient and are often due to physical activity, food, or medications.

PATHOPHYSIOLOGY

Retrograde movement of gastric contents into the esophagus, oral cavity, or lungs is the origin of symptoms or complications that define GERD. Reflux is normally prevented through muscle tone of the LES. Reduction in LES function or tone may allow reflux of gastric contents into the esophagus. Other physiologic and mucosal defense mechanisms may also become compromised and affect the refluxate composition and development of GERD. Such mechanisms include slowed esophageal clearance, decreased salivary buffering, impaired mucosal resistance, delayed gastric emptying, and increased intra-abdominal pressure.

Lower Esophageal Sphincter Pressure

In the normal state, the LES maintains a tonic pressure that separates gastric contents from the esophagus, relaxing during swallowing to allow esophageal contents to pass into the stomach. Decreased LES pressure can occur via spontaneous relaxation, increased intra-abdominal pressure, and an atonic LES. Spontaneous relaxation of the LES occurs during vomiting, belching, retching, and esophageal distention. Transient increases in intra-abdominal pressure may occur during straining, exercise, bending over, or Valsalva maneuver. An atonic LES allows unopposed passage of refluxate from the stomach into the esophagus. A hiatal hernia may cause or worsen GERD symptoms by increasing intragastric pressure and decreasing LES tone. Some foods and medications may worsen LES dysfunction, whereas others can directly irritate the esophageal mucosa (Table 18–1).

Esophageal and Mucosal Protection

Several normal processes protect the esophageal tissue and mucosal barrier from irritants such as refluxed gastric fluid. Swallowing enhances esophageal clearance by increasing salivary flow, which contains bicarbonate that buffers the acidic gastric contents. This usually maintains a neutral esophageal pH; however, salivary production decreases during sleep and in older persons, which may contribute to GERD symptoms. Mucus-secreting glands in the esophageal mucosa and submucosa also help neutralize acidic refluxate by releasing bicarbonate. Most patients with GERD do not produce abnormally large amounts of acid but slowed esophageal clearance of gastric contents increases contact time of

GERD, gastroesophageal reflux disease; LES, lower esophageal sphincter; NSAIDs, nonsteroidal anti-inflammatory drugs.

Adapted from May D, Thiman ML, Rao SSC. Gastroesophageal reflux disease. In: DiPiro JT, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill, 2020; with permission.

refluxate with esophageal mucosa, possibly leading to symptoms or erosion. Refluxate contains gastric acid, pepsin, bile acids, and pancreatic enzymes that promote mucosal erosion and GERD symptoms. The frequency and severity of symptoms do not correlate with the degree of esophageal damage.[4]

Gastric Emptying and Increased Abdominal Pressure

Gastric fluid volume depends on the rate of gastric acid secretion, stomach emptying time, and the amount of gastric fluid that refluxes from the duodenum into the stomach. Prolonged stomach emptying time increases the volume of fluid in the stomach, thereby increasing intragastric pressure. Increased gastric volume can increase the amount and frequency of fluid being refluxed, which may cause or worsen GERD symptoms. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with reflux.

Obesity is a major risk factor for developing GERD symptoms and complications. Patients with GERD and abdominal obesity have an increased risk of Barrett esophagus, esophageal adenocarcinoma, and erosive esophagitis.[4] Morbidly obese patients may also have more transient LES relaxations, incompetent LES function, and impaired esophageal motility.[7] Reduction in body mass index by at least 3.5 kg/m^2 or decreased waist circumference may decrease or eliminate GERD symptoms.[3,4,8]

Patient Encounter 1, Part 1

A 23-year-old African American man reports of heartburn and regurgitation 3 days/week. He reports no recent weight loss. He is attending college in an engineering program, and his diet consists of mostly fast food, pizza, and energy drinks. He has been self-medicating with OTC calcium carbonate tablets and famotidine for the last month with no improvement. His weight is 100 kg, and his height is 5 ft 11 in (180 cm). He has no known drug allergies.

Are this patient's symptoms consistent with GERD?

Would the patient's symptoms be described as typical, atypical, or alarm?

What risk factors does he have that may worsen GERD symptoms?

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT Patients with GERD may have symptoms classified as (a) typical, (b) atypical, or (c) alarm (see accompanying box Clinical Presentation of GERD).[3]

Diagnosis of GERD

Diagnosis of GERD is suggested when heartburn or regurgitation symptoms occur two or more times per week.[8] Initial diagnostic testing should be reserved for patients with atypical or alarm symptoms. **Endoscopy** is preferred for assessing mucosal injury and to identify complications such as **esophageal strictures** (which can cause difficulty swallowing) and erosive esophagitis due to repeated and prolonged exposure to gastric refluxate. A mucosal biopsy should be taken to identify Barrett esophagus, which is associated with an increased risk of developing esophageal cancer. Endoscopy may also be performed in patients not responding to an adequate trial of a twice-daily proton pump inhibitor (PPI).[1,3] **Ambulatory esophageal reflux monitoring** identifies excessive esophageal acid exposure and the frequency of reflux episodes. **Esophageal manometry** may be beneficial for patients who have failed twice-daily PPIs and have normal endoscopic findings or those contemplating antireflux surgery. These tests help to determine whether symptoms are acid related and

Clinical Presentation of GERD

Symptoms

- *Typical symptoms* (may be aggravated by activities that worsen reflux such as recumbent position, bending over, or eating a high-fat meal): Heartburn, often described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck and may be waxing and waning in character; hypersalivation; **regurgitation**; belching.
- *Atypical symptoms* (associated with GERD, but causality should only be considered if typical symptoms are also present): chronic cough, laryngitis, hoarseness, wheezing, noncardiac chest pain, asthma (~50% with asthma have GERD).
- *Alarm symptoms* (may indicate GERD complications such as Barrett esophagus, esophageal strictures, or esophageal adenocarcinoma and require further diagnostic evaluation): **Dysphagia**, **odynophagia**, weight loss, bleeding.

may also be useful in patients not responding to acid suppression therapy or prior to antireflux surgery.

GERD and dyspepsia (often occurring with peptic ulcer disease) commonly overlap in presentation. Dyspepsia is characterized predominantly by epigastric pain but may also be associated with other upper gastrointestinal (GI) symptoms including heartburn.[9] Care should be taken when evaluating patient symptom history to differentiate GERD from dyspepsia due to differing treatment strategies. Patients reporting epigastric pain for at least 1 month should be evaluated for dyspepsia. Although *Helicobacter pylori*-positive patients may present with gastritis, symptomatic reflux does not correlate well with active *H. pylori* infection. Routine screening for *H. pylori* in patients with GERD is controversial and not currently recommended.[3,10,11]

TREATMENT

Desired Outcomes

KEY CONCEPT The goals of GERD treatment are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.

General Approach to Treatment

KEY CONCEPT Treatment for GERD involves one or more of the following modalities: (a) patient-specific lifestyle changes, (b) pharmacologic intervention primarily with acid-suppressing therapy, or (c) antireflux surgery (Table 18–2).[3,12] The best initial therapeutic option depends on the frequency, severity, and type of symptoms and need for further diagnostic evaluation (Figure 18–1).[1,3,13,14]

Nonpharmacologic Therapy

▶ *Lifestyle Modifications*

Although most patients do not respond adequately to lifestyle changes alone, it is helpful to maintain these changes throughout therapy to reduce the need for long-term pharmacologic therapies. The most beneficial lifestyle changes include (a) losing weight if overweight or obese, particularly a reduction in waist circumference, and (b) elevating the head of the bed with a foam wedge if symptoms are worse when recumbent. Elevating the head of the bed decreases the contact time of gastric acid with the esophageal mucosa at night.[15]

Other lifestyle modifications should be considered based on patient circumstances. These might include (a) eating smaller meals and avoiding meals 3 hours before sleeping, (b) avoiding foods or medications that exacerbate GERD, (c) smoking cessation, and (d) avoiding alcohol. The patient's medication and food histories should be evaluated to identify potential factors that may exacerbate GERD symptoms (Table 18–1).

▶ *Surgical Treatment*

While pharmacologic therapies are typically the treatment of choice following lifestyle modifications, antireflux surgical options may be considered when there is a large hiatal hernia, evidence of aspiration or cardia dysfunction, or when pharmacologic management is undesirable due to side effects or adherence challenges in patients with well-documented GERD.[8,10] The goal of surgery is to reestablish the antireflux barrier, position the LES within the abdomen where it is under positive (intra-abdominal)

Table 18–2

Therapeutic Approach to GERD in Adults

Recommended Regimen	Brand Name	Oral Dose	Comments
Intermittent, Mild Heartburn (individualized lifestyle modifications + patient-directed therapy with antacids and/or nonprescription H$_2$RA *or* PPI)			
Individualized lifestyle modifications			Lifestyle modifications should be individualized for each patient
Patient-directed therapy with antacids (≥ 12 years old)			
Magnesium hydroxide/aluminum hydroxide with simethicone	Maalox	10–20 mL as needed or after meals and at bedtime	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention; do not exceed 16 teaspoonfuls per 24 hours
Antacid/alginic acid	Gaviscon	2–4 tablets or 10–20 mL after meals and at bedtime	Note: Content of alginic acid varies greatly among products; the higher the alginic acid, the better
Calcium carbonate	Tums	500 mg, 2–4 tablets as needed	
Patient-directed therapy with nonprescription H$_2$RA (up to twice daily) (≥ 12 years old)			
Cimetidine Famotidine Nizatidine	Tagamet HB Pepcid AC Axid AR	200 mg 10–20 mg 75 mg	If symptoms are unrelieved with lifestyle modifications and nonprescription H$_2$RA after 2 weeks, patient should seek medical attention
Patient-directed therapy (> 18 years old) with nonprescription PPI (taken once daily)			
Esomeprazole Lansoprazole Omeprazole Omeprazole/sodium bicarbonate	Nexium 24HR Prevacid 24HR Prilosec OTC Zegerid OTC	20 mg 15 mg 20 mg 20 mg/1100 mg	If symptoms are unrelieved with lifestyle modifications and nonprescription PPI after 2 weeks, patient should seek medical attention

(*Continued*)

Table 18–2

Therapeutic Approach to GERD in Adults (*Continued*)

Recommended Regimen	Brand Name	Oral Dose	Comments
Symptomatic Relief of GERD (individualized lifestyle modifications + prescription-strength H$_2$RA or PPI)			
Individualized lifestyle modifications			Lifestyle modifications should be individualized for each patient
Prescription-strength H$_2$RA			
Cimetidine (off-label use)	Tagamet	400 mg four times daily or 800 mg twice daily	• For typical symptoms, treat empirically with prescription-strength acid suppression therapy • If symptoms recur, consider maintenance therapy. Note: Most patients require standard doses for maintenance therapy
Famotidine	Pepcid	20 mg twice daily	
Nizatidine	Axid	150 mg twice daily	
Prescription-strength PPI			
Dexlansoprazole	Dexilant	30 mg once daily for 4 weeks	• For typical symptoms, treat empirically with prescription-strength acid suppression therapy • Patients with moderate-to-severe symptoms should receive a PPI as initial therapy • If symptoms recur, consider maintenance therapy
Esomeprazole	Nexium	20–40 mg once daily	
Lansoprazole	Prevacid	15 mg once daily	
Omeprazole	Prilosec	20 mg once daily	
Omeprazole/sodium bicarbonate	Zegerid	20 mg once daily	
Pantoprazole (Off-label use)	Protonix	40 mg once daily	
Rabeprazole	Aciphex	20 mg once daily	
Healing of Erosive Esophagitis or Treatment of Moderate-to-Severe Symptoms or Complications (individualized lifestyle modifications + high-dose H$_2$RA *or* PPI *or* antireflux surgery)			
Individualized lifestyle modifications			Lifestyle modifications should be individualized for each patient
PPI (up to twice daily for up to 12 weeks)			
Dexlansoprazole	Dexilant	60 mg daily	• For atypical or alarm symptoms, obtain endoscopy with biopsy to evaluate mucosa • If symptoms are relieved, consider maintenance therapy. PPIs are the most effective maintenance therapy for patients with atypical symptoms, complications, and erosive disease. Start with twice-daily PPI therapy if reflux chest syndrome present • Patients not responding to pharmacologic therapy should be evaluated via manometry and/or ambulatory reflux monitoring • Twice daily dosing of PPIs is considered off-label use
Esomeprazole	Nexium	20–40 mg daily	
Lansoprazole	Prevacid	30 mg once or twice daily	
Omeprazole	Prilosec	20 mg once or twice daily	
Rabeprazole	Aciphex	20 mg once or twice daily	
Pantoprazole	Protonix	40 mg once or twice daily	
High-dose H$_2$RA (for 8–12 weeks)			
Cimetidine	Tagamet	400 mg four times daily or 800 mg twice daily	Note: If high-dose H$_2$RA needed, may consider using PPI to lower cost, increase convenience, and increase tolerability Note: Four times daily use is considered off-label for nizatidine
Famotidine	Pepcid	20–40 mg twice daily	
Nizatidine	Aciphex	150 mg two–four times daily	
Interventional therapy			
Antireflux surgery			

GERD, gastroesophageal reflux disease; H$_2$RA, histamine-2 receptor antagonist; PPI, proton pump inhibitor.

Note: Ranitidine was withdrawn from the market by the FDA in April 2020.

pressure, and close any associated hiatal defect. Surgical options are effective in reducing GERD symptoms, with as many as 90% of patients symptom free after 10 years, and up to 60% remaining off PPIs at 17 years. Other studies have shown antireflux surgery provided more symptom control than omeprazole in patients with esophagitis in a 7-year follow-up study.[16] However, the evidence for surgery is not as strong in patients who do not respond to PPI therapy.[3,10] Roux-en-Y gastric bypass has been shown to reduce symptoms of GERD in obese patients; however, not all forms of bariatric surgery, such as vertical banded gastroplasty, have been shown to improve GERD symptoms.[3,17]

Fundoplication is frequently employed for surgical intervention; it increases LES pressure by wrapping the fundus of the stomach around the distal esophagus; the wrap may include the total esophageal circumference (Nissen fundoplication), only the posterior circumference (Toupet), or only the anterior circumference (Dor). Other forms of surgical intervention include magnetic sphincter augmentation, such as the LINX procedure, which involves implanting a band of interlinked titanium beads with magnetic cords around the LES to maintain LES pressure.[18] Alternatives include LES stimulators that are surgically inserted to modulate LES pressures and reduce refluxate from the stomach.[19] Endoscopic options include radiofrequency application at the esophagogastric junction and transoral incisionless fundoplication, both of which have shown limited success in reducing PPI use and GERD symptoms.[18]

Surgical options may be considered at any time during therapy; however, surgery is not recommended for patients who respond to adequate PPI therapy. Surgical therapies have significant inherent risks including mortality; therefore, it is critical to inform patients of the benefits and risks of procedures and select the most appropriate modality carefully.[3]

Pharmacologic Therapy

Pharmacologic therapies for GERD typically involve increasing the pH of gastric contents through either direct gastric acid neutralization or reducing acid production through inhibition of stimulation pathways, thereby reducing GERD symptoms and tissue damage. Pharmacologic options can be stratified by effectiveness: antacids are inferior to histamine-2 receptor antagonists (H_2RAs), and H_2RAs decrease acid secretion less than PPIs.[3]

▶ *Antacids and Alginic Acid*

Antacids are useful for intermittent treatment of GERD symptoms and can be used for patients with infrequent typical reflux symptoms. They are effective for immediate, symptomatic relief but require frequent dosing (Table 18–2). Aluminum or magnesium-containing antacids may result in electrolyte abnormalities, particularly in patients with renal impairment. Antacids are usually well tolerated, and potential side effects include constipation or diarrhea depending on the formulation being used. Antacids may also chelate with medications such as fluoroquinolones, tetracyclines, iron products, and thyroid hormones; therefore, doses should be separated by several hours to avoid decreased efficacy.

Alginic acid creates a viscous barrier that can aid in acid neutralization and is often used in combination with antacids.[18]

▶ *Histamine-2 Receptor Antagonists*

The H_2RAs (cimetidine, famotidine, nizatidine) decrease acid secretion by blocking histamine$_2$-receptors in gastric parietal cells. H_2RAs provide relief from typical acute GERD symptoms and can also be administered prophylactically. H_2RAs are more effective than antacids at controlling chronic GERD symptoms but less effective than PPIs. H_2RAs may be dosed intermittently or on a scheduled basis depending on the degree of symptom control (Table 18–2).

H_2RAs are generally well tolerated; side effects are mild and include headache and nausea. Cimetidine is a weak inhibitor of the cytochrome P-450 system with many common drug interactions; other H_2RAs have limited drug interactions. Cimetidine also has unique adverse effects such as gynecomastia and vitamin B_{12} deficiency, which limit patient tolerance during chronic therapy.[20] Most H_2RAs are renally eliminated and may require dose adjustment in renal dysfunction.

▶ *Proton Pump Inhibitors*

KEY CONCEPT PPIs (eg, omeprazole, lansoprazole) block gastric acid secretion by inhibiting gastric H^+/K^+-adenosine triphosphatase in gastric parietal cells, producing a profound, long-lasting antisecretory effect capable of maintaining the gastric pH above 4, even during postprandial acid surges. Primary uses of PPIs are treating frequent reflux symptoms and healing of gastric or esophageal ulcerations. **KEY CONCEPT** PPIs provide significant reduction in gastric acid and the greatest relief of symptoms, especially in patients with moderate-to-severe GERD, with high rates of healing erosive disease. PPIs are available as both prescription and nonprescription products with various formulations available (Table 18–2).

Because PPIs degrade in acidic environments, they are typically formulated in delayed-release capsules or tablets. For patients unable to swallow intact capsules (including children) or those with nasogastric tubes, the capsule contents can be mixed in applesauce or orange juice. Esomeprazole pellets can be mixed with water prior to administration.[21]

Most patients should be instructed to take their PPI in the morning, 30 to 60 minutes before breakfast to maximize efficacy. Due to their slow onset of action, PPIs are most effective when taken on a scheduled basis. Patients requiring a second dose if nighttime symptoms are predominant should take the dose before the evening meal. Dexlansoprazole and the combination product omeprazole–sodium bicarbonate may be taken without regard to food.[12] All PPIs can decrease the absorption of medications that require an acidic environment to be absorbed (eg, dabigatran, encapsulated itraconazole, dipyridamole) and are metabolized by the cytochrome P-450 system to some extent.[22,23]

PPIs are generally well tolerated; the most common side effects are headache and GI effects such as diarrhea and nausea. Several concerns have been raised about consequences of long-term PPI use. Renal complications (acute kidney injury and chronic kidney disease), bone fractures, and dementia have been reported from retrospective observational studies and case reports; however, prospective data are limited and additional study is needed to determine causality.[24] Reduced absorption of micronutrients such as calcium, magnesium, and vitamin B_{12} with long-term use has also been reported in observational studies; however, routine screening and supplementation of these vitamins and minerals based solely on chronic PPI use is not warranted.[3,10,13] In patients with documented hypocalcemia, it is reasonable to replete calcium with the citrate rather than the carbonate salt due to improved absorption in a less acidic environment.[25]

Concerns for drug interactions with clopidogrel and PPIs that inhibit CYP 2C19 were initially raised by pharmacodynamic studies showing possible attenuation of clopidogel's antiplatelet function. Clopidogrel is a prodrug requiring a two-step activation via CYP 2C19, which may be competitively depleted due to metabolism of PPIs.[26,27] However, the 2010 COGENT study found no meaningful interaction or increase in the incidence of myocardial infarction in patients who used omeprazole with aspirin and clopidogrel.[28] Although the COGENT study had several limitations, the interaction between clopidogrel and PPIs is not considered to be clinically significant, and use of PPIs may decrease GI-related events such as upper GI hemorrhage when used with dual antiplatelet agents. Use of a PPI with clopidogrel should be considered based on the individual patient's cardiovascular and bleeding risk. If patients or providers wish to avoid the combination, alternatives include switching to a P2Y12 inhibitor not activated by CYP2C19, switching to a PPI with less CYP2C19 metabolism, or changing to an H_2RA.[29]

Infectious complications attributed to chronic PPI use include spontaneous bacterial peritonitis, small intestinal bacterial overgrowth, *Clostridium difficile* infection, and pneumonia.[30] Studies have been mostly small observational trials attributing a low-to-moderate overall increased infection risk with PPI treatment. The potential risks of chronic PPI use must be evaluated on an individual basis to guide clinical decisions.

▶ *Prokinetic Agents and Sucralfate*

Metoclopramide, a central dopamine antagonist, accelerates gastric emptying and can increase LES pressure. Metoclopramide has been studied for GERD symptom relief in conjunction with a PPI; however, potential side effects can be significant and include extrapyramidal effects and tardive dyskinesia.[3] Domperidone is a peripherally acting dopamine antagonist that does not have central nervous system toxicities; however, it is not approved for use in the United States and requires monitoring for QT prolongation. In patients without gastroparesis, there is no clear role for the use of prokinetic agents for treatment of GERD.[3]

Sucralfate, a nonabsorbed aluminum salt of sucrose octasulfate, has limited value for treating GERD. Sucralfate is suboptimal compared with PPI therapy and has no role in nonpregnant patients with GERD.[3]

Initial Therapy of GERD

▶ *Self-directed Therapy*

Many patients who have heartburn symptoms two or more times per week may successfully self-treat with a short-term (maximum 2-week) course of nonprescription PPI therapy. Although this strategy is neither sensitive nor specific for diagnostic purposes, it is a reasonable initial option to achieve symptom control. Patients experiencing symptoms beyond the 2-week course should be evaluated by a provider.[8]

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: ADHD

FH: Mother has GERD, Father has hypertension

SH: Currently in his final year in college. Lives in an apartment with two other roommates. Does not smoke. Reports drinking about six alcoholic beverages per week

Meds: Dexmethylphenidate 20 mg daily

ROS: (+) Heartburn, regurgitation; (–) chest pain, nausea, vomiting, diarrhea, weight loss, change in appetite, shortness of breath or cough

PE: WNL

VS: BP 126/78 mm Hg, P 82 beats/min, RR 16 breaths/min, T 37°C (98.6°F)

CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended; (+) bowel sounds, (–) hepatosplenomegaly, heme (–) stool

Does this patient require further diagnostic evaluation based on his clinical presentation? If so, which procedure would you recommend?

What nonpharmacologic and pharmacologic changes would you recommend for his GERD therapy?

▶ *Provider-directed Therapy*

On presentation to a health-care provider, patients may have already attempted a nonprescription trial of self-directed therapy with all three of the major pharmacologic classes. After confirmation of a GERD diagnosis, a trial of a scheduled PPI for 8 weeks is typically recommended, monitoring for symptomatic improvement. Most patients with nonerosive GERD respond positively to a PPI trial and therefore should be evaluated for an appropriate long-term maintenance therapy. Adherence and appropriate administration should be monitored throughout therapy. For patients with refractory nocturnal symptoms or symptoms not controlled with daily therapy, a trial of twice-daily PPIs may provide benefit.[13]

Patients with erosive esophagitis on endoscopy should be treated with at least 8 weeks of twice-daily PPI therapy.[3] Maintenance therapy in these patients should be individualized after the initial treatment period; if PPIs are continued, they should be used at the lowest effective dose and schedule.[3]

Maintenance GERD Therapy

KEY CONCEPT Maintenance therapy may be necessary in patients with refractory symptoms while on maximal acid suppression (Table 18–2).[3,10,13] **KEY CONCEPT** Adding an H_2RA to a PPI regimen may provide initial benefit for refractory symptoms but may result in tachyphylaxis with continued use. While maintenance daily PPI therapy may be necessary in some patients, on-demand PPI dosing may also be effective.[31] On-demand therapy consists of stopping PPI therapy upon resolution of GERD symptoms, with reinitiation of therapy for 2 to 4 weeks if symptoms occur two or more times within 7 days while off therapy.[13] In a large prospective study of GERD patients (most of whom had erosive esophagitis) who used on-demand therapy, 70% had 0 or 1 relapse and only 30% changed to chronic daily PPI therapy after almost 1 year of follow-up.[32] Other studies found that on-demand therapy can decrease PPI exposure by 60% to 80%, with more than 80% of patients being willing to continue the dosing strategy when given the option.[33]

KEY CONCEPT Patients who wish to stop long-term PPI therapy should be slowly titrated off using a stepwise or prolonged taper due to the potential for rebound gastric acid hypersecretion with sudden withdrawal. Rebound hypersecretion can occur with continual PPI use for at least 2 months. For these reasons, the PPI dose and frequency should be tapered slowly, using H_2RAs for breakthrough symptoms. The duration of the taper must be individualized; rebound hypersecretion symptoms can last 3 months or longer after PPI discontinuation.[34]

Special Populations

▶ *Infants and Children with GERD*

Reflux is a common physiologic process in infants that may occur several times a day with no clinical consequence; however, as with adults, GERD is present when symptoms become troublesome or if complications are present.[35,36] Regurgitation is common in infants and may occur daily in as many as 50% of infants younger than 3 months.[35] Most babies who "spit up" are "happy spitters"; they are comfortable, gaining weight, and have no breathing problems caused by vomiting. More troublesome symptoms that require further investigation include vomiting, apnea, poor weight gain, sleep disturbances, and refusing to eat.[35,36]

Reflux episodes are common during transient LES relaxations not related to swallowing because of developmental immaturity of the LES.[35] Other causes include impaired luminal clearance of gastric acid and infant diet. Formula-fed infants are more likely than breastfed infants to exhibit GERD symptoms.[37] Children with neurologic impairment and impaired swallowing, obesity, repaired congenital abnormalities of the esophagus, cystic fibrosis, or hiatal hernia are at a higher risk for developing GERD.[35]

Patient Encounter 2

A 65-year-old, 5 ft 2 in (157 cm), 141-kg woman with a history of hypertension, diabetes, asthma, and GERD presents for her primary care appointment after 2 years of taking esomeprazole 20 mg daily. Her other medications include amlodipine 5 mg daily, albuterol inhaler as needed, and metformin 500 mg twice daily. The patient does not smoke or consume alcohol. Despite good adherence to her PPI regimen, the patient reports having heartburn three times a week. Her primary care physician wants to address the GERD and asks for your recommendations for better symptom control.

VS: BP 140/72 mm Hg, P 80 beats/min, RR 18 breaths/min, T 37°C (98.6°F)
Laboratory values are within normal limits; A1C 5.9% (0.059; 41 mmol/mol Hb).

What nonpharmacologic treatment options are available for treating this patient's symptoms?

Create a pharmacotherapy plan for this patient.

What counseling points should be discussed with the patient regarding any regimen change?

How would you monitor for effectiveness of the treatment plan?

Patient Encounter 3

A 23-year-old woman presents to the pharmacy counter with a bottle of over-the-counter omeprazole to purchase. The patient reports that she is pregnant (approximately 12-week gestation) and has been having occasional heartburn (about one time per week).

What is the most appropriate treatment recommendation for this patient?

What counseling points should be discussed with the patient regarding safety of medication use in pregnancy?

Lifestyle modifications should be emphasized in pediatric patients with uncomplicated GERD. Symptoms usually resolve by 12 to 18 months of life and often respond to supportive therapy, including dietary adjustments such as smaller meals and more frequent feedings. Milk protein allergy in infants can mimic the presentation of GERD, so changes in maternal diet such as restricting milk may be useful in breastfed infants, switching to an extensively hydrolyzed protein or amino acid-based formula, or thickening infant formula with rice cereal. However, excessive thickening of infant formula is discouraged, particularly in preterm infants due to concerns of increased risk for necrotizing enterocolitis.[36] Postural management (ie, positioning the infant in an upright position, especially after meals) may be helpful but should not be used to treat GERD symptoms in sleeping infants. In older children, as with adults, maintaining a healthy body weight is recommended.[35]

If a 2- to 4-week trial of lifestyle modifications is not effective, medical therapy may be indicated. Acid suppression with a PPI is the mainstay of pharmacologic therapy for pediatric GERD.[35] Monotherapy with an H_2RA can be used if PPIs are unavailable or contraindicated in specific patients. A 4- to 8-week course can be attempted, followed by a taper. If symptoms return or if the patient is unable to discontinue the PPI (or H_2RA), evaluation by a pediatric gastroenterologist is recommended, and an endoscopy may be required.[35] Chronic use of antacids or routine use of prokinetics or sucralfate is not recommended.

Increased use of PPIs in children has led to concerns because long-term safety is unknown. Therefore, clinicians must carefully weigh potential risks versus benefits along with appropriate indications for therapy and duration of treatment.[38]

▸ *GERD During Pregnancy*

GERD is common during pregnancy, and 30% to 50% of pregnant women report heartburn symptoms. Lifestyle modifications such as eating smaller meals can reduce heartburn and regurgitation. Mild-to-moderate GERD symptoms can be treated with antacids that have limited systemic absorption, such as calcium, magnesium, and aluminum. Antacids containing magnesium trisilicate specifically should be avoided due to risk of respiratory distress, cardiovascular impairment, hypotonia, and nephrolithiasis if used for long periods of time at high doses. Also, compounds containing sodium bicarbonate should be avoided due to risk of metabolic alkalosis in both the mother and the fetus, as well as precipitating fluid overload.[39] Pregnant patients with severe, frequent heartburn can be started on a PPI. A large retrospective

Patient Care Process

Collect Information:

- Perform a medication history to determine use of prescription, nonprescription, and dietary supplements.
- Identify patient allergies and intolerances that may affect current or planned pharmacotherapy.
- Review the patient's medical and surgical history for issues that may be related to GERD.

Assess the Information:

- Determine whether the patient is taking medications or eating foods that may worsen GERD symptoms (Table 18–1).
- Document severity, characteristics, and frequency of GERD symptoms (eg, typical or alarm symptoms).
- Assess the efficacy, safety, and patient adherence of current therapies and identify any significant adverse effects or interactions.

Develop a Care Plan:

- Implement lifestyle modifications that the patient is willing to do to reduce GERD symptoms.
- Decide if self-treatment is an option or if the patient should be referred to a physician.
- Choose medications and doses that are appropriate considering symptoms, drug or food interactions, and the patient's ability to obtain the chosen therapies that will likely improve quality of life.

Implement the Care Plan:

- Educate the patient about the chosen drug therapy including medication administration, potential adverse effects, and follow-up parameters.
- Educate the patient about symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia.
- Discuss the importance of weight loss and dietary changes (if appropriate) for reducing GERD symptoms.
- Address any patient concerns about the GERD management plan.

Follow-up: Monitor and Evaluate:

- Instruct the patient on the proper time for reassessment if symptoms have not resolved.
- Review medication adherence and timing of doses.
- Monitor for adverse drug effects and determine a plan if symptoms recur.
- Refer patients with atypical or alarm symptoms to their physician for further diagnostic evaluation.
- Determine if long-term maintenance therapy is necessary after completion of the initial course of therapy.

cohort of over 5000 patients found no increase in the number of birth defects in infants exposed to PPIs in utero.[39,40]

OUTCOME EVALUATION

- Monitor for symptom relief and the presence of symptoms.
- Record the frequency and severity of symptoms by interviewing the patient after 4 to 8 weeks of acid-suppressing therapy. Continued symptoms may indicate the need for long-term maintenance therapy.
- **KEY CONCEPT** Review the patient profile for drugs that may aggravate GERD.
- Monitor for adverse drug reactions, drug–drug interactions, and adherence.
- Reassess the need for continued PPI therapy at the completion of the recommended treatment regimen (Table 18–2).

Abbreviations Introduced in This Chapter

GABA	Gamma-aminobutyric acid
GERD	Gastroesophageal reflux disease
H_2RA	Histamine-2 receptor antagonist
LES	Lower esophageal sphincter
PPI	Proton pump inhibitor

Peptic Ulcer Disease

Ashley H. Meredith

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Recognize differences between ulcers induced by *Helicobacter pylori* (H. pylori), nonsteroidal anti-inflammatory drugs (NSAIDs), and stress-related mucosal damage (SRMD) in terms of risk factors, pathogenesis, signs and symptoms, clinical course, and prognosis.
2. Identify desired therapeutic outcomes for patients with *H. pylori*–associated and NSAID-induced ulcers.
3. Select an appropriate *H. pylori* eradication regimen that considers patient-specific factors and approaches to improve regimen adherence.
4. Determine the appropriate management for a patient taking a nonselective NSAID who is at high risk for ulcer-related gastrointestinal (GI) complications (eg, GI bleed) or who develops an ulcer.
5. Utilize an algorithm for the evaluation and treatment of a patient with signs and symptoms suggestive of an *H. pylori*–associated or NSAID-induced ulcer.
6. Given patient-specific information and a prescribed treatment regimen, develop a monitoring plan for drug therapy to eradicate *H. pylori* or treat an active NSAID-induced ulcer or GI complication.

INTRODUCTION

Peptic ulcer disease (PUD) refers to a defect in the gastric or duodenal mucosal wall that extends through the **muscularis mucosa** into the deeper layers of the submucosa.[1] PUD is a significant cause of morbidity and associated with substantial health care costs.[2,3] Although there are many etiologies of PUD, the three most common are (a) *Helicobacter pylori* (H. pylori) infection, (b) use of nonsteroidal anti-inflammatory drugs (NSAIDs), and (c) stress-related mucosal damage (SRMD).

Complications of PUD include gastrointestinal (GI) bleeding, perforation, and obstruction. Complications of untreated or undiagnosed *H. pylori* infection include gastric cancer and PUD. This chapter focuses mainly on pharmacotherapy of PUD related to *H. pylori* infection or NSAID use. Prophylaxis of SRMD in hospitalized patients is discussed briefly.

EPIDEMIOLOGY AND ETIOLOGY

PUD affects approximately 10% of women and 12% of men in the United States, resulting in 4 million cases annually.[4] The mean direct medical cost (including pharmacy, inpatient, and outpatient costs) was $23,819 per patient per year in one study evaluating workplace absences, short-term medical disability, worker's compensation, and medical and pharmacy claims for six large US employers.[5]

The prevalence of *H. pylori* infection in the United States and Canada is about 30%, whereas the global prevalence is greater than 50%. Factors that influence the incidence and prevalence of *H. pylori* infection include age, ethnicity, sex, geography, and socioeconomic status.

Helicobacter Pylori

H. pylori is usually contracted in the first few years of life and tends to persist indefinitely unless treated. The infection normally resides in the stomach and is transmitted through ingestion of fecal-contaminated water or food. The organism causes **gastritis** in all infected individuals, but fewer than 10% will develop symptomatic PUD.

Nonsteroidal Anti-Inflammatory Drugs

Nearly half of people with chronic NSAID ingestion experience nausea and dyspepsia. Peptic ulceration occurs in up to 30% of chronic NSAID (including aspirin) users, with GI bleeding or perforation occurring in 1.5% of patients who develop an ulcer.[2] Ulcer-related complications result in 100,000 hospitalizations and more than 20,000 deaths in the United States each year.[2]

Risk factors for NSAID-induced PUD and complications are presented in Table 19–1. Risk factors are generally additive. Corticosteroid therapy is not an independent risk factor for ulceration but increases PUD risk substantially when combined with NSAID therapy.[6] Whether *H. pylori* infection is a risk factor for NSAID-induced ulcers remains controversial; however, *H. pylori* and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and also appear to have synergistic effects.[7,8]

Stress-Related Mucosal Damage

SRMD occurs most frequently in critically ill patients due to mucosal defects caused by gastric mucosal ischemia and intraluminal acid.[9] The ulcers are usually superficial, but SRMD may

Table 19–1

Risk Factors for Ulcers and GI Complications Related to NSAID Use

- Age older than 65 years
- Concomitant anticoagulant use
- Preexisting coagulopathy (elevated INR or thrombocytopenia)
- Concomitant corticosteroid therapy
- Previous PUD or PUD complications (bleeding/perforation)
- Cardiovascular disease and other comorbid conditions
- Multiple NSAID use (eg, low-dose aspirin plus another NSAID)
- Longer duration of NSAID use
- High-dose NSAID use

GI, gastrointestinal; INR, international normalized ratio; NSAID, nonsteroidal anti-inflammatory drug; PUD, peptic ulcer disease.

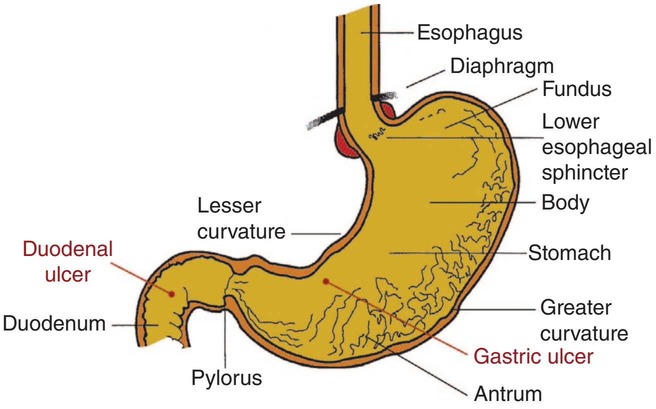

FIGURE 19–1. Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers. (From Love BL, Mohorn PL. Peptic ulcer disease and related disorders. In: DiPiro JT, Yee GC, Posey L, Haines ST, Nolin TD, Ellingrod V, eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020: Chapter 50)

also penetrate into the submucosa and cause significant GI bleeding. Physiologically stressful situations that lead to SRMD include sepsis, organ failure, prolonged mechanical ventilation, thermal injury, and surgery. Critical care patients with these specific characteristics are at highest risk.[10]

Zollinger–Ellison Syndrome

Zollinger–Ellison syndrome (ZES) is caused by a gastrin-producing tumor called a gastrinoma. The resulting gastric acid hypersecretion causes diarrhea and malabsorption. Ulcers tend to be numerous and have a high risk of perforation and bleeding.[11] Treatments include surgical resection when feasible and high-dose oral proton pump inhibitor (PPI) therapy.

Other Causative Factors

Cigarette smoking is associated with a higher prevalence of ulcers in *H. pylori*-infected patients.[2] The detrimental effects of smoking on the gastric mucosa may involve increased pepsin secretion, duodenogastric reflux of bile salts, elevated levels of free radicals, and reduced prostaglandin-2 (PG_2) production, resulting in decreased mucus and bicarbonate secretion.[12]

Although psychosocial factors such as life stress, personality patterns, and depression may influence PUD prevalence, a clear causal relationship has not been demonstrated.[2] Dietary factors such as coffee, tea, cola, alcohol, and spicy foods may cause dyspepsia but have not been shown to independently increase PUD risk.

PATHOPHYSIOLOGY

Ulcers related to *H. pylori* infection more commonly affect the duodenum (duodenal ulcers [DUs]), whereas NSAID-related ulcers more frequently affect the stomach (gastric ulcers [GUs]) (Figure 19–1). However, ulcers may be found in either location from either cause.[11]

Ulcer formation in the GI tract results from disrupted homeostasis between factors that break down food (eg, gastric acid and pepsin) and those that promote mucosal defense and repair (eg, bicarbonate, mucus secretion, and PGs).

Gastric Acid and Pepsin

Hydrochloric acid and pepsin are the primary substances that cause gastric mucosal damage in PUD. Three different stimuli (histamine, acetylcholine, and gastrin) cause acid secretion through interactions with the histaminic, cholinergic, and gastrin receptors on the surface of parietal cells. Gastric acid output occurs in two stages: (a) basal acid output in the fasting state and (b) maximal acid output in response to meals. Basal acid secretion follows a circadian cycle and is modulated by the effects of acetylcholine and histamine on parietal cells.[13]

Food increases gastric acid secretion in two ways: (a) vagus nerve stimulation in response to sight, smell, or taste; and (b) stomach distention during the gastric and intestinal phases of acid secretion.

After stimulation by histamine, acetylcholine, or gastrin, acid is secreted by the H^+-K^+-$ATPase^+$ (proton) pump, located on the luminal side of parietal cells. Acid secretion in PUD is usually normal or only slightly elevated. NSAID ingestion does not usually affect acid secretion, whereas *H. pylori* infection often slightly increases acid output.[13]

Pepsinogen released from chief cells in the body of the stomach is converted to pepsin in an acidic environment; pepsin initiates protein digestion and collagen proteolysis and serves as a signal for the release of other digestive enzymes such as gastrin and cholecystokinin.[14] The proteolytic activity of pepsin appears to influence ulcer formation.

Mucosal Defense and Repair

Several normal processes prevent mucosal damage and subsequent ulcer formation. The buffering action of the mucus/phospholipid and bicarbonate barrier shields the gastric epithelial surface from gastric acid.[2] This allows an acidic environment in the gastric lumen but a near neutral pH on the epithelial lining.

PGs inhibit gastric acid secretion and protect gastric mucosa by stimulating mucus, bicarbonate, and phospholipid production. PGs also increase mucosal blood flow and stimulate epithelial cell regeneration.[2] Damage to the mucosal defense system is the primary method by which *H. pylori* and NSAIDs cause peptic ulcers.

▸ *Helicobacter pylori*

H. pylori, a Gram-negative rod, is found on the surface of the gastric epithelium. Flagella provide motility that allows the organism to penetrate the mucous gel barrier and infect epithelial cells.[6] Cellular invasion by *H. pylori* is necessary for an active infection. The organism survives in the acidic milieu of the stomach by producing urease, an enzyme that hydrolyzes the urea in gastric juice into carbon dioxide and ammonia.[6]

H. pylori may cause gastroduodenal mucosal injury through (a) direct mucosal damage, (b) alterations in host inflammatory responses, and (c) hypergastrinemia and elevated acid secretion.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs can cause gastric mucosal damage by two mechanisms: (a) direct irritation of the gastric epithelium and (b) systemic inhibition of endogenous mucosal PG synthesis. Direct irritation occurs because NSAIDs are weak acids. Less acidic agents, such as nonacetylated salicylates, may lead to decreased GI toxicity.[6] Direct irritant effects contribute to NSAID-induced gastritis but play only a minor role in the development of NSAID-induced PUD.

Systemic inhibition of PG synthesis is the primary means by which NSAIDs cause PUD. NSAID inhibition of PG production by blocking the cyclooxygenase-2 (COX-2) enzyme produces beneficial analgesic and anti-inflammatory effects. However, NSAIDs may also block the COX-1 enzyme, which produces PGs that provide gastroprotection. NSAIDs given parenterally (eg, ketorolac) and rectally (eg, indomethacin) have an incidence of PUD similar to oral NSAIDs. Topical NSAIDs (eg, diclofenac) are unlikely to cause PUD because very low serum concentrations are achieved. The antiplatelet effects of NSAIDs may worsen bleeding complications associated with PUD.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation

See text box for the clinical presentation of PUD. Dyspepsia (upper abdominal discomfort) is found in 10% to 40% of the general population. PUD is found in 5% to 15% of patients with dyspepsia.

PUD can be classified as uncomplicated or complicated. Uncomplicated disease is typically characterized by mild epigastric pain, whereas complicated disease involves acute upper GI complications such as GI bleeding, obstruction, or perforation. Bleeding may be occult or may present as melena or hematemesis. Up to 20% of patients who develop a PUD-related hemorrhage do not have prior symptoms. Gastric outlet obstruction is usually caused by ulcer-related inflammation or scar formation. Patients typically present with early satiety after meals, nausea, vomiting, abdominal pain, and weight loss. Perforation requires emergent surgical intervention, and these patients should not undergo endoscopy.

Clinical Presentation of PUD

Symptoms

- Dyspepsia and mild epigastric pain that may be described as burning, gnawing, or aching in character.
- Epigastric pain with DUs typically occurs 1 to 3 hours after meals or at night and is often relieved by food.
- Pain with GUs is often aggravated by food.
- Abdominal pain may be described as burning or a feeling of discomfort.
- Pain severity often fluctuates and the character can vary from dull to sharp.
- Patients may also complain of heartburn, belching, bloating, nausea, or vomiting.

Signs

- Weight loss may be associated with nausea and vomiting.
- Complications such as bleeding, perforation, or obstruction may occur.
- Alarm findings include family history of upper GI malignancy, unintentional weight loss, overt GI bleeding, iron deficiency anemia, progressive dysphagia or odynophagia, early satiety, persistent vomiting, palpable mass, or lymphadenopathy.

Diagnosis

Radiologic and/or endoscopic procedures are usually required to document the presence of ulcers. Because endoscopic testing is invasive and expensive, it is only indicated in patients 60 years of age or older with new-onset dyspepsia.[15] Patients with dyspepsia who are younger than 60 years may forego endoscopy but should be tested for *H. pylori* using noninvasive methods and treated if positive.[15] Those who test negative for *H. pylori* should be offered a trial (4–8 weeks) of acid suppression therapy or proceed to endoscopy. Persistent dyspepsia despite a trial of acid suppressive therapy warrants upper endoscopy evaluation.[1]

Testing for *H. pylori* infection is indicated in patients with active PUD, history of documented PUD, low-grade gastric mucosa-associated lymphoid tissue (MALT) lymphoma, or history of endoscopic resection of early gastric cancer.[16] Diagnostic tests to detect *H. pylori* presence can be either endoscopic or nonendoscopic.[16,17] Endoscopic diagnosis involves extraction of gastric tissue samples that are subsequently tested for *H. pylori*.[16] Histology is the standard identification method, but culture, polymerase chain reaction (PCR), and the rapid urease test can also identify *H. pylori* in tissue samples.[18]

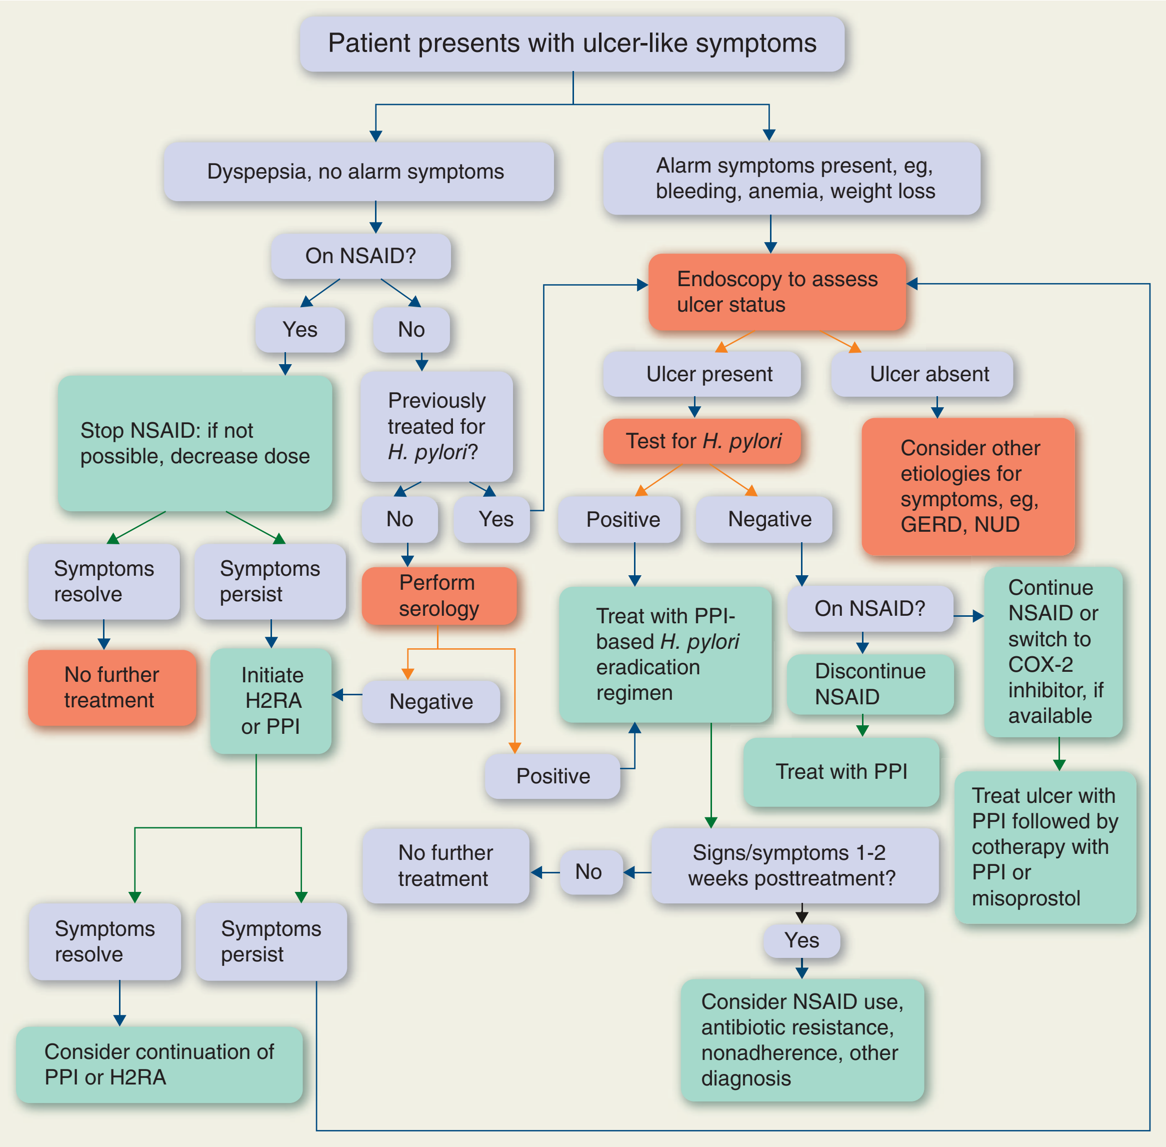
Nonendoscopic testing methods for *H. pylori* include the urea breath test, serologic testing, and stool antigen assay.[16,17] These tests are less invasive and less expensive than endoscopy. The urea breath test is usually first line because of its high sensitivity and specificity and short turnaround time.[18] Concomitant acid-suppressive or antibiotic therapy may give false-negative results.[18] The urea breath test can also be used to confirm eradication of *H. pylori* infection.[18]

Serologic testing provides a quick (within 15 minutes) office-based assessment of exposure to *H. pylori*, but it cannot differentiate active infection from previously treated infection; patients can remain seropositive for years after eradication. Serologic testing is also less sensitive and specific than the urea breath test.[17] Serologic testing is recommended in patients with recent or current antibiotic or acid-suppressive therapy.[18]

Stool antigen assays can be useful for initial diagnosis or to confirm *H. pylori* eradication. They have high sensitivity and specificity and are affected less by concomitant medication use.[17] Use of antimicrobial agents within 4 weeks, PPIs within 2 weeks, and histamine-2 receptor antagonists (H_2RAs) within 24 hours of testing can suppress the infection and reduce the sensitivity of testing.[17]

TREATMENT

The treatment selected for PUD depends on the etiology of the ulcer, whether the ulcer is new or recurrent, and whether complications have occurred. Figure 19–2 shows an algorithm for evaluation and treatment of a patient with signs and symptoms suggestive of an *H. pylori*–associated or NSAID-induced ulcer.



Patient presents with ulcer-like symptoms
Dyspepsia, no alarm symptoms
Alarm symptoms present, eg, bleeding, anemia, weight loss
On NSAID?
Yes
No
Endoscopy to assess ulcer status
Stop NSAID: if not possible, decrease dose
Previously treated for *H. pylori*?
Ulcer present
Ulcer absent
Test for *H. pylori*
Consider other etiologies for symptoms, eg, GERD, NUD
No
Yes
Positive
Negative
Symptoms resolve
Symptoms persist
Perform serology
Treat with PPI-based *H. pylori* eradication regimen
On NSAID?
Continue NSAID or switch to COX-2 inhibitor, if available
No further treatment
Initiate H2RA or PPI
Negative
Discontinue NSAID
Treat with PPI
Positive
Treat ulcer with PPI followed by cotherapy with PPI or misoprostol
No further treatment
No
Signs/symptoms 1-2 weeks posttreatment?
Symptoms resolve
Symptoms persist
Yes
Consider continuation of PPI or H2RA
Consider NSAID use, antibiotic resistance, nonadherence, other diagnosis

FIGURE 19–2. Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. (COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; H_2RA, H_2-receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; NUD, nonulcer dyspepsia; PPI, proton pump inhibitor.) (From Love BL, Mohorn PL. Peptic ulcer disease and related disorder. In: DiPiro JT, Yee GC, Posey L, Haines ST, Nolin TD, Ellingrod V, eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020: Chapter 50.)

Desired Outcomes

The goals of PUD therapy are to resolve symptoms, reduce acid secretion, promote epithelial healing, prevent ulcer-related complications, and prevent ulcer recurrence. For *H. pylori*–related PUD, eradication of *H. pylori* is an additional outcome.

Nonpharmacologic Therapy

▶ *Risk Factor Avoidance*

KEY CONCEPT Patients with PUD should avoid exposure to factors known to worsen the disease, exacerbate symptoms, or lead to ulcer recurrence. Patients should be advised to reduce psychological stress and avoid cigarette smoking, alcohol consumption, and NSAID or aspirin use, if possible. Patients who require chronic NSAID therapy (eg, for rheumatoid arthritis) may be given prophylaxis with misoprostol or a PPI (see Prevention of NSAID-Induced Ulcers section).

▶ *Surgery*

The high success rates of medical therapies have reduced the need for surgical procedures. Elective surgeries performed for PUD have decreased dramatically since the 1980s, mainly due to *H. pylori* eradication.[19] Surgical interventions are generally reserved for complicated or refractory PUD.

For patients with acute GI bleeding, endoscopic hemostasis can be achieved using contact thermal therapy, mechanical therapy using clips, or epinephrine injection followed by either thermal or mechanical therapy.[19] Angiography with embolization of bleeding lesions can be used if the bleeding cannot be stopped endoscopically and the patient is either high risk for surgery or not a surgical candidate.[19]

Pharmacologic Therapy

▶ *Treatment of* Helicobacter pylori*–Associated Ulcers*

The goal of *H. pylori* therapy is to eradicate the organism using an effective antibiotic-containing regimen. KEY CONCEPT Reliance on

Table 19–2

Drug Regimens to Eradicate *Helicobacter pylori*

Treatment Regimen	Medications	Duration
Clarithromycin triple therapy	Clarithromycin 500 mg BID + amoxicillin 1 g BID OR metronidazole 500 mg TID + PPI BID	14 days
Bismuth quadruple therapy[a]	Bismuth subsalicylate 300 mg QID + metronidazole 250–500 mg QID + tetracycline 500 mg QID + PPI BID	10–14 days
Concomitant therapy[a]	Clarithromycin 500 mg BID + amoxicillin 1 g BID + nitroimidazole[c] 500 mg BID + PPI BID	10–14 days
Sequential therapy	Amoxicillin 1 g BID + PPI BID followed by: clarithromycin 500 mg BID + nitroimidazole[c] 500 mg BID + PPI BID	5–7 days 5–7 days
Hybrid therapy	Amoxicillin 1 g BID + PPI BID followed by amoxicillin 1 g BID + clarithromycin 500 mg BID + nitroimidazole[c] 500 mg BID + PPI BID	7 days 7 days
Levofloxacin triple therapy	Levofloxacin 500 mg daily + amoxicillin 1 g BID + PPI BID	10–14 days
Levofloxacin sequential therapy	Amoxicillin 1 g BID + PPI BID followed by amoxicillin 1 g BID + levofloxacin 500 mg daily + nitroimidazole[c] 500 mg BID + PPI BID	5–7 days 5–7 days
Rifabutin triple therapy[b]	Rifabutin 300 mg daily + amoxicillin 1 g (BID or TID)[d] + PPI BID	10 days
High-dose dual therapy	Amoxicillin (1 g TID or 750 mg QID) + PPI (TID or QID)	14 days
Combination Therapies		
PREVPAC	Clarithromycin 500 mg BID + amoxicillin 1 g BID + lansoprazole 30 mg BID (contained in blister pack cards)	10–14 days
Pylera + omeprazole	(Bismuth subcitrate potassium 140 mg + metronidazole 125 mg + tetracycline 125 mg) three capsules QID + omeprazole 20 mg BID	10 days

[a] Regimens with strong recommendation based on current guidelines.

[b] Salvage regimen only.

[c] Metronidazole or tinidazole.

[d] Dosing varied in clinical trials.

BID, twice daily; H_2RA, histamine-2 receptor antagonist; PPI, proton pump inhibitor; QID, four times daily; TID, three times daily.

From Chey WD, Leontiadis GI, Howden CW, et al. ACG Clinical Guideline: treatment of *Helicobacter pylori* infection. Am J Gastroenterol. 2017;112:212–238.

conventional acid-suppressive drug therapy alone as an alternative to *H. pylori* eradication is inappropriate because it is associated with a higher incidence of ulcer recurrence and ulcer-related complications. Reinfection rates are generally low after the initial course of therapy as long as the patient is adherent. In addition to proven efficacy, the optimal treatment regimen should cause minimal adverse events, have low risk for development of bacterial resistance, and be cost-effective.[16,17]

H. pylori treatment regimens are presented in Table 19–2. **KEY CONCEPT** Eradication therapy should be pursued in all patients who test positive for *H. pylori* infection. Several regimens are recommended as first-line eradication therapy. Different antibiotics should be used if a second course of *H. pylori* eradication therapy is required. The cure rates of *H. pylori* with H_2RAs in combination with antibiotics are lower than when PPIs are included in the regimen.[16]

Important considerations in selecting first-line treatment regimens include presence of a penicillin allergy and previous exposure to macrolide antibiotics. Acceptable first-line regimens that carry strong recommendations include bismuth quadruple therapy as well as concomitant therapy. Other acceptable regimens for first-line treatment with weak recommendations include (a) clarithromycin triple therapy in regions with clarithromycin resistance less than 15% when a patient has no previous macrolide exposure, (b) sequential therapy, (c) hybrid therapy, (d) levofloxacin triple therapy, and (e) fluoroquinolone sequential therapy. Substitution of one PPI for another is acceptable and does not affect eradication rates. Alcohol consumption must be considered prior to selecting a metronidazole containing treatment regimen.[16]

The duration of therapy for *H. pylori* eradication is controversial; US guidelines recommend either 10 or 14 days.[16] A treatment duration of 14 days should be considered because of higher eradication rates than with a 10-day course; however, the data supporting this recommendation are based on a relatively small number of participants in clinical trials.[16,20] Treatment courses longer than 14 days may decrease adherence and increase drug costs; ultimately, the most effective eradication regimens still fail in 10% to 20% of patients.[16]

Bismuth-based four-drug regimens have clinical cure rates similar to three-drug PPI-based regimens.[21] Bismuth salts promote ulcer healing through antibacterial and mucosal protective effects. Disadvantages of bismuth-based regimens include frequency of administration (four times a day), risk for salicylate toxicity in renal impairment, and bothersome side effects (eg, stool and tongue discoloration, constipation, nausea, vomiting).[16]

Pylera and PREVPAC are proprietary products designed to improve regimen adherence (Table 19–2). Pylera is a combination product, whereas PREVPAC is a conveniently packaged eradication regimen. Both products are substantially more expensive than their individual generic and nonprescription components.

Recent literature has indicated a potential role for probiotics in first-line treatment of *H. pylori*. Probiotic therapy has been associated with increased cure rates and reduced side effects

Patient Encounter 1

A 55-year-old man presents with abdominal pain and indigestion that occur two to three times per week. He also reports that his abdominal pain worsens a couple of hours after eating. He does not report any recent antibiotic use.

PMH: Hypertension × 5 years, hyperlipidemia × 7 years

FH: Mother alive at 81 with hypertension, type 2 diabetes; father alive at 83 with hypertension

SH: Smokes half pack per day; occasional alcohol use; no illicit drug use

Allergies: Sulfa

Meds: Lisinopril 40 mg daily, amlodipine 10 mg daily, atorvastatin 40 mg daily, ibuprofen 200 mg as needed for headache

Based on this patient's clinical presentation, what is the most appropriate course of action to establish a diagnosis?

The patient receives a diagnosis of Helicobacter pylori infection based on the diagnostic method recommended. What eradication therapy would you recommend?

The patient completed the course of eradication therapy recommended; however, he returns with similar symptoms 3 months later. What regimen would you recommend for eradication therapy?

compared to conventional eradication regimens. However, further study is needed due to limitations of the available evidence. Current guidelines reinforce several areas for additional research regarding optimal dosing of probiotic therapy.[16]

Patients may remain infected with *H. pylori* after the initial treatment course because of reinfection, nonadherence, or antimicrobial resistance. Factors associated with decreased adherence include polypharmacy, need for frequent drug administration or long treatment duration, and use of drugs that may cause intolerable side effects. Potential adverse drug effects include taste disturbances (clarithromycin and metronidazole), nausea, vomiting, abdominal pain, and diarrhea. Superinfections with oral thrush or vaginal candidiasis can occur. Alcohol should be avoided during treatment with metronidazole or tinidazole due to the potential for a disulfiram-like reaction.

Resistance data for *H. pylori* in the United States are limited. Data from a Veterans Affairs Medical Center demonstrated clarithromycin resistance rates exceeding the threshold for use in current guidelines. A threshold of 15% to 20% is recommended to differentiate between regions of high and low clarithromycin resistance. In the setting of resistance, efficacy of a three-drug regimen containing clarithromycin can decrease to 10% to 30%. Culture and sensitivity tests are not routinely performed with *H. pylori* infection unless a patient has already failed two different treatment regimens; these tests are not widely available in the United States.[16,20]

Initiation of a second *H. pylori* treatment regimen after failure of the initial treatment is usually associated with a lower success rate. Reasons for failure are often the same as for failure of the initial regimen. Selection of a salvage treatment regimen should be based on the initial treatment the patient received, history of quinolone exposure, and penicillin allergy status.

- If clarithromycin triple therapy was used as the initial treatment regimen and the patient is not penicillin allergic, recommended salvage therapies include (a) bismuth quadruple therapy, (b) levofloxacin triple therapy, (c) rifabutin triple therapy, or (d) high-dose dual therapy. For patients who received initial clarithromycin triple therapy and are penicillin allergic, bismuth quadruple therapy is recommended.
- When bismuth quadruple therapy was the initial treatment regimen and the patient is not penicillin allergic, recommended salvage regimens include (a) levofloxacin triple therapy, (b) concomitant therapy, (c) rifabutin triple therapy, or (d) high-dose dual therapy. Levofloxacin triple therapy should be avoided in patients with previous quinolone exposure. Salvage regimens are less well defined for patients who received bismuth quadruple therapy as initial treatment and are penicillin allergic.
- There is no standard third-line therapy for *H. pylori* treatment.[16]

Confirmation of *H. pylori* infection eradication is recommended in all treated patients.[16] Testing should occur at least 4 weeks after completion of the eradication regimen and 1 to 2 weeks after discontinuation of PPI.[16] Eradication may be confirmed by either the urea breath test or stool antigen testing. Eradication may also be confirmed by endoscopy, but this should only be done when endoscopy is required because it is more expensive and invasive.[17]

▶ *Treatment of NSAID-Induced Ulcers*

Treatment recommendations to heal NSAID-induced ulcers or provide maintenance therapy in patients receiving NSAIDs are shown in Table 19–3. Choice of regimen depends on whether NSAID use is to be continued. NSAIDs should be discontinued and replaced with alternatives (eg, acetaminophen), when possible. For patients who cannot discontinue NSAID therapy, PPIs, H_2RAs, or sucralfate are effective for ulcer healing and to prevent further recurrences.[11] PPIs are usually preferred because

Patient Encounter 2

A 61-year-old man presents with persistent epigastric pain and bloating. His chief complaint today is, "It feels like my ulcer is back!"

PMH: Hypertension × 15 years

FH: Mother deceased at age 66, cancer; father alive at 85 with hypertension, dyslipidemia

SH: Nonsmoker, 1 to 2 alcoholic beverages three times weekly, no illicit drug use

Allergies: NSAIDs

Meds: Lisinopril 40 mg daily, hydrochlorothiazide 25 mg daily, amlodipine 10 mg daily

The patient previously completed the following course for *Helicobacter pylori* eradication but admits to maybe missing a day or two:

- PREVPAC for 14 days

H. pylori recurrence is confirmed with a urea breath test.

What are possible reasons for treatment failure in this patient?

What regimen would you recommend for salvage eradication therapy?

Table 19–3

Oral Drug Regimens to Heal Peptic Ulcers or Maintain Ulcer Healing in the Absence of Antibiotic Therapy

Drug	DU or GU Healing	Maintenance of DU or GU Healing
Mucosal Protectant		
Sucralfate	1 g four times a day 2 g two times a day	1 g four times a day 1–2 g two times a day
H_2-Receptor Antagonists		
Cimetidine	300 mg four times a day 400 mg two times a day 800 mg at bedtime	400–800 mg daily
Famotidine	20 mg two times a day 40 mg at bedtime	20–40 mg daily
Nizatidine	150 mg two times a day 300 mg at bedtime	150–300 mg daily
Proton Pump Inhibitors		
Dexlansoprazole	30–60 mg daily	30–60 mg daily
Esomeprazole	20–40 mg daily	20–40 mg daily
Lansoprazole	15–30 mg daily	15–30 mg daily
Omeprazole	20–40 mg daily	20–40 mg daily
Pantoprazole	40 mg daily	40 mg daily
Rabeprazole	20 mg daily	20 mg daily

DU, duodenal ulcer; GU, gastric ulcer.

they provide more rapid relief of symptoms, have the strongest acid suppression, and heal ulcers more quickly than H_2RAs or sucralfate.[11] Standard doses of H_2RAs effectively heal DUs but are minimally effective in GUs. A PPI provides equivalent efficacy with treatment duration of only 4 weeks. PPI therapy should only be continued for longer than 4 weeks if an ulcer is confirmed to still be present or if the patient develops severe complications from PUD.

▸ *Prevention of NSAID-Induced Ulcers*

Prophylactic regimens against PUD are often required in patients receiving long-term NSAID or aspirin therapy for osteoarthritis, rheumatoid arthritis, or cardioprotection.[22] Misoprostol, H_2RAs, PPIs, and COX-2 selective inhibitors have been evaluated in controlled trials to reduce the risk of NSAID-induced PUD. KEY CONCEPT In patients at risk for NSAID-induced ulcers, PPIs at standard doses reduce the risk of both GUs and DUs as effectively as misoprostol and more effectively than H_2RAs. In addition, PPIs are generally better tolerated than misoprostol.

Misoprostol A synthetic prostaglandin E_1 (PGE_1) analog that exogenously replaces PG stores, misoprostol is indicated for reducing the risk of NSAID-induced GUs in patients at high risk of complications from ulcers (eg, the elderly and patients with concomitant debilitating disease), as well as patients at high risk of developing gastric ulceration, such as patients with a history of ulcers. Misoprostol 200 mcg four times a day reduces ulcer complications by inhibiting acid secretion and promoting mucosal defense. It is superior to H_2RAs for prevention of NSAID-induced ulcers.[23] Misoprostol use is limited by a high frequency of bothersome GI effects such as abdominal pain, flatulence, and diarrhea, and it is contraindicated in pregnancy due to potential abortifacient effects. Arthrotec is a combination product that contains diclofenac (either 50 or 75 mg) and misoprostol 200 mcg in a single tablet.

H_2-Receptor Antagonists The efficacy of H_2RAs (eg, famotidine 40 mg daily) in preventing NSAID-related ulcers varies. DUs appear to respond better than GUs (the most frequent type of ulcer associated with NSAIDs). Higher doses of H_2RAs (eg, famotidine 40 mg twice daily) may reduce the risk of NSAID-induced GUs and DUs but results from clinical trials are variable.

Duexis, a prescription combination product containing ibuprofen 800 mg and famotidine 26.6 mg, is indicated for relief of signs and symptoms of rheumatoid arthritis and osteoarthritis and to decrease the risk of developing upper GI ulcers. The recommended dosage is one tablet orally three times daily. Clinical trials evaluating this agent are 6 months or less in duration and primarily evaluated patients younger than 65 years with no ulcer history.

Proton Pump Inhibitors PPI therapy is more effective than H_2RAs in reducing the risk of nonselective NSAID-related GUs and DUs.[23] PPIs are as effective as misoprostol but better tolerated. All PPIs are effective when used in standard doses. In patients who experience a PUD-related bleeding event while taking aspirin but who require continued aspirin therapy, the addition of a PPI reduces the incidence of recurrent GI bleeding.[24] Prevacid NapraPAC provides naproxen (either 250, 375, or 500 mg) and lansoprazole 15 mg in individual blister packages. Vimovo provides naproxen (either 375 or 500 mg) and esomeprazole 20 mg in each tablet.

COX-2 Selective Inhibitors NSAIDs with COX-2 selectivity were developed in an attempt to reduce the incidence of PUD and its complications. KEY CONCEPT Selective COX-2 inhibitors are no more effective than the combination of a PPI and a nonselective NSAID in reducing the incidence of ulcers. Celecoxib is the only agent in this class available in the United States. There was no difference in cardiovascular outcomes when celecoxib was compared to ibuprofen and naproxen.[25,26]

Sucralfate This drug is a negatively charged, nonabsorbable agent that forms a complex by binding with positively charged proteins in exudates, forming a viscous, paste-like adhesive substance that protects the ulcerated area of the gastric mucosa against gastric acid, pepsin, and bile salts.[6] Limitations of sucralfate include the need for multiple doses per day, large tablet size, and interaction with a number of other medications (eg, digoxin, fluoroquinolones).

Adverse effects of sucralfate include constipation, nausea, metallic taste, and the possibility for aluminum toxicity in patients with renal failure. Sucralfate is effective for treatment of NSAID-related ulcers when the NSAID will be stopped, but it is not recommended for NSAID-related ulcer prophylaxis.

▸ *Prevention of Stress-Related Mucosal Damage*

Prevention of stress ulcers involves maintaining hemodynamic stability to maximize mesenteric perfusion and pharmacologic suppression of gastric acid production. Stress ulcer prophylaxis (SUP) is only indicated in intensive care unit (ICU) patients with certain risk factors (see Table 19–4).[9,27] The clinician must weigh the risks and benefits of using acid suppression, especially PPIs, in low-risk patients. PPIs and H_2RAs are the drugs of choice for SUP; however, antacids and sucralfate may be acceptable options in some patients.

Table 19–4

Appropriate Indications for Stress Ulcer Prophylaxis in Intensive Care Unit Patients

- Mechanical ventilation for longer than 48 hours
- Coagulopathy or hepatic failure (platelet count < 50 × $10^3/\text{mm}^3$ [50 × 10^9/L], INR > 1.5, or aPTT > two times control)
- History of GI ulceration or bleeding within 1 year of admission
- Head trauma or Glasgow Coma Score of 10 or less (or inability to obey simple commands)
- Thermal injuries to more than 35% of body surface area
- Multiple traumas (injury severity score of 16 or greater)
- Partial hepatectomy
- Transplant patients in the ICU perioperatively
- Spinal cord injuries
- Two of the following risk factors: sepsis, ICU stay for more than 1 week, occult bleeding lasting 6 or more days, and use of high-dose corticosteroids (> 250 mg/day of hydrocortisone or equivalent)

aPTT, activated partial thromboplastin time; GI, gastrointestinal; ICU, intensive care unit; INR, international normalized ratio.

Data from Plummer MP, Reintam Blaser A, Deane AM. Stress ulceration: prevalence, pathology and association with adverse outcomes. Crit Care. 2014;18(2):213 and Nissen SE, Yeomans ND, Solomon DH. Cardiovascular safety of celecoxib, naproxen, or ibuprofen for arthritis. N Engl J Med. 2016;375:2519–2529.

▶ *Long-Term Maintenance of Ulcer Healing*

KEY CONCEPT Low-dose maintenance therapy with a PPI or H_2RA is only indicated in patients with severe complications secondary to PUD, such as gastric outlet obstruction or patients who need to be on long-term NSAIDs or high-dose corticosteroids and are at high risk for bleeding. Drug regimens and doses for PUD treatment and maintenance are presented in Table 19–3.

▶ *Treatment of GI Bleeding*

The immediate priorities in treating patients with a bleeding peptic ulcer are to achieve IV access, correct fluid losses, and restore hemodynamic stability. Insertion of a nasogastric tube is helpful in initial patient assessment, but the absence of bloody or coffee-ground material in any gastric content drainage does not definitively rule out ongoing or recurrent bleeding.

Patients should be started on IV PPI therapy because optimal platelet aggregation, partially inhibited fibrinolysis, and better clot stabilization on the ulcer are achieved when the gastric pH is greater than 6.[28] Intravenous PPI therapy should be continued for 72 hours (because most rebleeding occurs during this time) followed by oral PPI therapy. Three-day PPI infusion therapy has been shown to be as effective as twice-daily IV PPI therapy.[28]

▶ *Treatment of Refractory Ulcers*

Refractory ulcers are defined as ulcers that fail to heal despite 8 to 12 weeks of acid suppressive therapy.[1] The presence of refractory ulcers requires a thorough assessment, including evaluation of medication adherence, extensive counseling and questioning regarding recent over-the-counter and prescription medication use, and testing for *H. pylori* using a different method than previously done, if testing was negative. Changing from H_2RA therapy to a PPI should be considered.[6] Other considerations include esophagogastroduodenoscopy (EGD) with biopsy of the

Patient Encounter 3

A 63-year-old woman presents with reports of dark, tarry stools for 3 days. She denies coffee-ground emesis or recent weight loss but reports occasional heartburn and belching.

PMH: Hypertension × 20 years, type 2 diabetes × 15 years, dyslipidemia × 15 years, osteoarthritis × 10 years, asthma × 25 years, myocardial infarction 5 years ago

FH: Mother deceased at age 82, stroke; father deceased at age 74, MI; one sister alive at 66 with hypertension, type 2 diabetes, and dyslipidemia

SH: Denies smoking, alcohol, or illicit drug use

Allergies: NKDA

Meds: Lisinopril 40 mg daily, amlodipine 10 mg daily, metformin 1000 mg twice daily, glipizide 10 mg twice daily, rosuvastatin 20 mg daily, naproxen 500 mg two times daily, aspirin 81 mg daily, prednisone 5 mg daily, albuterol 2 puffs every 4 to 6 hours as needed for shortness of breath, fluticasone/salmeterol 250/50 mcg 1 inhalation twice daily, Tums Extra Strength as needed for heartburn

Other: An endoscopy reveals a duodenal ulcer that is negative for *Helicobacter pylori*

What risk factors does this patient have for GI complications related to NSAID use?

Make a recommendation for treatment of this patient's ulcer.

Discuss the use of prophylactic therapy in this patient after the treatment course is completed.

Patient Encounter 4

A 53-year-old man is brought to the surgical ICU after emergency surgery following a motor vehicle accident with significant head trauma. The patient is intubated and placed on mechanical ventilation. The physician would like him to remain mechanically ventilated and NPO (nothing by mouth) for several days until he improves clinically.

PMH: Hypertension × 20 years

FH: Father with hypertension

SH: Nonsmoker; 1 drink 1–2 times weekly; no illicit drug use

Allergies: Penicillin

Meds: Lisinopril/hydrochlorothiazide 20/25 mg daily, aspirin 81 mg daily, oxycodone 5 mg/acetaminophen 325 mg two tablets every 8 hours for surgical site pain

Based on this patient's clinical presentation, is he a candidate for stress ulcer prophylaxis?

What pharmacologic therapy would you recommend for this patient?

Four days later, the patient's condition has improved significantly and he is extubated. He is transferred to a general medicine floor and begins a regular diet that is well tolerated. He is alternating between oxycodone/acetaminophen and acetaminophen alone to relieve incision site pain. He is now sitting up in bed and feeling much better. Is this patient currently a candidate for stress ulcer prophylaxis?

Patient Care Process: Peptic Ulcer Disease

Collect Information:

- Obtain a history of prescription and over-the-counter medications and dietary supplements.
- Verify patient allergies and intolerances.
- Review the medical history and physical assessment findings.
- Speak with the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Based on review of signs and symptoms and assessment of risk factors (Table 19–1), determine whether the patient is experiencing signs or symptoms of PUD.
- Review available diagnostic tests (eg, serologic testing, urea breath test, stool antigen assay, endoscopy) to determine etiology of peptic ulcer.
- If patient is already receiving pharmacotherapy, assess its efficacy, safety, and patient adherence.
- Assess the potential for drug interactions, particularly in patients taking regimens containing metronidazole, clarithromycin, or cimetidine.

Develop a Care Plan:

- If patient has been diagnosed with a peptic ulcer, determine which course of therapy is indicated.
- Recommend an appropriate regimen (Tables 19–2 and 19–3) that will eradicate *Helicobacter pylori* and/or heal the peptic ulcer.
- Avoid drug classes to which the patient is allergic.
- If the patient has been treated for *H. pylori* previously, recommend different antibiotics if this episode is a result of treatment failure.
- Evaluate patient accessibility to medication (eg, formulary status, insurance coverage).

Implement the Care Plan:

- Inform patient about potential adverse drug effects and drug interactions.
- Educate the patient on the importance of adherence to eradication and ulcer-healing therapy.
- Identify appropriate lifestyle modifications.

Follow-up: Monitor and Evaluate:

- Assess patient adherence and progress toward efficacy and safety goals.
- Monitor annually for signs and symptoms of complications such as unintentional weight loss or bleeding.
- Evaluate the need for a prophylactic acid suppressive regimen in patients requiring chronic NSAID therapy.

ulcer to exclude malignancy, *H. pylori* testing (if not done initially), serum gastrin measurement to exclude ZES, and gastric acid studies.

OUTCOME EVALUATION

- Obtain a baseline complete blood count (CBC). Recheck the CBC if the patient exhibits alarm signs or symptoms.
- Obtain a baseline serum creatinine. Calculate the estimated creatinine clearance and adjust the dose of H_2RAs and sucralfate if needed.
- Obtain a history of symptoms from the patient. Monitor for improvement in pain symptoms (eg, epigastric or abdominal pain) daily.
- Monitor the patient for development of any alarm signs and symptoms.
- Recommend a follow-up visit if signs and symptoms worsen at any time or do not improve within the defined treatment period.
- Assess for potential drug interactions whenever there is a change in the patient's medications.
- Educate the patient on the importance of adhering to the *H. pylori* eradication regimen.
- Monitor the patient for complications related to antibiotic therapy (eg, diarrhea or oral thrush) during and after completion of *H. pylori* eradication therapy.
- Recommend follow-up care if the patient's signs and symptoms do not improve after completion of *H. pylori* eradication therapy.

Abbreviations Introduced in This Chapter

COX	Cyclooxygenase
DU	Duodenal ulcer
EGD	Esophagogastroduodenoscopy
GI	Gastrointestinal
GU	Gastric ulcer
H_2RA	Histamine-2 receptor antagonist
INR	International normalized ratio
MALT	Mucosa-associated lymphoid tissue
NSAID	Nonsteroidal anti-inflammatory drug
NUD	Nonulcer dyspepsia
PG	Prostaglandin
PGE_1	Prostaglandin E1
PPI	Proton pump inhibitor
PUD	Peptic ulcer disease
SRMD	Stress-related mucosal damage
SUP	Stress ulcer prophylaxis
ZES	Zollinger–Ellison syndrome

Inflammatory Bowel Disease

Brian A. Hemstreet

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Characterize the pathophysiologic mechanisms underlying inflammatory bowel disease (IBD).
2. Recognize the signs and symptoms of IBD, including major differences between ulcerative colitis (UC) and Crohn disease (CD).
3. Identify appropriate therapeutic outcomes for patients with IBD.
4. Describe pharmacologic treatment options for patients with acute or chronic symptoms of UC and CD.
5. Create a patient-specific drug treatment plan based on symptoms, severity, and location of UC or CD.
6. Recommend appropriate monitoring parameters and patient education for drug treatments for IBD.

INTRODUCTION

KEY CONCEPT The term inflammatory bowel disease (IBD) encompasses ulcerative colitis (UC) and Crohn disease (CD). Both disorders are associated with acute and chronic inflammation of the gastrointestinal (GI) tract. Differences exist between UC and CD with regard to regions of the GI tract that may be affected and the distribution and depth of intestinal inflammation. Patients with IBD may also develop inflammation involving organs other than the GI tract, known as *extraintestinal manifestations*. Symptoms of IBD are associated with significant morbidity, reduction in quality of life, and costs to the health-care system.[1–6]

EPIDEMIOLOGY AND ETIOLOGY

IBD is most common in Western countries such as the United States and Northern Europe. The age of initial presentation is bimodal, with patients typically diagnosed between the ages of 20 to 40 or 60 to 80 years. Approximately 1.5 million Americans have UC or CD.[2] Up to 70,000 new cases of IBD are diagnosed in the United States each year.[3]

Men and women are approximately equally affected by IBD in Western countries.[6] In general, White patients are affected more often than African American and Asian patients, and persons of Jewish descent are also at higher risk.[1,5,6] A positive family history of IBD is found in 8% to 14% of patients, and genetic risk may be more of a contributing factor in some ethic groups.[1,2,6]

The cause of IBD is not fully understood. Dysregulation of the inflammatory response within the GI tract in response to environmental or microbiologic factors is thought to be the prevailing mechanism.[3–5] The fact that a positive family history is a strong predictor of IBD supports the theory that genetic predisposition is involved in many cases. Many potential candidate genes have been identified.[1,2,4–6]

An alteration in the inflammatory response regulated by intestinal epithelial cells may also contribute to development of IBD. This may involve inappropriate processing of antigens presented to the GI epithelial cells.[3–5,7,8] The inflammatory response in IBD may be directed at bacteria that normally colonize the GI tract. Products derived from these bacteria may translocate across the mucosal layer of the GI tract and interact with various cells involved in immunologic recognition. The result is T-cell stimulation, excess production of proinflammatory cytokines, and persistent inflammation within the GI tract. Drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs) that disrupt the integrity of the GI mucosa may facilitate mucosal entry of intestinal antigens and lead to IBD flares.[9]

Use of oral contraceptives has been associated with increased development of CD in White patients in some cohort studies, but a strong causal relationship has not been proven.[5] Use of antibiotics in childhood and low levels of vitamin D have also been reported to increase risk of UC and CD.[5]

Smoking has protective effects in UC, leading to reductions in disease severity.[1,5] The opposite is true in CD because smoking may lead to increases in symptoms or worsening of the disease in Caucasian and Middle Eastern migrants.[5] Tea or coffee consumption is protective in Asian patients.[5]

PATHOPHYSIOLOGY

Ulcerative Colitis

The inflammatory response in UC is propagated by atypical type 2 helper T cells that produce proinflammatory cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor-α (TNF-α).[1,3,4,10,11] Alterations in colonocyte function, epithelial cell function, and in trefoil factors are implicated, as are alterations in intestinal bacterial composition, known as *dysbiosis*.[1] The potential role of environmental factors in development of UC implies that the immune response is directed against an unknown antigen. The findings that development and severity of UC are reduced in patients who smoke, those who have had appendectomies, and patients who were breastfed may support the theory that these factors may somehow modify either the genetic component or phenotypic response to immunologic stimuli.[3–5]

The inflammatory process within the GI tract is limited to the colon and rectum in patients with UC (Figure 20–1). Most

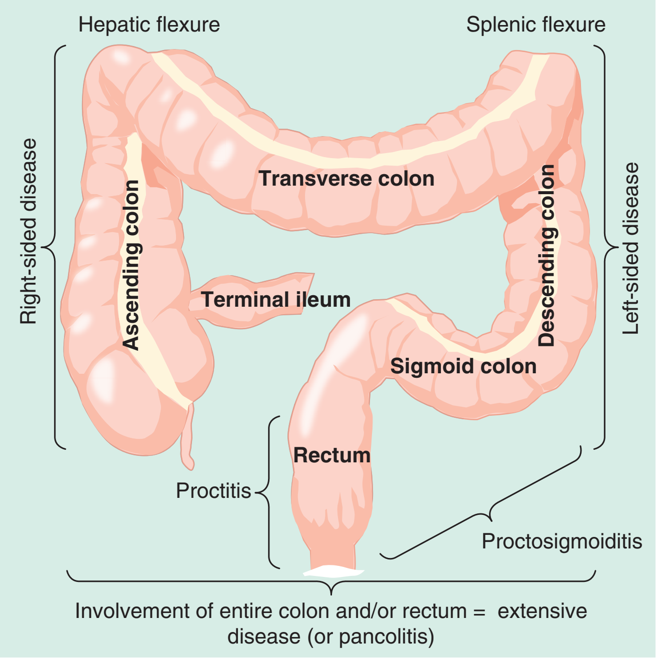

FIGURE 20–1. Major GI landmarks and disease distribution in inflammatory bowel disease.

patients with UC have involvement of the rectum (**proctitis**) or both the rectum and the sigmoid colon (**proctosigmoiditis**). Inflammation involving the entire colon is referred to as **extensive colitis**. Left-sided (distal) disease, defined as inflammation extending from the rectum to the splenic flexure, occurs in 16% to 45% of patients.[1,3,8,10] Up to 20% of cases of UC involve mild inflammation of the terminal ileum, referred to as *backwash ileitis*.[1]

The pattern of inflammation in UC is continuous and confluent throughout the affected areas of the GI tract. The inflammation is superficial and does not typically extend below the submucosal layer of the GI tract (**Figure 20–2**). Ulceration or erosion of the GI mucosa may be present, with loss of the normal vascular patter and friability.[1] Formation of **crypt abscesses** within the mucosal layers of the GI tract is characteristic of UC and may help to distinguish it from CD. Severe inflammation may also result in areas of hypertrophied GI mucosa, which may manifest as **pseudopolyps** within the colon.[1,10,11] The inflammatory response may progress in severity, leading to significant GI bleeding.

Transmural disease may result in penetration or fistula formation

FIGURE 20–2. Depth of disease penetration in ulcerative colitis and Crohn disease.

Crohn Disease

As with UC, the immune activation seen in CD involves the release of many proinflammatory cytokines. Cytokines thought to play major roles in CD are derived from T-helper type 1 cells and include interferon-γ, transforming growth factor-β, TNF-α, and IL-1, IL-6, IL-8, IL-12, and IL-23. TNF-α, IL-12, and IL-23 are major contributors to the inflammatory process and development of fibrosis in CD.[2–6,11,12] TNF-α effects include activation of macrophages, procoagulant effects in the vascular endothelium, and increased production of matrix metalloproteinases in mucosal cells.[10–15] TNF-α is also thought to induce production of nuclear factor κβ, which stimulates further production of TNF-α and other proinflammatory cytokines.[3,11] Alterations in Paneth cell function may also dictate the phenotypes of CD that are observed.[12] IL-12 and IL-23 are involved in T-cell and lymphocyte differentiation and expansion as part of the inflammatory process.[13]

In contrast to UC, the inflammation in CD may affect any part of the entire GI tract from the mouth to the anus. The small intestine is most commonly involved, and the terminal ileum and cecum are usually affected. Approximately 20% of patients have isolated colonic involvement, whereas inflammation proximal to the small intestine is almost never seen without the presence of small or large intestinal disease.[2,6]

The pattern of inflammation in CD is discontinuous; areas of inflammation are intermixed with areas of normal GI mucosa, resulting in characteristic “skip lesions.” Superficial **aphthous ulcers** may also develop in the GI mucosa. These ulcers may coalesce into larger linear ulcers, resulting in fissure formation as they increase in depth, giving rise to the characteristic “cobblestone” pattern observed upon examination of the mucosa.

The inflammation may be **transmural**, penetrating to the muscularis or serosal layers of the GI tract (Figure 20–2). This propensity for transmural involvement may lead to serious complications such as **strictures**, **fistulae**, abscesses, and perforation.[2,11] Although rectal inflammation is typically less common in CD than UC, several types of perianal lesions may be observed including skin tags, hemorrhoids, fissures, anal ulcers, abscesses, and fistulae.[14]

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT Differentiation between UC and CD is based on signs and symptoms as well as characteristic endoscopic findings, including the extent, pattern, and depth of inflammation. See accompanying box for the clinical presentation of IBD.

Extraintestinal Manifestations and Complications of IBD

KEY CONCEPT Patients may manifest signs and symptoms of disease in areas outside the GI tract (extraintestinal manifestations).[1,6,15] Painful joint complications associated with IBD include sacroiliitis

Clinical Presentation of IBD

General

- Patients with UC or CD may present with similar symptoms.
- The onset may be insidious and subacute.
- Some patients present with extraintestinal manifestations before GI symptoms occur.
- It may be impossible to distinguish between UC and CD in approximately 10% of cases. These patients are described as having "indeterminate colitis."

Symptoms

- *Ulcerative colitis*: Diarrhea (bloody, watery, or mucopurulent), rectal bleeding, abdominal pain/cramping, weight loss and malnutrition, **tenesmus**, constipation (with proctitis)
- *Crohn disease*: Diarrhea (less bloody than UC), rectal bleeding (less than UC), abdominal pain/cramping, weight loss and malnutrition (more common than UC), fatigue/malaise

Signs

- *Ulcerative colitis*: Fever, tachycardia (with severe disease), dehydration, arthritis, hemorrhoids, anal fissures, perirectal abscesses
- *Crohn disease*: Fever, tachycardia (with severe disease), dehydration, arthritis, abdominal mass and tenderness, perianal fissure or fistula

Laboratory Tests

- *Ulcerative colitis*: Leukocytosis, decreased hematocrit/hemoglobin, elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), positive test for fecal occult blood, (+) perinuclear antineutrophil cytoplasmic antibodies (pANCA; up to 70% of patients), and elevated fecal calprotectin
- *Crohn disease*: Leukocytosis, decreased hematocrit/hemoglobin, elevated ESR or CRP, positive test for fecal occult blood, (+) anti–*Saccharomyces cerevisiae* antibodies (up to 50% of patients), hypoalbuminemia with severe disease, and elevated fecal calprotectin

and ankylosing spondylitis. Ocular involvement with episcleritis, uveitis, or iritis may manifest as blurred vision, eye pain, and photophobia. Associated skin findings include pyoderma gangrenosum (papules and vesicles that develop into painful ulcerations) and erythema nodosum (red nodules of varying size typically found on the lower extremities). Nephrolithiasis may also develop at a higher rate in patients with IBD. Oxalate stones are more common in CD, and uric acid-containing stones are more common in UC.[15]

Liver and biliary manifestations of IBD include increased incidence of gallstone formation in patients with CD and development of sclerosing cholangitis or cholangiocarcinoma in patients with UC. Patients with UC are at increased risk for developing colorectal cancer and should undergo periodic cancer screening. Ongoing inflammation due to active IBD may induce a hypercoagulable state, resulting in higher rates of both arterial and venous thromboembolism, including deep vein thrombosis and pulmonary embolism. Likewise, inflammation and recurrent blood loss may result in chronic anemia. Patients with IBD also have higher rates of osteopenia, osteoporosis, and fractures, which are most strongly associated with use of corticosteroids.[16]

A serious complication of UC is toxic megacolon, defined as dilation of the transverse colon greater than 5.5 cm (2.2 in.).[1] Patients with toxic megacolon typically manifest systemic signs of severe inflammation such as fever, tachycardia, and abdominal distention.[1] Surgical intervention, including colonic resection, may be necessary to acutely manage toxic megacolon.

Patients with CD may develop significant weight loss or nutritional deficiencies secondary to malabsorption of nutrients in the small intestine, or as a consequence of multiple small- or large-bowel resections. Common nutritional deficiencies in IBD include vitamin B_{12}, fat-soluble vitamins, zinc, folate, and iron. Malabsorption in children with CD may contribute to significant reductions in growth and development.[2,6,15]

Diagnosis

Because patients often present with nonspecific GI symptoms, initial diagnostic evaluation includes methods to characterize the disease and rule out other potential etiologies. This may include stool cultures to examine for infectious causes of diarrhea.[8] Use of fecal calprotectin, a protein found in neutrophil granulocytes and released during leukocyte trafficking, is measured in the stool and may help to differentiate IBD from nonorganic disease (intestinal damage due to external causes such as drugs or mechanical intervention).[6,8] Levels greater than 120 mcg/g are considered abnormal.

Endoscopic approaches are typically used and may include colonoscopy, proctosigmoidoscopy, or possibly upper GI endoscopy in patients with suspected CD. Endoscopy is useful for determining the disease distribution, pattern and depth of inflammation, and to obtain mucosal biopsy specimens. Supplemental information from imaging procedures, such as computed tomography, abdominal X-ray, abdominal ultrasound, or intestinal barium studies may provide evidence of complications such as obstruction, abscess, perforation, or colonic dilation.[8]

The information derived from diagnostic testing and the patient's medical history and symptoms are used to gauge disease severity. Traditionally, the severity of active IBD is classified as mild, moderate, severe, or fulminant.[1,2] These categories are determined using a mix of signs, symptoms, and laboratory markers such as daily stool count, hydration status, presence of tachycardia, and elevated ESR or CRP.

A clinical care pathway developed by the American Gastroenterological Association (AGA) provides guidance on assessing severity of UC based on risk for colectomy.[17] After a diagnosis is made, inflammatory status (based on signs/symptoms, lab markers, and endoscopic findings), comorbidities, and therapy-related complications (if the patient is already receiving treatment) are assessed. Patients are then stratified according to low risk for colectomy (limited anatomic extent and mild endoscopic disease) or high risk for colectomy (extensive colitis, age less than 40 years, deep ulcers, high ESR/CRP, steroid dependence, history of hospitalization, and *Clostridioides difficile* or cytomegalovirus infection).

The AGA also developed a similar clinical decision support tool for managing CD.[18] Initially, the patient's inflammatory status, comorbidities, and disease and therapy-related complications are assessed. Categorization is slightly different from UC, and patients are considered low risk (age at initial diagnosis

Patient Encounter 1

A 28-year-old woman presents to the clinic for initial treatment of UC. A colonoscopy revealed disease confined to the rectum. She reports 2 to 3 loose stools per day on 2 to 3 days per week with intermittent tenesmus. This has caused a significant impact on her daily activities and quality of life. Her medical history is significant for seasonal allergies and she takes nonprescription cetirizine as needed. She reports no tobacco use and social intake of alcohol. She has an allergy to penicillin (hives). Her medical provider has determined this episode to be of mild to moderate severity and would like to initiate a mesalamine suppository.

How does the effectiveness of the mesalamine suppository compare to the oral formulations?

How would you educate this patient on the appropriate use of the mesalamine suppository?

over 30 years, limited anatomic involvement, no perianal and/or severe rectal disease, superficial ulcers, no prior surgical resection, and no stricturing and/or penetrating disease) or moderate-to-high risk (age at initial diagnosis less than 30 years, extensive anatomic involvement, perianal and/or severe rectal disease, deep ulcers, prior surgical resection, and stricturing and/or penetrating disease).

TREATMENT

Desired Outcomes

Treatment goals for IBD involve both management of active disease and prevention of disease relapse. **KEY CONCEPT** Major treatment goals include alleviation of signs and symptoms and suppression of inflammation during acute episodes and maintenance of remission thereafter. Addressing active IBD in a timely and appropriate manner may prevent major complications and reduce the need for hospitalization or surgical intervention.

Once control of active disease is obtained, treatment regimens are designed to achieve these long-term goals: (a) maintain remission and prevent disease relapse, (b) improve the patient's quality of life, (c) prevent the need for surgical intervention or hospitalization, (d) manage extraintestinal manifestations, (e) prevent malnutrition, and (f) prevent treatment-associated adverse effects.

General Approach to Treatment

Pharmacologic interventions for IBD are designed to target the underlying inflammatory response. **KEY CONCEPT** When designing a drug regimen for treatment of IBD, several factors should be considered, including the patient's symptoms; medical history; current medication use; drug allergies; and extent, location, and severity of disease. The history may also help identify a family history of IBD or potential exacerbating factors, such as tobacco or NSAID use.

Nonpharmacologic Therapy

No specific dietary restrictions are recommended for patients with IBD, but avoidance of high-residue foods in patients with strictures may help prevent obstruction.[1,6,7] Avoidance of excess dietary fat and foods containing emulsifying agents (eg, mayonnaise, salad dressing, ice cream) may also be preferred.[7] Nutritional strategies in patients with longstanding IBD may include vitamin and mineral supplementation and intake of soluble fiber.[7] Administration of vitamin B_{12}, folic acid, fat-soluble vitamins, and iron may be needed to prevent or treat deficiencies. In severe cases, enteral or parenteral nutrition may be needed to achieve adequate caloric intake.[7]

Patients with IBD, particularly those with CD, are also at risk for bone loss. This may be a function of malabsorption of vitamin D or repeated courses of corticosteroids.[15,16] Risk factors for osteoporosis should be determined, and baseline bone density measurement may be considered.[16] Vitamin D and calcium supplementation should be used in all patients receiving long-term corticosteroids. Oral bisphosphonate therapy may also be considered in patients receiving prolonged courses of corticosteroids or in those with osteopenia or osteoporosis.

Surgical intervention is an option in patients with complications such as fistulae or abscesses, or in patients with medically refractory disease. UC is curable with performance of a total colectomy; patients with UC may opt to have a colectomy to reduce the chance of developing colorectal cancer. Patients with CD may have affected areas of intestine resected. Unfortunately, CD may recur following surgical resection. Repeated surgeries in CD may lead to significant malabsorption of nutrients and drugs consistent with development of short-bowel syndrome.

Pharmacologic Therapy

Several pharmacologic classes are available for acute treatment and maintenance therapy of IBD. Selection of an initial agent for patients with active IBD should be designed to deliver maximum efficacy while minimizing toxicity. Response rates to individual classes of medications for both UC and CD are discussed within the specific treatment section for each disease.

▶ *Symptomatic Interventions*

Patients with active IBD often have severe abdominal pain and diarrhea. Medications used to manage these symptoms may have adverse consequences. **KEY CONCEPT** Antidiarrheal medications that reduce GI motility such as loperamide, diphenoxylate/atropine, and codeine should be avoided in patients with active IBD due to the risk of precipitating acute colonic dilation (toxic megacolon).[1,2,6] Drugs with anticholinergic properties, such as hyoscyamine and dicyclomine, are often used to treat intestinal spasm and pain, but these drugs may also reduce GI motility and should generally be avoided in active IBD.

Patients who have had multiple intestinal resections due to CD may have diarrhea related to the inability to reabsorb bile salts. Cholestyramine may improve diarrheal symptoms in this population.[14] NSAIDs should be avoided for pain management because they can worsen IBD symptoms. Opioid analgesics should be used with caution because they may significantly reduce GI motility.

▶ *Aminosalicylates*

The aminosalicylates are among the most commonly used drugs for inducing and maintaining remission in patients with mild to moderate IBD (Table 20–1). These drugs are designed to deliver 5-aminosalicylate (5-ASA, mesalamine) to areas of inflammation within the GI tract. The mechanism of mesalamine is not fully understood, but it appears to have favorable anti-inflammatory effects. The delivery of mesalamine to the affected sites is accomplished by either linking mesalamine to a carrier molecule or altering the formulation to release drug in response to changes in intestinal pH. Topical suppositories and enemas are designed to deliver mesalamine directly to the distal colon and rectum.[10,19–21]

Table 20–1

Aminosalicylates for Treatment of IBD

Drug	Trade Names	Formulation	Strengths	Daily Dosage Range (g)	Site of Action
Sulfasalazine	Azulfidine Azulfidine EN-tabs	Immediate-release or enteric-coated tablets Suspension	500 mg 250 mg/5 mL	1.6–4.8	Distal ileum and colon
Mesalamine	Rowasa	Enema	4 g/60 mL	4	Distal left colon and rectum
Mesalamine	Asacol Asacol-HD	Delayed-release resin tablet	400, 800 mg	1.6–4.8	Distal ileum and colon
	Delzicol	Delayed-release capsule	400 mg	1.6–4.8	Distal ileum and colon
	Canasa	Rectal suppository	1000 mg	1	Rectum
	Pentasa	Delayed-release capsule	250, 500 mg	2–4	Small bowel and colon
	Lialda	MMX-formulated pH-dependent polymer film–coated tablet	1.2 g	1.2–4.8	Terminal ileum and colon
	Apriso	Enteric-coated granules in polymer matrix	375 mg	1.5	Colon
Olsalazine	Dipentum	Delayed-release capsule	250 mg	1–3	Colon
Balsalazide	Colazal	Delayed-release capsule	750 mg	2–6.75	Colon
	Giazo	Tablet	1.1 g	2.2–6.6	Colon

The prototypical aminosalicylate is sulfasalazine, which chemically is mesalamine linked by a diazo bond to the carrier molecule sulfapyridine. This linkage prevents premature absorption of mesalamine in the small intestine. Once sulfasalazine is delivered to the colon, bacterial degradation of the diazo bond frees mesalamine from sulfapyridine. Sulfapyridine is then absorbed and excreted renally while mesalamine acts locally within the GI tract.

Newer mesalamine products utilize nonsulfapyridine methods for drug delivery. Olsalazine consists of two mesalamine molecules linked together, whereas balsalazide uses the inert carrier molecule 4-aminobenzoyl-β-alanine. Both drugs use a diazo bond similar to sulfasalazine. Lialda is a proprietary multimatrix (MMX) mesalamine formulation with a pH-sensitive coat that releases in the terminal ileum, allowing for once-daily dosing.[19–21] Apriso contains enteric-coated mesalamine granules also with a polymer matrix for extended release that can be given once daily.

Sulfasalazine is associated with various adverse effects, most of which are thought to be due to the sulfapyridine component. Common dose-related adverse effects include headache, dyspepsia, nausea, vomiting, and fatigue.[20–22] Idiosyncratic effects include bone marrow suppression, reduction in sperm counts in males, hepatitis, and pulmonitis. Hypersensitivity reactions may occur in patients allergic to sulfonamide-containing medications.

Nonsulfapyridine-based aminosalicylates are better tolerated than sulfasalazine. Although the types of adverse effects are similar, they occur much less frequently. However, olsalazine is associated with a higher incidence of secretory diarrhea than other aminosalicylates. These agents can be used safely in patients with a reported sulfonamide allergy, but they are more expensive than generic sulfasalazine.

▶ *Corticosteroids*

Corticosteroids have potent anti-inflammatory properties and are used in active IBD to suppress inflammation rapidly. They may be administered systemically or delivered locally to the site of action (Table 20–2). Corticosteroids usually improve symptoms and disease severity rapidly, but use should be restricted to short-term management of active disease. Long-term systemic corticosteroid use is associated with significant adverse effects, including cataracts, skin atrophy, hypertension, hyperglycemia, adrenal suppression, osteoporosis, increased risk of infection, and delayed growth in children, among others.[22–24]

Budesonide is a high-potency glucocorticoid used in IBD that has low systemic bioavailability when administered orally or rectally.[23,24] Oral formulations may release in either the terminal ileum or colon. Rectal foam formulations reach up to 40 cm from the anal verge. Compared to traditional corticosteroids, budesonide may reduce long-term adverse effects and can be used for induction therapy.[22–24]

▶ *Immunomodulators and Immunosuppressants*

Agents targeting the immune response or cytokines involved in IBD are potential treatment options (Table 20–3). Azathioprine

Table 20–2

Corticosteroids for Treatment of IBD

Drug	Trade Names	Daily Dose
Prednisone	Generic	20–60 mg orally
Prednisolone	Generic	20–60 mg orally
Methylprednisolone	Medrol (orally) Solu-Medrol (IV)	15–60 mg orally or IV
Hydrocortisone	Solu-Cortef	300 mg IV in three divided doses
	Cortenema	100 mg rectally at bedtime
	Cortifoam	90 mg rectally once or twice daily
	Anusol-HC	25–50 mg rectally twice daily
	Proctocort	30 mg rectally twice daily
Budesonide	Uceris 9-mg tablet	9 mg orally once daily
	Entocort 3-mg capsule	9 mg orally once daily
	Ortikos 6, 9 mg capsule	6 or 9 mg orally once daily
	Uceris rectal foam	2 mg twice daily, then once daily

ALGRAWANY

Table 20–3

Immunomodulators and Biologic Agents for Treatment of IBD

Drug	Trade Name(s)	Dose
Azathioprine	Imuran, Azasan	1.5–2.5 mg/kg/day orally
Mercaptopurine	Purinethol, Purixan	1.5–2.5 mg/kg/day orally
Methotrexate	Trexall	15–25 mg weekly (IM/SC/orally)
Cyclosporine	Sandimmune	4 mg/kg/day IV continuous infusion
Infliximab	Remicade	Induction: 5 mg/kg IV at 0, 2, and 6 weeks; 10 mg/kg per dose IV for nonresponders Maintenance: 5 mg/kg IV every 8 weeks
Infliximab-dyyb	Inflectra	
Infliximab-abda	Renflexis	
Adalimumab	Humira	Induction: 160 mg SC day 1 (given as four 40-mg injections in 1 day or as two 40-mg injections per day for 2 consecutive days), then 80 mg SC 2 weeks later (day 15) Maintenance: 40 mg SC every other week, starting on day 29 of therapy
Adalimumab-bwwd	Hadlima	
Adalimumab-adbm	Cyltezo	
Adalimumab-adaz	Hyrimoz	
Adalimumab-afzb	Abrilada	
Adalimumab-atto	Amjevita	
Certolizumab	Cimzia	Induction: 400 mg SC initially, then 400 mg SC at 2 and 4 weeks Maintenance: 400 mg SC every 4 weeks if initial response
Golimumab	Simponi	200 mg SC at week 0 and 2; then every 4 weeks
Natalizumab	Tysabri	Induction/maintenance: 300 mg IV every 4 weeks; discontinue by 12 weeks if no response or if unable to withdraw steroids within 6 months
Vedolizumab	Entyvio	300 mg IV at weeks 0, 2, and 6; then every 8 weeks; discontinue if no response at 14 weeks
Ustekinumab	Stelara	Weight-based initial IV dose < 55 kg (260 mg), 55–85 kg (390 mg), > 85 kg (520 mg); then 90 mg SC every 8 weeks
Tofacitinib	Xeljanz, Xeljanz XR	10 mg orally twice daily or 22 mg XR once daily for 8 weeks; may continue for up to 16 weeks Maintenance: 5 mg twice daily or 11 mg XR once daily

IM, intramuscular; IV, intravenously; SC, subcutaneously, XR, extended release.

and 6-mercaptopurine (6-MP) are immunomodulators that inhibit purine biosynthesis and reduce IBD-associated GI inflammation. They are most useful for maintaining remission of IBD or reducing the need for long-term use of corticosteroids.[1,6,25–27] Use in active disease is limited by their slow onset of action, which may be as long as 3 to 12 months. Azathioprine is metabolized to 6-MP, which is further metabolized to the active 6-thioguanine (6-TGN) nucleotide, which functions as a purine antagonist. Evaluation of 6-TGN concentrations can be performed in patients who may not be responding to therapy or may be experiencing toxicity. Adverse effects associated with azathioprine and 6-MP include hypersensitivity reactions resulting in pancreatitis, fever, rash, hepatitis, and leukopenia.[22,25–27] Patients should be tested for activity of thiopurine methyltransferase (TPMT), the major enzyme responsible for metabolism of azathioprine prior to use. Deficiency or reduced activity of TPMT may result in toxicity from azathioprine and 6-MP and may require dose reductions.

Methotrexate, also an immunomodulator, is a folate antagonist used primarily for maintaining remission of CD. It may be administered orally, subcutaneously, or IV and may have a steroid-sparing effect in patients with steroid-dependent disease.[1,6,27] Long-term methotrexate use may result in serious adverse effects, including hepatotoxicity, pulmonary fibrosis, and bone marrow suppression.

Cyclosporine is a cyclic polypeptide immunosuppressant typically used to prevent organ rejection in transplant patients. Its use in IBD is restricted to patients with fulminant or refractory symptoms in patients with active disease. Significant toxicities associated with cyclosporine are nephrotoxicity, risk of infection, seizures, hypertension, and liver function test abnormalities.[1,6,22]

▶ *Biologic Agents*

Several biologic agents targeting TNF-α are used for treatment of IBD (Table 20–3). Reduction in TNF-α activity is associated with improvement in the underlying inflammatory process. Infliximab is a chimeric anti–TNF-α agent (ie, 75% human, 25% mouse), certolizumab is a pegylated antibody fragment, and both adalimumab and golimumab are humanized anti–TNF-α antibodies.[28]

"Biosimilars" are highly similar to an Food and Drug Administration (FDA)-approved biologic agent (called the reference product) and have been shown to have no clinically meaningful differences in efficacy or adverse effects from the reference product.[28] They are not identical in structure or considered generically equivalent to the originator compound because of molecular complexity and production using recombinant DNA techniques in living organ systems. However, some biosimilars may be considered to be interchangeable with the reference product. The FDA will approve a biosimilar product only if it has the same mechanism of action, route of administration, dosage form, and strength as the reference product. Also, a biosimilar can only be approved for the indications that were previously approved for the reference product. Biosimilars have a nonproprietary name plus an FDA-designated suffix consisting of four lowercase letters that have no intended meaning. Several biosimilars are approved for use in UC and CD: Infliximab-dyyb, infliximab-abda, infliximab-qbtx, infliximab-axxq, adalimumab-adbm, adalimumab-atto, adalimumab-adaz, adalimumab-afzb, and adalimumab-bwwd. Despite being FDA approved, the adalimumab biosimilar agents were not commercially available at the time of this writing due to ongoing legal disputes with the manufacturers of the reference products.

Disadvantages of anti-TNF biologic therapy include the need for parenteral administration, significant drug cost, and the potential for serious adverse effects. Adalimumab, golimumab, and certolizumab are administered subcutaneously, whereas infliximab requires intravenous (IV) infusion. Adverse effects of IV infliximab may include infusion-related reactions such as fever, chest pain, hypotension, and dyspnea. Antibodies may develop to infliximab over time that may reduce its efficacy and predispose patients to development of infusion-related adverse effects.

All TNF-α inhibitors have been associated with reactivation of serious infections, particularly intracellular pathogens such as tuberculosis, as well as hepatitis B.[22,27] Biologic agents should not be used in patients with existing infections, and patients should be screened for latent tuberculosis and viral hepatitis prior to initiating therapy. Exacerbation of heart failure is also a potential adverse effect, so these agents should be avoided in patients with advanced or decompensated heart failure.[22] Anti–TNF-α agents also carry a risk of developing lymphoma, including a rare form known as hepatosplenic T-cell lymphoma. The risk appears to be highest in younger male patients and those using concomitant azathioprine or 6-MP.[22,27,28]

Natalizumab and vedolizumab are humanized monoclonal antibodies that antagonize integrin heterodimers, prevent α_4-mediated leukocyte adhesion to adhesion molecules, and prevent migration across the endothelium.[28,29] Natalizumab is associated with development of progressive multifocal leukoencephalopathy (PML). Vedolizumab carries a theoretical risk of PML, but this has not been reported to date. Use of natalizumab is restricted to patients who have failed all other therapies, including anti–TNF-α agents, whereas vedolizumab is a first-line alternative to anti-TNF therapy.[29]

Ustekinumab is a biologic therapy that blocks IL-21 and IL-23 action by binding to the p40 protein subunit used by these cytokines.[30] It is approved for use in moderate-to-severe UC and CD and is generally reserved for patients failing other therapies. Tofacitinib is an inhibitor of Janus kinase (JAK) and is approved for moderate to severe UC.[31] While tofacitinib is an attractive option due to its oral route of administration, it is associated with severe toxicities, such as risk of thrombosis and bone marrow suppression, and also has several drug interactions that require dose adjustment. For these reasons, it is recommended for use only after failure or intolerance of any TNF agents.[36,37]

▶ *Other Agents*

Antibiotics have been used in IBD based on the rationale that they may interrupt the inflammatory response directed against endogenous bacterial flora. Metronidazole and ciprofloxacin have been the two most widely studied agents. Metronidazole may benefit some patients with pouchitis (inflammation of surgically created intestinal pouches) and patients with CD who have had ileal resection or have perianal fistulas.[32] Ciprofloxacin has shown some efficacy in refractory active CD and may be used in combination with metronidazole. Long-term metronidazole use is associated with development of peripheral neuropathy.

Because smoking is associated with reduced UC symptoms, transdermal nicotine has been studied as a potential treatment option. Improvement in mild to moderate UC symptoms may be seen and may be more evident in patients who are ex-smokers.[1,33] Daily doses between 15 and 25 mg appear to be most effective.

Probiotics such as *Lactobacillus acidophilus* or *Bifidobacterium* have been used with the rationale that modification of host flora may alter the inflammatory response. There are minimal data to support use of probiotics in CD.[32,34] There is limited evidence for use in UC; however, the probiotic preparation VSL#3 demonstrated efficacy in reducing recurrence of pouchitis in patients with ileal pouch anal anastomosis and may prevent relapse in mild to moderate disease.[34–36]

Treatment of UC

In general, the approach to treatment of UC is based on the severity, location, and extent of disease. Both the AGA and the American College of Gastroenterology (ACG) have recently published evidence-based guidelines to assist clinicians with therapy recommendations.[35–37] The ACG guidelines also provide poor prognostic factors that are associated with a more aggressive disease course and possible need for colectomy.[36] These include age less than 40 years, extensive colitis, severe endoscopic disease, hospitalization, elevated CRP, and low serum albumin. If multiple factors are present, more aggressive treatment may need to be initiated to prevent poor outcomes.

▶ *Induction Therapy for Mild to Moderate UC*

KEY CONCEPT Treatment of acute episodes of UC is dictated by the severity and extent of disease. First-line therapy of mild to moderate disease involves oral or topical aminosalicylate derivatives, oral or topical budesonide, or oral prednisone and/or rectal steroids. The recommended treatment approach for UC is outlined in Figure 20–3. Topical mesalamine is superior to both topical corticosteroids and oral aminosalicylates for inducing remission in active mild-to-moderate UC in patients with distal disease.[21,24,35,36] Enemas are appropriate for patients with left-sided disease because the medication will reach the splenic flexure. Suppositories deliver mesalamine up to approximately 20 cm and are most appropriate for treating proctitis.[20] The combination of oral and topical mesalamine preparations is more effective and recommended in patients with extensive or left-sided disease.[20,35,36] The oral mesalamine dose target dose should be 2 to 3 g/day, with doses of greater than 3 g/day reserved for lack of response to standard doses.[35,36] Use of once-daily formulations may improve patient adherence. Induction of remission may require 4 to 8 weeks of therapy at appropriate treatment doses. Switching to an alternate formulation of mesalamine may be considered in nonresponsive patients.[36]

Topical corticosteroids have a limited role and are reserved for patients who are intolerant or unresponsive to topical mesalamine. Patients should be properly educated about appropriate use of topical products, including proper administration and adequate retention to maximize efficacy. The oral budesonide MMX formulation is recommended for patients unresponsive to optimized topical or oral mesalamine.[35,36] Oral prednisone is also an option; however, its effects are systemic, and oral formations targeting specific areas of the colon are not available. Patients requiring systemic corticosteroids should have them tapered over 4 to 12 weeks.[23]

▶ *Induction Therapy for Moderate to Severe UC*

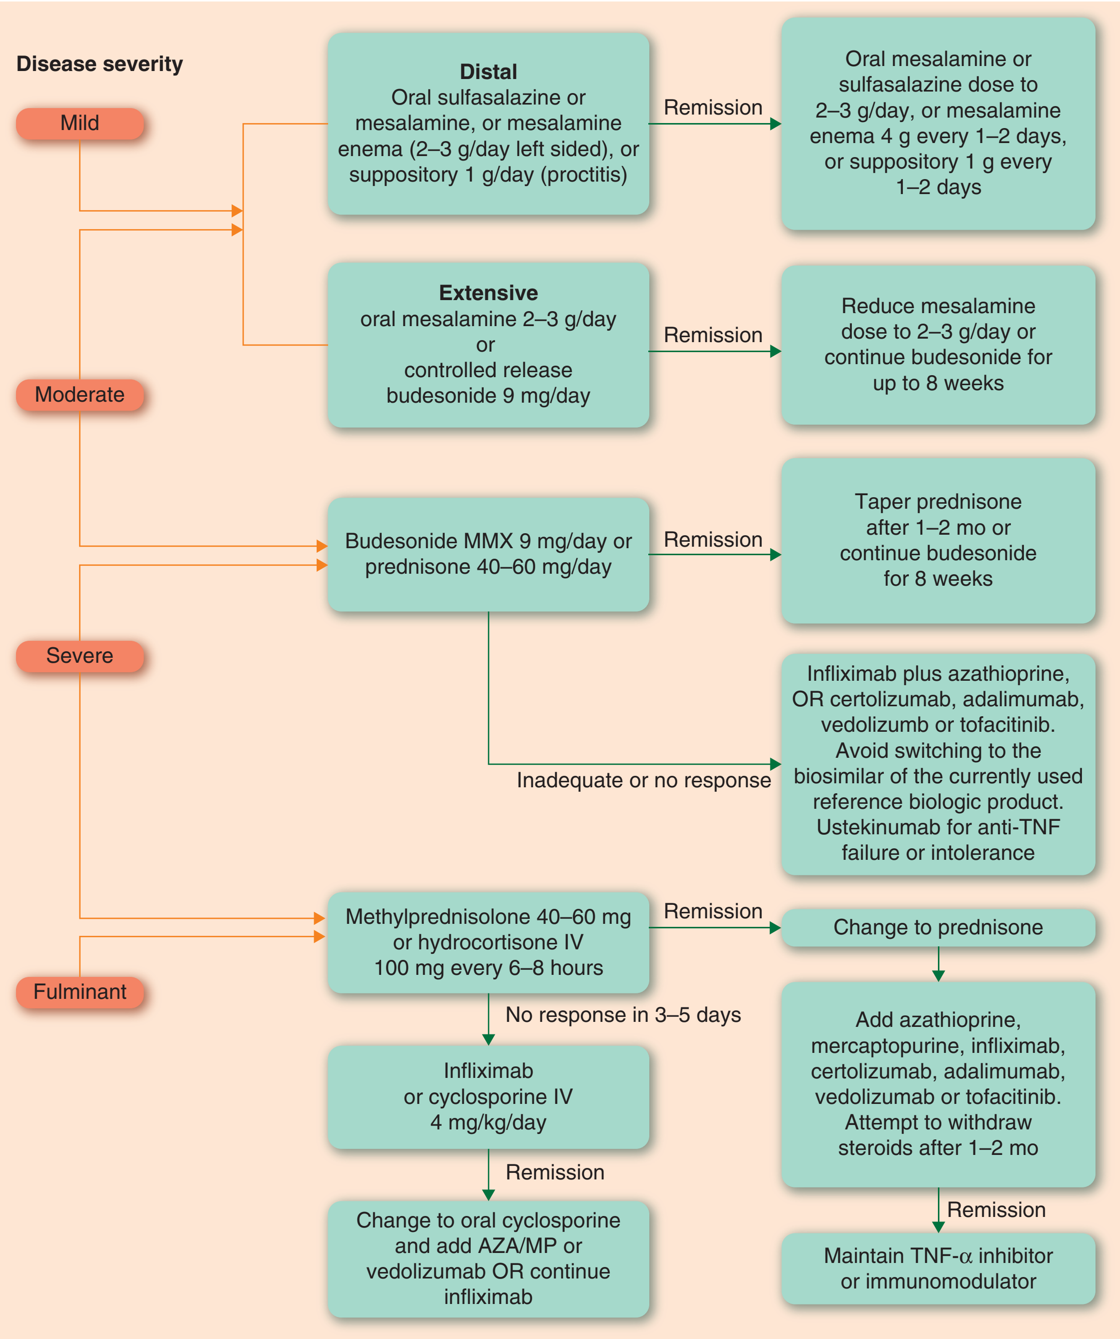
Oral budesonide MMX may be used for short-term treatment of patients with moderately active extensive UC, whereas short-term

Patient Encounter 2, Part 1

A 27-year-old Hispanic man with mild UC presents to the gastroenterology clinic because of a 2-week history of crampy abdominal pain and 2 to 3 loose stools 2 to 3 days/week. He denies vomiting, fever, or chills.

What other pertinent information from the history would be beneficial to help determine the cause of his symptoms?

What additional information would you obtain prior to recommending drug therapy?



Disease severity
Mild
Moderate
Severe
Fulminant
Distal
Oral sulfasalazine or mesalamine, or mesalamine enema (2–3 g/day left sided), or suppository 1 g/day (proctitis)
Remission
Oral mesalamine or sulfasalazine dose to 2–3 g/day, or mesalamine enema 4 g every 1–2 days, or suppository 1 g every 1–2 days
Extensive
oral mesalamine 2–3 g/day or controlled release budesonide 9 mg/day
Remission
Reduce mesalamine dose to 2–3 g/day or continue budesonide for up to 8 weeks
Budesonide MMX 9 mg/day or prednisone 40–60 mg/day
Remission
Taper prednisone after 1–2 mo or continue budesonide for 8 weeks
Inadequate or no response
Infliximab plus azathioprine, OR certolizumab, adalimumab, vedolizumb or tofacitinib. Avoid switching to the biosimilar of the currently used reference biologic product. Ustekinumab for anti-TNF failure or intolerance
Methylprednisolone 40–60 mg or hydrocortisone IV 100 mg every 6–8 hours
Remission
Change to prednisone
No response in 3–5 days
Infliximab or cyclosporine IV 4 mg/kg/day
Add azathioprine, mercaptopurine, infliximab, certolizumab, adalimumab, vedolizumab or tofacitinib. Attempt to withdraw steroids after 1–2 mo
Remission
Change to oral cyclosporine and add AZA/MP or vedolizumab OR continue infliximab
Remission
Maintain TNF-α inhibitor or immunomodulator

FIGURE 20–3. Treatment approaches for ulcerative colitis. (AZA, azathioprine, IV, intravenous; MMX, multimatrix system; MP, mercaptopurine, TNF, tumor necrosis factor.) (Reproduced with permission from Hemstreet B. Inflammatory bowel disease. In: DiPiro JT, Yee GC, Posey LM, et al/, eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. McGraw-Hill: New York. www.accesspharmacy.com).

(less than 4 weeks) prednisone 40 to 60 mg/day (or equivalent) is recommended for any disease extent in patients with moderate to severe disease.[23,36,37] Biologic agents are generally considered the mainstay of therapy for moderate to severe UC. The choice of agent depends on previous exposure to biologic agents. For treatment-naive patients, infliximab or vedolizumab in combination with an immunomodulator (eg, azathioprine) is recommended. Recent data demonstrated that the efficacy of vedolizumab is superior to adalimumab in moderate to severe UC.[38] For patients previously exposed to infliximab, ustekinumab or tofacitinib are recommended.[37]

▶ *Treatment of Acute Severe UC*

Patients with acute severe UC (ASUC) generally require hospitalization. A course of methylprednisolone 40 to 60 mg IV per day should be initiated.[36,37] Infliximab as a single dose or cyclosporine (given as a continuous IV infusion of 2–4 mg/kg/day) can be used for patients not responding to IV methylprednisolone after 3 to 4 days.[36,37]

▶ *Maintenance of Remission in UC*

Unfortunately, up to 50% of patients receiving oral therapies and up to 70% of untreated patients relapse within 1 year after achieving remission.[1,36] For this reason, patients may require maintenance drug therapy indefinitely to preserve remission.

KEY CONCEPT Maintenance of remission of UC may be achieved with oral or topical aminosalicylates. In patients with mildly active proctitis, mesalamine suppositories 1 g daily are recommended, whereas mesalamine enemas are appropriate for left-sided disease and may often be dosed 2 to 3 times weekly. Oral mesalamine at doses of at least 2 g/day is recommended and may be combined with topical therapies to maintain remission.[36]

Oral or topical corticosteroids are not effective for maintaining remission and should be avoided due to the high incidence of adverse effects. Budesonide oral MMX may be continued for up to 8 weeks; however, systemic corticosteroids should be tapered over 4 to 12 weeks in moderately active UC patients achieving remission.[22,23,37]

KEY CONCEPT Immunomodulators (eg, azathioprine, 6-MP), anti-TNF agents (eg, infliximab, adalimumab, golimumab), vedolizumab, ustekinumab, or tofacitnib can be used to maintain UC remission in moderately to severely active patients who achieve remission or in those who develop corticosteroid dependency. In general, mesalamine products should be discontinued in patients who progress to moderately to severely active disease, because its effectiveness is diminished. Intermittent anti-TNF agent dosing may be used to maintain remission and reduce the need for corticosteroids in patients with moderate to severe UC. Combining a thiopurine and anti-TNF agent is more effective, and patients may be able to be transitioned to azathioprine monotherapy. Vedolizumab may be used as an alternate maintenance option if patients had a favorable response to induction therapy and is also recommended in combination with azathioprine.[36,37] Ustekinumab or tofacitinib can be continued if the patient responds, and thiopurine monotherapy can be considered in patients who achieve corticosteroid-induced remission.[36] For patients with ASUC, if remission with infliximab is achieved, this agent can be continued as maintenance therapy, while azathioprine or vedolizumab are recommended as maintenance therapies in patients achieving remission with cyclosporine.[36] Colectomy is an option for patients with progressive disease who cannot be maintained on drug therapy alone.

▶ *Treatment of CD*

See Table 20–4 for a summary of the AGA treatment recommendations for CD based on risk level.

▶ *Low-Risk Active CD*

KEY CONCEPT Induction of remission in low-risk patients with mild to moderate active CD may be accomplished with oral budesonide, with or without azathioprine, in patients with ileal and/or proximal colonic involvement and no to minimal systemic symptoms, or a tapering course of prednisone with or without azathioprine in patients with diffuse or left colonic involvement. Budesonide MMX 9 mg orally once daily for up to 8 weeks is effective for low-risk, active CD in patients with involvement of the terminal ileum or ascending colon, with success expected in 50% to 69% of patients.[2,6,18,32,39] Because the formulation releases budesonide in the terminal ileum, it is not effective in reaching sites distal to the ascending colon.[39] Conventional oral corticosteroids (eg, prednisone, methylprednisolone) may also be used with or without an immunomodulator and are preferred if there is diffuse or left-sided disease.[39] However, other oral corticosteroids carry a higher risk of adverse effects than budesonide.[6,22,32]

Sulfasalazine or mesalamine products have demonstrated minimal efficacy in patients with ileal, ileocolonic, or colonic CD but are often used due to their more favorable adverse effect profile when compared to corticosteroids.[2,6,32] Metronidazole or ciprofloxacin have not demonstrated efficacy as primary induction therapies and should be avoided.[32]

Table 20–4

Crohn Disease Initial Inductive and Maintenance Therapy Based on Risk

Risk Level	Inductive Therapy	Maintenance Therapy (Remission)
Low risk	1. Ileum and/or proximal colon with no to minimal systemic symptoms. Options: • Oral budesonide 9 mg/day without or without azathioprine • Tapering course of prednisone with or without azathioprine 2. Diffuse or left colon with no to minimal systemic symptoms. Options: • Tapering course of prednisone with or without azathioprine	Options: • Stop therapy and observe (high chance of relapse over 1 year) • Oral budesonide 6 mg/day (prolongs median time to relapse by about 114 days, but no difference in remission rates vs placebo at 1 year) • Immunosuppressive therapy (azathioprine, mercaptopurine, and methotrexate are effective in maintaining prednisone- or prednisolone-induced remissions but are associated with rare risk of infection and lymphoma)
Moderate to high risk	Moderately severe Crohn disease. Options: • Systemic corticosteroids • Use anti-TNF monotherapy over no therapy or thiopurine monotherapy • Use anti-TNF agent plus thiopurine over monotherapy with either thiopurine or anti-TNF agent • Use methotrexate for patients who do not tolerate thiopurine plus anti-TNF agent	Options: • Steroid-induced remission: Use thiopurine or methotrexate over no immunomodulator; or use anti-TNF agent with or without thiopurine over no anti-TNF agent • Anti-TNF alone or anti-TNF plus thiopurine-induced remission: Use anti-TNF agent with or without thiopurine over no anti-TNF agent

Thiopurine = azathioprine or mercaptopurine.

Anti-TNF agent = adalimumab, certolizumab, golimumab, infliximab.

Adapted from: Sandborn WJ. Crohn's disease evaluation and treatment: clinical decision tool. Gastroenterology. 2014;147:702–705.

▶ *Moderate- to High-Risk Active CD*

Patients with moderate- to high-risk CD may be treated with oral corticosteroids (eg, prednisone 40–60 mg daily). Per the AGA recommendations (Table 20–4), moderately severe patients can be treated with anti-TNF monotherapy or anti-TNF therapy combined with a thiopurine.[32,40,41] Methotrexate can be used in patients who do not tolerate purine therapy.

For patients with perianal fistulae, antibiotics (metronidazole or ciprofloxacin), infliximab, adalimumab, and certolizumab are appropriate treatment options. Complex perianal fistulae may require surgical intervention but may also be amenable to treatment with antibiotics, azathioprine, 6-MP, or anti–TNF-α agents.[14,32,41,42]

Many patients with severe CD require hospitalization for appropriate treatment. Patients should be assessed for possible surgical intervention if abdominal distention, masses, abscess, or obstruction are present. Daily IV corticosteroid doses equivalent to prednisone 40 to 60 mg may be tried as initial therapy to rapidly suppress severe inflammation.

Anti-TNF agents or vedolizumab may be used in severe active CD. Anti-TNF therapy can be combined with a thiopurine for increased effectiveness.[18,27,28,32,41] Patients failing to respond should have drug trough concentrations and antidrug antibodies assessed if anti-TNF agents are being used. Depending on the outcome, this may necessitate a dose increase or a switch to another drug within the class.[43,44] Ustekinumab is generally reserved for outpatients with severe disease who have failed other traditional therapies.

Adjunctive therapy with fluid and electrolyte replacement should be initiated. Nutritional support with enteral or parenteral nutrition may be indicated for patients unable to eat for more than 5 to 7 days. Limited evidence indicates that cyclosporine or tacrolimus are effective as salvage therapy for patients who fail IV corticosteroid therapy.[32] Surgical intervention may ultimately be necessary for medically refractory disease.

▶ *Maintenance of Remission in CD*

Patients with CD are at high risk for disease relapse after induction of remission. Within 2 years, up to 80% of patients experience a relapse; therefore, many patients require indefinite maintenance therapy. **KEY CONCEPT** Maintenance of remission of CD may be achieved with immunosuppressants (azathioprine, 6-MP, or methotrexate), biologic agents (infliximab, adalimumab, certolizumab pegol, vedolizumab, ustekinumab), and less frequently with oral or topical aminosalicylate derivatives.

In contrast to their use in UC, sulfasalazine and the newer aminosalicylates are marginally effective in preventing CD relapse in patients with medically induced remission, with success rates of only 10% to 20% at 1 year.[2,32,41] Despite not being recommended as first-line therapy, aminosalicylates are routinely used to attempt maintenance of remission of CD.[41]

The anti-TNF agents are effective in maintaining remission in CD.[26,27,32,41] Azathioprine and 6-MP in oral doses up to 2.5 mg/kg/day have also been shown to maintain remission in 45% of patients for up to 5 years and may be preferred for maintenance following a steroid-induced remission.[25,27,28,32] There is evidence to support use of combination therapy with an anti-TNF agent or vedolizumab plus azathioprine or methotrexate to maintain remission in CD in patients achieving steroid-induced remission.[27,28,32] Anti-TNF agents are preferred for patients with surgically induced remission and may also be combined with azathioprine in this situation.[42] Vedolizumab or ustekinumab may be used for maintenance in patients unresponsive to anti–TNF-α agents.[32,41]

Patient Encounter 2, Part 2: Medical History and Physical Examination

PMH: Mild extensive UC diagnosed 4 months ago

FH: Both parents alive; father has a history of myocardial infarction; mother has a history of hypothyroidism

SH: Works as IT support professional for a cable company, social alcohol use; no tobacco use

Allergies: Penicillin (rash)

Meds: Apriso 1.5 g/day in the morning and mesalamine enema 1 g nightly

ROS: (+) Diarrhea, abdominal pain

PE:

VS: BP 121/68 mm Hg, P 99 beats/min, RR 18/min, T 37.7°C (99.8°F)

CV: Tachycardia with normal rhythm. No murmurs, rubs, or gallops

HEENT: Slightly dry mucous membranes

Skin: No evidence of tenting

Abd: Soft, nondistended, mild diffuse tenderness, (+) bowel sounds, (–) hepatosplenomegaly, (–) masses, heme (+) stool

MS: 5/5 strength in upper and lower extremities; normal ROM

Labs:

Sodium 132 mEq/L (mmol/L)
Potassium 3.7 mEq/L (mmol/L)
Chloride 100 mEq/L (mmol/L)
Bicarbonate 25 mEq/L (mmol/L)
BUN 15 mg/dL (5.4 mmol/L)
Serum creatinine 1 mg/dL (88 μmol/L)
Glucose 100 mg/dL (5.6 mmol/L)
AST 21 IU/L (0.35 μkat/L)
ALT 20 IU/L (0.33 μkat/L)
Albumin 3.9 g/dL (39 g/L)
CRP 3.1 mg/dL (31 mg/L)
A1C 5% (0.05; 31 mmol/mol Hb)
ESR 100 mm/hr
Hemoglobin 10 g/dL (100 g/L; 6.21 mmol/L)
Hematocrit 37% (0.37)
WBC 16.0 × $10^3/mm^3$ (16.0 × $10^9/L$)
Platelets 460 × $10^3/mm^3$ (460 × $10^9/L$)

Abdominal X-ray: (–) obstruction, free-air, or colonic dilation

Colonoscopy: Superficial continuous inflammation involving the rectum and extending proximally with evidence of recent bleeding, (–) polyps or strictures, biopsy taken

Pathology: Evidence of crypt abscesses

What factors should you consider in choosing appropriate therapy for this patient?

What treatment options would you consider at this time?

What are some important educational points you would provide to this patient regarding appropriate use of his medication?

Patients not responding to anti-TNF agents should have drug trough levels obtained and be assessed for presence of antibodies.[43] Dose escalation or switching to another anti-TNF agent may be required. Similarly, evaluation of azathioprine metabolites, particularly 6-thioguanine, should be performed to evaluate the need for dose escalation if there is lack of response or in the setting of potential thiopurine toxicity.[35,44]

Systemic or topical corticosteroids should not be used for maintaining remission in patients with CD. Unfortunately, up to 50% of patients treated acutely with corticosteroids become dependent on them to prevent symptoms.[2] Budesonide 6 mg (2 × 3-mg Entocort capsules) orally once daily may be used in place of conventional corticosteroids after remission induction in mild to moderate CD or in patients dependent on corticosteroids for up to 4 months; however, it has minimal effectiveness.[2,22,41]

Treatment of IBD in Special Populations (Table 20–5)

▶ *Older Persons*

Approximately 10% to 30% of patients with IBD initially develop symptoms after age 60.[45] In general, IBD presents similarly in older patients and younger individuals. Elderly patients may have more comorbid diseases, some of which may make the diagnosis of IBD more difficult. Such conditions include ischemic colitis, diverticular disease, and microscopic colitis. Increased age is also associated with a higher incidence of adenomatous polyps, but the onset of IBD at an advanced age does not appear to increase the risk of developing colorectal cancer. Older patients may also use more medications, particularly NSAIDs, which may induce or exacerbate colitis. Adherence may be more challenging for older patients, especially for injectable products, and costs of some

Table 20–5

Dosing Considerations of IBD Therapies in Special Populations

Therapy	Pediatric Patients	Older Patients	Pregnancy
Sulfasalazine	Age > 2 years: 40–60 mg/kg/day in 3–6 divided doses; 30 mg/kg/day in 3–6 divided doses for maintenance	No specific changes	Category B[a] Administer folic acid 2 mg daily during prenatal period and pregnancy
Mesalamine	No specific changes; Balsalazide indicated for age > 5 years	No specific changes	Category B (Olsalazine Category C) Generally considered safe and effective
Corticosteroids	No specific changes	No specific changes Elderly patients at high risk for osteoporosis	Older agents not rated Budesonide category C Generally considered safe and effective
TNF-α inhibitors	Infliximab indicated for pediatric patients: 5 mg/kg at 0, 2, and 6 weeks, then every 8 weeks Adalimumab indicated for patients age ≥ 6 or greater: 80 mg (< 40 kg), 40 mg week 2, then 20 mg every other week or 160 mg (> 40 kg) initial followed by 80 mg week 2, then 40 mg every other week	Avoid in patients with heart failure Elderly patients at higher risk for infections	Category B Pregnancy registry for adalimumab via manufacturer
Natalizumab	Dose of 3 mg/kg IV at 0, 4, and 8 weeks reported; data are lacking in children	No specific changes	Category C Report pregnancy to manufacturer's pregnancy registry
Vedolizumab	Not indicated	No specific changes	Category B Manufacturer pregnancy exposure registry
Ustekinumab	Not indicated	No specific changes	Manufacturer pregnancy exposure registry
Azathioprine, 6-Mercaptopurine	1.5–2 mg/kg/day to start	No specific changes	Category D Accepted as safe Avoid initiating during pregnancy, but continue if patient is already receiving when pregnant
Methotrexate	17 mg/m^2 orally/SC/IM	No specific changes	Category X Contraindicated
Cyclosporine	No specific changes	No specific changes	Category C Use only in refractory patients
Tofacitinib	Not indicated	Adjust for renal/hepatic function	Manufacturer pregnancy exposure registry
Metronidazole	30–50 mg/kg/day divided every 6 hours	No specific changes	Category B Use short courses if possible
Ciprofloxacin	Avoid use	Adjust dose for CrCl < 50 mL/min (0.83 mL/s)	Category C Consider other alternatives

[a] In 2015, the FDA recommended that the pregnancy categories be replaced with narrative recommendations to better inform clinical decision-making. Drugs submitted for approval after June 30, 2015 will use this new designation immediately, whereas those approved after June 30, 2001 will be gradually phased in (https://www.drugs.com/pregnancy-categories.html).

CrCl, creatinine clearance; IM, intramuscular; SC, subcutaneously.

agents may be problematic depending on the patient's financial or insurance situation.

Treatment of older patients with IBD is similar to that for younger patients, but special consideration should be given to some of the medications used. Corticosteroids may worsen diabetes, hypertension, heart failure, or osteoporosis. The TNF-α inhibitors should be used cautiously in patients with heart failure and should be avoided in New York Heart Association class III or IV disease. Older patients requiring major surgical interventions may be at higher risk for surgical complications or may not meet eligibility criteria for surgery because of comorbid conditions, age-related organ dysfunction, or reduced functional status.[45]

▶ *Children and Adolescents*

Crohn disease occurs more often than UC in pediatric patients, accounting for up to 73% of pediatric IBD cases.[46] Approximately 6% to 15% of children with IBD present at 6 years of age or younger, which is referred to as very-early-onset IBD (VEO-IBD).[47] Both forms of IBD may present similarly in children, with abdominal pain and diarrhea being common. However, risk of growth failure secondary to inadequate nutritional intake and failure to thrive or pubertal delay may be an initial presentation of IBD, especially in CD. Aggressive nutritional interventions may be required to facilitate adequate caloric intake.

The aminosalicylates, azathioprine, 6-MP, and infliximab are all viable options for treatment and maintenance of IBD in pediatric patients.[48,49] Corticosteroids should be reserved for short-term use as induction therapy. Infliximab is approved for use in the United States for patients 6 to 17 years of age with moderate-to-severe active CD. Use of immunosuppressive therapy or infliximab may help reduce overall corticosteroid exposure. Adalimumab is also approved for use in patients 6 years of age or older with CD. Certolizumab, natalizumab, vedolizumab, and ustekinumab are only FDA approved for use in adults with IBD; data in children are limited.

▶ *Pregnant Women*

Inducing and maintaining remission at least 3 to 6 months prior to conception is the optimal approach in women with IBD who plan to become pregnant. Pregnant women with IBD are at higher risk of spontaneous abortion, preterm birth, low birth weight infants, and complications of delivery such as preeclampsia and liver and platelet disorders.[50] Given these implications, preconception counseling should be provided, and good communication among medical providers is necessary. Health-care maintenance should be optimized, including ensuring vaccination schedules are up to date, and disease severity should be assessed.[50]

The aminosalicylates are considered safe in pregnancy, but sulfasalazine is associated with folate malabsorption. Because pregnancy results in a higher folate requirement, pregnant patients treated with sulfasalazine should be supplemented with folic acid 1 mg orally twice daily. Patients also may need vitamin B_{12} and iron supplementation. Methotrexate is a known abortifacient and should be discontinued at least 3 months prior to patients becoming pregnant and an alternate medication initiated.[51] Thiopurines and biologic agents are considered low risk in pregnant women, and systemic corticosteroids can be used intermittently for disease flares.[50]

As pregnancy progresses, there is a potential risk of increased placental transfer of biologic drugs. Recommendations are to modify the dosing schedule in the third trimester to allow for the last dose to be given as far in advance of delivery as possible to reduce placental transfer.[50] This may require evaluation of trough concentrations of the anti-TNF agents.[44] Metronidazole carries a theoretical risk of mutagenicity in humans, but short courses are generally safe during pregnancy. Prolonged use of metronidazole should be avoided in pregnant patients due to lack of safety data supporting its use. Ciprofloxacin should be avoided in pregnant women. Last, the safety of continuing current therapies for IBD should be evaluated if the patient is considering breastfeeding to assess potential risk if the drugs are transferred into breast milk.

OUTCOME EVALUATION

- Monitor for improvement of symptoms in patients with active IBD, such as reduction in the number of daily stools, abdominal pain, fever, and heart rate.
- For patients in remission, assure that proper maintenance doses are used and inform the patient to seek medical attention if symptoms recur or worsen.
- Evaluate patients receiving systemic corticosteroid therapy for improvement in symptoms and opportunities to taper or discontinue therapy. For patients using more than 5 mg daily of prednisone for more than 2 months or for steroid-dependent patients, consider the following:
    - Central bone mineral density testing to evaluate need for calcium, vitamin D, or bisphosphonate therapy
    - Periodic monitoring of blood glucose, lipids, and blood pressure
    - Evaluation for evidence of Cushingoid features or signs or symptoms of infection
- When considering treatment with azathioprine or 6-MP, obtain baseline complete blood count (CBC), liver function tests, and TPMT activity. These tests, except TPMT, should be monitored closely (every 2–4 weeks) at the start of therapy and then approximately every 3 months during maintenance therapy.
- With azathioprine and 6-MP, monitor for hypersensitivity reactions including severe skin rashes and pancreatitis. Educate the patient regarding signs and symptoms of pancreatitis (nausea, vomiting, and abdominal pain).
- Prior to initiating methotrexate therapy, obtain CBC, serum creatinine, liver function tests, chest X-ray, and pregnancy test (if female). Monitor blood counts weekly for 1 month, then monthly thereafter.
- Prior to initiating anti-TNF therapy, ustekinumab, vedolizumab, or tofacitinib, obtain a tuberculin skin test to rule out latent tuberculosis, monitor for signs and symptoms of tuberculosis, and measure viral hepatitis serologies. Also monitor patients with a prior history of hepatitis B virus infection for signs of liver disease, such as jaundice. Assure that patients do not have a clinically significant systemic infection or New York Heart Association class III or IV heart failure.
- In patients receiving infliximab, monitor for infusion-related reactions such as hypotension, dyspnea, fever, chills, or chest pain when administering IV doses.
- Recommended trough concentrations for anti-TNF biologic agents are infliximab ≥ 5 mcg/mL (mg/L), adalimumab ≥ 7.5 mcg/mL (mg/L), and certolizumab ≥ 20 mcg/mL (mg/L).[43,44] If trough concentrations are not

Patient Care Process

Collect Information:

- Evaluate the medical record to determine the extent and location of IBD.
- Assess for evidence of extraintestinal manifestations or GI complications related to IBD.
- Interview the patient to evaluate the impact on quality of life and to identify psychosocial problems related to the presence of IBD.

Assess the Information:

- Assess inflammatory status, severity, and classify as high versus low risk for colectomy.
- Determine if the patient is treatment-naive or if they are currently receiving pharmacotherapy.
- Evaluate the patient's current medication doses and adherence to therapy. Identify potential barriers to adherence, such as cost or inability to properly use certain drug formulations.
- Identify adverse effects related to current therapy.

Develop a Care Plan:

- Based on the current therapy and disease severity and location, choose appropriate drug(s) and formulations to target the regions of intestinal inflammation.
- Process any prior authorizations for insurance providers that require this.

Implement the Care Plan:

- Remove or switch medications that may be exacerbating IBD symptoms.
- Educate the patient on proper use of drug therapy, including when to expect symptom improvement after initiation of treatment and which signs or symptoms to report that might be adverse drug effects.
- Provide a detailed description of the tapering schedule for corticosteroids if applicable.
- Refer patients to available support groups or IBD organizational resources if they are having difficulty coping with their disease.

Follow-up: Monitor and Evaluate:

- Depending on disease severity, follow up in 2 to 4 weeks. Earlier telephone follow-up may be required to determine whether the patient is achieving some relief of symptoms.
- Assess adherence to therapy and determine if drug concentrations should be evaluated if lack of response is present.
- Assess patient quality of life and impact of treatment on ability to perform daily activities.

adequate, check for antidrug antibody levels. Based on the result, this may necessitate a dose increase or change to another agent.[43.44]

- In patients with fistulae, monitor at every anti-TNF therapy dosing interval for evidence of fistula closure and overall reduction in the number of fistulae.
- If receiving natalizumab or vedolizumab therapy, monitor for signs of PML such as mental status changes, signs of liver disease (eg, jaundice), and hypersensitivity reactions following administration.

Abbreviations Introduced in This Chapter

5-ASA	5-Aminosalicylate
6-MP	6-Mercaptopurine
ASUC	Acute severe ulcerative colitis
CD	Crohn disease
CRP	C-reactive protein
ESR	Erythrocyte sedimentation rate
HLA	Human leukocyte antigen
IBD	Inflammatory bowel disease
IL	Interleukin
NSAID	Nonsteroidal anti-inflammatory drug
pANCA	Perinuclear antineutrophil cytoplasmic antibodies
PR	Per rectum
TNF-α	Tumor necrosis factor-α
TPMT	Thiopurine methyltransferase
UC	Ulcerative colitis
VEO-IBD	Very-early-onset inflammatory bowel disease

Nausea and Vomiting

Sheila Wilhelm and Melissa Lipari

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify common causes of nausea and vomiting.
2. Describe the pathophysiologic mechanisms of nausea and vomiting.
3. Distinguish between simple and complex nausea and vomiting.
4. Create goals for treating nausea and vomiting.
5. Describe attributes of available antiemetic therapies.
6. Recommend treatment regimens for nausea and vomiting associated with cancer chemotherapy, surgery, pregnancy, or motion sickness.
7. Outline a monitoring plan to evaluate treatment outcomes for nausea and vomiting.

INTRODUCTION

Nausea and vomiting result from complex interactions of the gastrointestinal (GI) system, the vestibular system, and the brain and have a variety of causes. Preventing and treating nausea and vomiting requires pharmacologic and nonpharmacologic measures tailored to individual patients and situations.

EPIDEMIOLOGY AND ETIOLOGY

KEY CONCEPT Nausea and vomiting are symptoms that can be due to many different causes such as GI, cardiac, neurologic, and endocrine disorders and various medications (Table 21–1).[1,2] Cancer chemotherapy agents are rated according to their emetogenic potential, and antiemetic therapy is prescribed based on these ratings. Radiation therapy can induce nausea and vomiting, especially when it is used to treat abdominal malignancies.[3]

Oral contraceptives, hormone therapy, and opioids can cause nausea and vomiting.[1] Some medications, such as digoxin, cause nausea and vomiting in a dose-related fashion, which may indicate excessive drug concentrations. Ethanol and other toxins also cause nausea and vomiting.

Postoperative nausea and vomiting (PONV) occurs in 30% of surgical patients overall and in up to 70% of high-risk patients.[4] Risk factors for PONV include female sex, history of motion sickness or PONV, nonsmoking status, and use of opioids postoperatively.[5] The choice of anesthetic agents and duration of surgery may also contribute to PONV.[4,5]

Nausea and vomiting of pregnancy (NVP) affects 50% to 80% of pregnant women, especially early in pregnancy.[6] In 0.3% to 3% of pregnancies, this can lead to hyperemesis gravidarum, a potentially life-threatening condition of prolonged nausea, vomiting, and resultant malnutrition.[6]

PATHOPHYSIOLOGY

Nausea is the unpleasant subjective feeling of the need to vomit.[1,2] Autonomic symptoms of pallor, tachycardia, diaphoresis, and salivation often accompany nausea. Vomiting (or emesis) is a forceful oral expulsion of upper GI contents due to sustained contractions in the abdominal and thoracic musculature.[1] Specific areas in the central nervous system (CNS) and GI tract are stimulated when the body is exposed to noxious stimuli or GI irritants: the chemoreceptor trigger zone (CTZ) in the area postrema of the fourth ventricle of the brain, the vestibular apparatus, visceral afferents from the GI tract, and the cerebral cortex.[1] These in turn stimulate regions of the reticular areas of the medulla within the brainstem. This area is the central vomiting center, which coordinates the impulses sent to the salivation and respiratory centers, and the pharyngeal, GI, and abdominal muscles that lead to vomiting (Figure 21–1).[7]

The CTZ, located outside the blood–brain barrier, is exposed to cerebrospinal fluid and blood.[1] Therefore, it is easily stimulated by uremia, acidosis, and circulating toxins such as chemotherapeutic agents. The CTZ has many 5-hydroxytryptamine (serotonin) type 3 (5-HT_3), neurokinin-1 (NK_1), and dopamine type 2 receptors (D_2).[8] Visceral vagal nerve fibers are rich in 5-HT_3 receptors. They respond to GI distention, mucosal irritation, and infection.

Motion sickness is caused by stimulation of the vestibular system, rich in histaminic (H_1) and muscarinic cholinergic receptors.[9] The cerebral cortex is affected by sensory input such as sights, smells, or emotions that can lead to vomiting. This area is involved in anticipatory nausea and vomiting associated with chemotherapy.

Nausea and vomiting can be classified as either simple or complex.[10] Simple nausea and vomiting occurs occasionally and is either self-limiting or relieved by minimal therapy. It does not detrimentally affect hydration status, electrolyte balance, or weight. Alternatively, complex nausea and vomiting requires

Table 21–1

Causes of Nausea and Vomiting

GI or Intraperitoneal	Cardiac	Neurologic	Therapy or Toxin Induced	Endocrine/Metabolic
Mechanical obstruction	Cardiomyopathy	Vestibular disease	Antibiotics	Pregnancy (NVP or hyperemesis gravidarum)
Achalasia	Myocardial infarction	Motion sickness	Antiarrhythmics	Uremia
Enteric infections	Heart failure	Labyrinthitis	Aspirin	Diabetic ketoacidosis
Pancreatitis		Migraine headache	Cancer chemotherapy	Hyperthyroidism
Inflammatory bowel disease		Increased intracranial pressure	Digoxin	Parathyroid disease
Irritable bowel syndrome		Intracranial hemorrhage	Iron	Addison disease
Cholecystitis		Meningitis	Lead	
Hepatitis		Hydrocephalus	Marijuana	
Gastroparesis		Psychogenic causes	Oral antidiabetics	
Gastroesophageal reflux		Eating disorders	Oral contraceptives	
Peptic ulcer disease		Depression	Opioids	
Peritonitis		Anxiety disorders	Anticonvulsants	
			Radiation therapy	
			Ethanol	

more aggressive therapy because electrolyte imbalances, dehydration, and weight loss may occur.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the accompanying box for the clinical presentation and diagnosis of nausea and vomiting.

TREATMENT

Desired Outcomes

The primary goals of treatment are to relieve the symptoms of nausea and vomiting, increase quality of life, and prevent complications such as dehydration or malnutrition. Drug therapy for nausea and vomiting should be safe, effective, and economical.

General Approach to Treatment

KEY CONCEPT To treat nausea and vomiting most effectively, it is important to first identify and treat the underlying cause. Profuse or prolonged vomiting can lead to complications of dehydration and metabolic abnormalities. Patients must have adequate hydration and electrolyte replacement orally (if tolerated) or IV to prevent and correct these problems. Some pharmacologic treatments work locally in the GI tract, whereas others work in the CNS.[1]

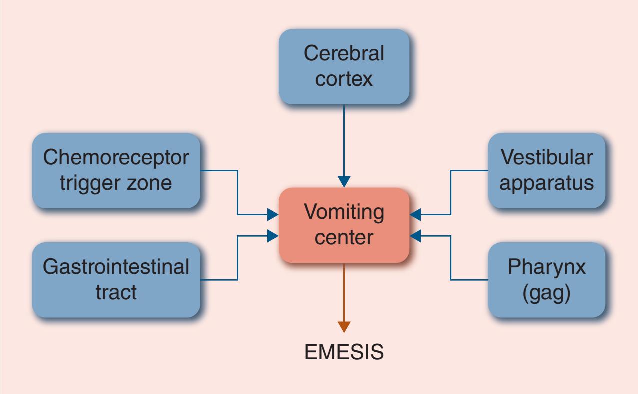

FIGURE 21–1. Primary afferent components to the vomiting center. (Reproduced, with permission, from Toy EC, Loose DS, Tischkau SA, Pillai AS, eds. Case Files: Pharmacology, 3rd ed. New York, NY: McGraw-Hill; 2014.)

Nonpharmacologic Therapy

KEY CONCEPT Nonpharmacologic approaches to nausea and vomiting include dietary, physical, and psychological measures. Dietary management is important when treating NVP due to concern for teratogenic effects with drug therapies.[11] Recommendations include eating frequent, small meals; avoiding spicy or fatty foods; eating high-protein snacks; avoiding iron-containing pills; and eating bland or dry foods the first thing in the morning.[6,11]

Clinical Presentation and Diagnosis of Nausea and Vomiting

Symptoms

- Patients with nausea often complain of autonomic symptoms such as diaphoresis, disinterest in surroundings, pallor, faintness, and salivation.

Signs

- With complex and prolonged nausea and vomiting, patients may show signs of malnourishment, weight loss, and dehydration (dry mucous membranes, skin tenting, tachycardia, and lack of axillary moisture).

Laboratory Tests

- Dehydration, electrolyte imbalances, and acid–base disturbances may be evident in complex and prolonged nausea and vomiting.
- Dehydration is suggested by elevated blood urea nitrogen (BUN), serum creatinine (SCr), and BUN-to-SCr ratio (20:1 or greater using traditional units of measurement [100:1 or greater using SI units of mmol/L]).
- Calculated fractional excretion of sodium (FeNa) less than 1% (0.01) indicates dehydration and reduced renal perfusion.
- Low serum chloride and elevated serum bicarbonate levels indicate metabolic alkalosis.
- Hypokalemia may occur from GI potassium losses and intracellular potassium shifts to compensate for alkalosis.

The dietary supplement ginger (500–1000 mg daily given in three to four divided doses) was effective in NVP in some studies and is recommended in treatment guidelines.[6,11]

Acupressure and electroacupoint stimulation of the P6 (Neiguan) point on the inside of the wrist seem safe and cost-effective; however, efficacy data for treatment of NVP, PONV, and motion sickness are conflicting.[6,12,13] Hypnosis and psychotherapy are also safe during pregnancy and in situations where adverse drug effects and interactions are a concern.

Pharmacologic Therapy

Table 21–2 contains the names, usual dosages, and common adverse effects of the pharmacologic treatments for nausea and vomiting.[1,4,10,14]

▶ *Anticholinergics (Scopolamine)*

Scopolamine blocks muscarinic receptors in the vestibular system, thereby halting signaling to the CNS. It is effective for preventing and treating motion sickness and has some efficacy in preventing PONV.[15] Scopolamine is available as an adhesive transdermal patch that is effective for up to 72 hours after application. This may be beneficial for patients unable to tolerate oral medications or those requiring continuous prevention of motion sickness (eg, passengers on cruise ships). Transdermal scopolamine should be applied 4 hours prior to motion sickness triggers and the evening before surgery if used to prevent PONV. Scopolamine is associated with adverse anticholinergic effects such as sedation, visual disturbances, dry mouth, and dizziness. These adverse effects are worsened when a patient is taking concurrent anticholinergic agents, and these agents should be used with caution in older adults.

▶ *Antihistamines*

Antihistamines are used to prevent and treat nausea and vomiting due to motion sickness, vertigo, or migraine headache.[1,9,16] Their efficacy is presumably due to the high concentration of H_1 and muscarinic cholinergic receptors within the vestibular system. First-generation antihistamines cause undesired effects including drowsiness, blurred vision, and urinary retention. Although first-generation antihistamines are effective, the second-generation antihistamines cetirizine and fexofenadine were found to be ineffective for treating motion sickness, perhaps because they lack CNS depressant properties.[17]

Some first-generation antihistamines such as diphenhydramine, dimenhydrinate, doxylamine, and meclizine are available without a prescription, making self-treatment convenient. The combination of doxylamine and vitamin B6 (pyridoxine) has efficacy in NVP. Antihistamines are available in a variety of dosage forms, including oral capsules, tablets, and liquids. Liquid formulations are convenient for children or adults who are unable to swallow solid dosage forms.

▶ *Dopamine Antagonists*

Stimulation of D_2 receptors in the CTZ leads to nausea and vomiting (Figure 21–1). There are three main groups of dopamine antagonists: phenothiazines, butyrophenones, and prokinetic agents. Phenothiazine antiemetics act primarily via a central antidopaminergic mechanism in the CTZ.[1] Phenothiazines used to treat nausea and vomiting include promethazine, prochlorperazine, and chlorpromazine. Availability in multiple dosage forms (ie, oral, parenteral, rectal) permits use in a variety of settings including severe motion sickness or vertigo, gastritis or gastroenteritis, NVP, PONV, and chemotherapy-induced nausea and vomiting (CINV).[18,19]

Phenothiazines may cause sedation, orthostatic hypotension, and **extrapyramidal symptoms (EPS)** such as dystonia (involuntary muscle contractions), tardive dyskinesia (irreversible and permanent involuntary movements), and akathisia (motor restlessness or anxiety).[1,20] Chronic phenothiazine use has been associated with EPS, but single doses have also caused these effects.[21] Promethazine intravenous injection should not be administered in an undiluted bolus because this may lead to tissue necrosis requiring limb amputation.[20] The highest risk for this adverse event is when the medication is administered intra-arterially.

Droperidol, a butyrophenone, is another centrally acting antidopaminergic agent effective for preventing PONV.[1,4] It may also be used for treating CINV for patients who are intolerant to serotonin receptor antagonists and corticosteroids.[14] Its adverse effects include sedation, agitation, and restlessness. Droperidol carries a US FDA black box warning regarding the potential for QT interval prolongation and cardiac arrhythmias that may result in torsades de pointes and sudden cardiac death.[22] Droperidol should not be used in patients with a prolonged QT interval or in those who are at risk for developing a prolonged QT interval (eg, heart failure, electrolyte abnormalities, bradycardia, or concurrent use of medications that may prolong the QT interval).[22] A 12-lead electrocardiogram (ECG) is recommended prior to treatment with droperidol.

Haloperidol is another butyrophenone with some antiemetic effects at low doses (0.5–2 mg).[23] QTc prolongation is a concern with haloperidol use. However, in a meta-analysis of PONV therapy with low-dose haloperidol versus a 5-HT_3 receptor antagonist, nausea and vomiting reduction as well as incidence of QTc prolongation did not differ significantly between treatments.[24]

Metoclopramide and domperidone (not available in the United States) act as D_2-receptor antagonists centrally in the CTZ and peripherally in the GI tract.[1] They also display cholinergic activity, which increases lower esophageal sphincter tone and promotes gastric motility. Their antiemetic and prokinetic effects are useful in PONV, CINV, gastroparesis, and gastroesophageal reflux disease (GERD).[1,4,14] Metoclopramide is available in injectable, oral solid, and oral liquid dosage forms, allowing for its use in both hospitalized and ambulatory patients.

Metoclopramide crosses the blood–brain barrier and has centrally mediated adverse effects. Young children and the elderly are especially susceptible to these effects, which include somnolence, reduced mental acuity, anxiety, depression, and EPS and occur in 10% to 20% of patients.[1,25]

Domperidone minimally crosses the blood–brain barrier and is less likely to cause centrally mediated adverse effects.[1,25] It should not be used for patients with underlying long QT interval or for those taking medications that prolong the QT interval. Both metoclopramide and domperidone can cause hyperprolactinemia, galactorrhea, and gynecomastia.

▶ *Corticosteroids*

Oral or IV corticosteroids, especially dexamethasone and methylprednisolone, are used alone or in combination with other antiemetics for preventing and treating PONV, CINV, or radiation-induced nausea and vomiting.[3,8,14,23] Efficacy is thought to be due to release of 5-HT, reduced permeability of the blood–brain barrier, and decreased inflammation.[26] Common adverse effects with short-term use include GI upset, anxiety, insomnia, and hyperglycemia.[14] Adverse effects associated with long-term use (eg, decreased bone mineral density, diabetes, cataracts) are not usually seen when corticosteroids are used for acute nausea and vomiting.

Table 21–2

Antiemetic Agents: Usual Doses for Adults and Children and Adverse Effects

Drug	Adult Dosing	Pediatric Dosing	Adverse Effects[a]
Anticholinergics			
Scopolamine	TD: 1.5 mg patch applied 1 or more hours before the procedure, 4 hours prior to motion sickness triggers, repeated every 72 hours as needed	N/A	Most common: Dry mouth, drowsiness, blurred vision Rare: Disorientation, dizziness, hallucinations
Antihistamines			
Cyclizine	Oral: 50 mg every 4–6 hours as needed	Oral: 6–11 years: 25 mg every 6–8 hours as needed (max: 3 tablets/day)	Most common: Sedation, dry mouth, constipation Less common: Confusion, blurred vision, urinary retention
Dimenhydrinate	Oral: 50–100 mg every 4–6 hours as needed	Oral: 2–6 years, 12.5–25 mg every 6–8 hours not to exceed 75 mg in 24 hours; 6–12 years, 25–50 mg every 6–8 hours, not to exceed 150 mg in 24 hours	
Diphenhydramine	Oral: 25–50 mg every 4–6 hours IV/IM: 10–50 mg every 2–4 hours as needed	Oral/IV/IM: 2–6 years, 6.25 mg every 4–6 hours	
Doxylamine	Oral: 20–40 mg daily	N/A	
Hydroxyzine	Oral/IV/IM: 25–100 mg every 4–6 hours as needed	Oral: 0.6 mg/kg IM: 0.5–1 mg/kg	
Meclizine	Oral: 12.5–25 mg every 12–24 hours as needed	Oral: ≥12 years: use adult dose	
Phenothiazines			
Chlorpromazine	Oral: 10–25 mg every 4–6 hours as needed IV/IM: 25–50 mg every 4–6 hours as needed	Oral: ≥ 6 months, 0.5 mg/kg every 4–6 hours as needed IV/IM: ≥ 6 months, 0.5–1 mg/kg every 6–8 hours	Most common: Sedation, lethargy, skin sensitization Less common: Cardiovascular effects, EPS, cholestatic jaundice, hyperprolactinemia
Prochlorperazine	Oral: 5–10 mg three to four times a day as needed Supp: 25 mg twice daily as needed IV/IM: 2.5–10 mg every 3–4 hours as needed	Oral: > 2 years and > 9 kg: 0.4 mg/kg/day or 10 mg/m^2 daily in two to three divided doses Supp: See oral dosing IM: > 2 years and > 9 kg: 0.13 mg/kg	Avoid using in pediatric patients if possible due to sensitivity to adverse effects. If use is considered necessary, employ the lowest effective dose
Promethazine	Oral/IM/IV/Supp: 12.5–25 mg every 4–6 hours as needed	Oral/IM/IV/Supp: ≥ 2 years, 0.25–0.5 mg/kg or 7.5–15 mg/m^2 four to six times daily	
Butyrophenones			
Droperidol	IM/IV: 0.625–2.5 mg every 4–6 hours as needed	IM/IV: 2–12 years: 0.05–0.1 mg/kg (max 2.5 mg) every 4–6 hours as needed	Most common: Sedation, hypotension, tachycardia Less common: EPS, dizziness, increased blood pressure, chills, hallucinations, QT prolongation
Haloperidol	Oral, IM/IV: 0.5–5 mg every 12 hours as needed	N/A	
Benzamides			
Domperidone	Oral: 10–20 mg every 4–8 hours as needed Supp: 30–60 mg every 4–8 hours as needed	Oral: 0.2–0.4 mg/kg every 4–8 hours as needed for CINV prophylaxis Supp: Max daily dose based on weight	Most common: Sedation, restlessness, diarrhea (metoclopramide), agitation, CNS depression Less common: EPS, hypotension, neuroleptic syndrome, supraventricular tachycardia (with IV), QT prolongation, serotonin syndrome (when used with serotonergic agents)
Metoclopramide	PONV: 10–20 mg oral/IV/IM 10 min prior to anesthesia CINV Prophylaxis: 1–2 mg/kg oral/IV every 2–4 hours	N/A	
Trimethobenzamide	IM: 200 mg two to four times a day as needed	Not recommended	

(*Continued*)

Table 21–2

Antiemetic Agents: Usual Doses for Adults and Children and Adverse Effects (*Continued*)

Drug	Adult Dosing	Pediatric Dosing	Adverse Effects[a]
Corticosteroids			
Dexamethasone	*CINV*: 12–20 mg oral/IV day 1, then 8–12 mg oral/IV daily *PONV*: 4–5 mg oral/IV at induction of anesthesia	*CINV*: 10 mg/m^2 prior to chemotherapy then 5 mg/m^2	Most common: GI upset, anxiety, insomnia Less common: Hyperglycemia, facial flushing, euphoria, perineal itching or burning (with dexamethasone)
